Using thin film transistor (TFT) technology developed for flat panel displays, large arrays of phototransistors can be fabricated on amorphous silicon to form imaging devices that can be used in place of other imaging technologies such as vidicon tubes or even film. Examples of this are the very large area detectors (hundreds of square centimeters) being investigated for use in medical radiography by combining the TFT arrays with radiographic phosphor screens [4] or coupled to semiconductor films [5].

Novel Silicon Photojunction Detector Structures

Silicon p - i - n Detectors

Silicon p - i - n diodes are an extension of the standard p - n junction diodes, but are more attractive for low-noise applications due to reduced capacitance in these devices [1]. The reduction in capacitance is achieved by incorporating an intrinsic region between the p and n regions. This increases the depletion width of the detector and thereby lowers its capacitance. Silicon p - i - n detectors can be designed to have higher frequency response than p - n junctions and therefore are more popular.

In operation, p - i - n detectors are similar to p - n junction detectors, but the surface region (either p or n) is made thin so that the optical photons penetrate this entrance layer and are stopped in the intrinsic (i -region) where electron-hole pairs are produced, as shown in Figure 56.4. These electron-hole pairs are swept toward the appropriate electrodes due to applied electric field. For fabrication, p - i - n detectors require high resistivity material and typical photodiodes have thickness ranging from 100 to 500 μm . Important applications of p - i - n detectors include optical sensing of scintillated light in CT scanners, general scintillation spectroscopy, charged particle spectroscopy, and high-speed sensing applications.

Silicon Drift Detectors

Silicon drift photodiodes are an extension of the p - i - n geometry and been extensively studied in recent years to provide very low capacitance (<1 pF for 1 cm^2 detector with 300 μm thickness) [7]. This is achieved by reducing the area of ohmic electrode (anode in most cases) significantly as compared to the entrance electrode as shown in Fig. 56.4(f). Since the charge sensing electronics is connected to the smaller electrode, the device capacitance is proportional to its size and not to the actual detector area. Thus by exploiting this concept, significantly lower capacitance has been achieved than in comparable p - i - n detector.

In drift detectors, it is important to ensure that charges created over the entire active volume will be collected at the anode. In order to achieve this, drift rings are provided around the anode. The outermost ring is biased at highest potential, with the inner rings biased to lower potentials in a successive manner. This arrangement creates a potential minimum at the anode and thereby enables efficient charge collection over the entire detector volume. A variety of device geometries are being explored based on this concept and in some instances these detectors are capable of providing position sensitive detection as well. While these detectors are in the research stage, excellent performance has been demonstrated by prototype detectors. These detectors, when they are commercially available, will have the potential of replacing p - i - n diodes in many applications.

Silicon Avalanche Photodiodes

While the conventional silicon diodes, such as $p-n$ junction diodes, $p-i-n$ diodes and drift diodes, have no gain, silicon avalanche photodiodes (APDs) have internal gain that enables them to operate with high signal-to-noise ratios and also places less stringent requirements on supporting electronics. In its simplest form, an APD is a $p-n$ junction operated close to its breakdown voltage in reverse bias. When photons are absorbed in silicon, electron-hole pairs are produced and are accelerated by the high electric field. These electrons gain sufficient velocity to generate additional free carriers by impact ionization, which provides the internal gain. APDs with small areas (few mm diameter) can be manufactured with standard planar processing and have a gain of a few hundred. These detectors are widely used in the telecommunications industry. It is difficult to fabricate high gain detectors with large areas using the planar process; however, special detector designs with beveled edges (see Figure 56.4) have been fabricated to provide high gain ($>10,000$) in large areas ($>1\text{ cm}^2$) [8]. The APD gain versus bias behavior for such a device is shown in Figure 56.9. Recent advances in surface preparation and dead layer reduction have extended the application of these detectors to the UV region. While they are relatively expensive, these detectors are well suited to a number of commercial applications such as medical imaging, astronomy, charged particle and x-ray detection, scintillation spectroscopy, and optical communications.

Amorphous Silicon Detectors

While impressive results have been obtained with various device structures on crystalline silicon such as drift detectors, APDs, and CCDs, they are limited to active areas of only a few square centimeters. As a result, considerable attention has been devoted to development of hydrogenated amorphous silicon (a-Si:H) [4]. This material is produced by an RF plasma technique in large areas ($30\text{ cm} \times 30\text{ cm}$) on glass substrates. The films are typically a few micrometers in thickness, although films as thick as $200\text{ }\mu\text{m}$ has been reported. Device structures such as $p-n$ junctions were developed initially for use in solar cells with lower cost than crystalline silicon devices.

Recently, more complicated devices such as $p-i-n$ sensors and thin film transistors (TFTs) have been fabricated from a-Si:H and have been configured in an array format as shown in Fig. 56.10. In these arrays (as large as $20\text{ cm} \times 20\text{ cm}$), each pixel consists (200 to $500\text{ }\mu\text{m}$) of a $p-i-n$ sensor connected to a TFT, and the entire array is read out in matrix fashion. These arrays are well suited for high-resolution document imaging and also for medical x-ray imaging applications with phosphors.

FIGURE 56.10 Schematic representation of a 2-D x-ray imager consisting of a-Si:H *p-i-n* diodes connected to a-Si:H TFTs for readout. The *p-i-n* diodes are coupled to a phosphor layer to increase sensitivity.

Novel Materials for Photodiodes and Bandgap Engineering

Important requirements for photodiodes include high quantum efficiency (QE), good charge collection efficiency, and low noise. The low noise requirement is satisfied by reducing detector capacitance and its dark current. In order to satisfy the QE requirements over a wide range of wavelengths, new semiconductor materials are being extensively investigated [9]. Since most semiconductors show high optical response near their bandgap, special materials are developed for various applications. Furthermore, since the bandgap represents a cut-off point in the optical response of the material, by selecting an appropriate material, it is possible to obtain response in a desired band [10]. For example, materials such as GaN and SiC are being explored to obtain UV detection with no sensitivity in the visible region. Other materials are being studied to exploit their unique properties such as high quantum efficiency, high-temperature operation, and high-speed response.

GaN

GaN is an attractive material for *UV photodiode* fabrication due to its wide bandgap ($E_g = 3.4$ eV). Due to the difficulty in growing bulk crystals of GaN, much of the work is done with films of GaN prepared by chemical vapor deposition or molecular beam epitaxy [11]. A variety of optical devices (e.g., blue LEDs and lasers, field effect transistors, photoconductive detectors, and photodiodes) have been fabricated using GaN films. GaN photodiodes have the capability of solar blind UV detection and are capable of fast response time due to high electron mobility (as high as $1000 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$), which is comparable to silicon.

SiC

SiC is another material that has shown promise for UV detection due to its wide bandgap ($E_g = 3.0$ eV and 3.2 eV for 6H and 4H phases, respectively) [12]. Various optical devices such as blue LEDs, lasers, and UV photodiodes have been developed from 6H-SiC due to the relative ease of doping this material to form *p* and *n* layers by ion implantation or epitaxial methods. SiC devices are also capable of high-temperature operation, and the photodiodes have shown high quantum efficiency ($>80\%$) in the 250 to 280 nm region. Low dark current is another attractive feature of these devices.

InI

Indium iodide is a wide bandgap semiconductor ($E_g = 2.0$ eV) being developed for detection in visible and near-UV region [13]. The resistivity of the material is quite high ($>10^{10} \Omega\text{-cm}$) and Schottky diodes

are fabricated using evaporated palladium electrodes. Because of the high resistivity, it is possible to deplete relatively large thickness (0.5 to 1 mm) at low bias (<200 V). One of the unique properties of InI photodiodes is their high quantum efficiency (>70%) in the 300 to 600 nm wavelength region, as shown in Figure 56.11, which in combination with its low dark current makes it attractive for low light level detection applications such as scintillation spectroscopy.

Alloys and Bandgap Engineering

In many instances, required properties are attained by bandgap engineering where two or more semiconductors are alloyed together to create a *ternary semiconductor*. The use of a ternary semiconductor provides the ability to tune the peak wavelength of a photodiode. When two binary compounds are combined, the resulting ternary material usually has properties that lie between those of the constituent binary compounds. Examples of some alloys developed in this manner include $\text{Hg}_x\text{Cd}_{1-x}\text{Te}$ for infrared detection, which is created from HgTe ($E_g = 0.14$ eV) and CdTe ($E_g = 1.45$ eV), $\text{Si}_x\text{Ge}_{1-x}$ which is a mixture of Si ($E_g = 1.1$ eV) and Ge ($E_g = 0.7$ eV) for infrared and visible detection, and $\text{TlBr}_x\text{I}_{1-x}$ which is a mixture of TlBr ($E_g = 2.7$ eV) and TlI ($E_g = 2.1$ eV) for visible detection. A discussion of some recent novel materials that are being developed is presented in the following section and a compilation of relevant properties of various semiconductor materials is presented in Table 56.3.

III–V Ternary Materials

Ternary alloys of GaN and AlN ($E_g = 6.2$ eV), $\text{Ga}_x\text{Al}_{1-x}\text{N}$, are also being investigated to create optimized UV detectors for desired wavelengths. In the ternary compound, the bandgap depends on the material composition or x and varies almost linearly from 3.4 to 6.2 eV. Such bandgap engineering is desirable to create material with required photoresponse. These devices are also expected to be capable of high

FIGURE 56.11 Quantum efficiency of an InI photodiode. The QE peaks at over 80% near the band edge and has a spectral sensitivity of about 70% into the near-UV.

TABLE 56.3 Properties of Semiconductor Materials Used for Construction of Photodiodes at 25°C

Material	Bandgap	Dielectric constant	Resistivity ($\Omega\text{-cm}$)	Electron mobility (cm^2/Vs)	Electron lifetime (s)	Hole mobility (cm^2/Vs)	Hole lifetime (s)	$\mu\tau(e)$ (cm^2/V)	$\mu\tau(h)$ (cm^2/V)
HgTe	0.14	6.4		22000		100			
InAs	0.36	12,5		30000		240

temperature operation due to the wide semiconducting bandgap of the material. Similar devices are also been studied from GaP ($E_g = 2.1$ eV) and AlP ($E_g = 2.9$ eV) for visible and near UV detection.

Another example is indium gallium arsenide, which is a mixture of InAs ($E_g = 0.36$ eV) and GaAs ($E_g = 1.43$ eV) and has been recently commercialized as an infrared detector material in the 1000 to 1700 nm region. InGaAs photodiodes in p - n diode, p - i - n diode, and avalanche photodiode configurations are available. InGaAs photodiode arrays coupled to amorphous silicon TFTs are being developed for large area infrared imaging. Other ternary III–V materials that have been investigated for similar reasons include GaAsP, GaNP, and BNP.

Heterojunction Photojunction Detectors

A heterojunction is a junction that exists at the interface of two different semiconductors. This concept can be exploited to produce photodiodes with unique properties such as tuned optical response in the region of interest (by adjusting the composition), and reduced optical absorption at the entrance (by irradiating the wider bandgap semiconductor that is transparent to the optical signal). A number of optical sensors have been fabricated using the heterojunction concept using mostly III–V compounds that can be tuned in composition to create heterojunctions with similar lattice constants in both the semiconductors. The research in the heterojunction devices has been aided considerably by the progress in molecular beam epitaxy. One unique application of the heterojunction concept is to fabricate detectors that have capability of distinguishing wavelengths above or below a certain level. This has been accomplished using a multilayer device (see Figure 56.12) that consists of two layers of $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$ which have different composition and, therefore, different bandgaps. The layer Q1 has a larger bandgap than Q2 and both are grown on InP. The optical response of this device when irradiated through the InP substrate is shown in Figure 56.12 and shows minimal overlap in the desired bands indicating successful wavelength discrimination.

FIGURE 56.12 Responsivity and quantum efficiency of a heterojunction photodiode versus wavelength. The insert shows the cross section of the photodiode

Defining Terms

Bandwidth, B : The range of frequencies over which the photodiode operates.

Breakdown voltage, V_b : The reverse bias voltage at which the applied field overcomes ability of the junction to block current and the device acts like a resistor. The reverse leakage current increases abruptly near this voltage.

Dark current, or reverse leakage current, I_d : The leakage current through the device when at the operating voltage with no incident signal.

Depletion region thickness: The depth of the depleted portion of the diode when at the operating voltage. Photodiodes are frequently operated fully depleted.

Junction capacitance, C_j : Capacitance of the photodiode which decreases as the depletion width increases.

Noise equivalent power, NEP: The incident power that generates a signal equal to the noise, i.e., signal-to-noise ratio (S/N or SNR) equals 1.

Operating bias: The applied voltage at which the device operates.

Peak wavelength: The wavelength with the highest quantum efficiency.

Quantum efficiency, η or QE: The efficiency of converting photons incident on the photodiode into electrons that are detected. Reflection of light from the surface and loss of electrons in the semi-

conductor reduce the efficiency. Reflection losses can be minimized using an antireflection coating on the surface of the device.

Responsivity, (amps/watt): A measure of the signal current produced as a function of the optical power incident on the photodiode.

Spectral response: The quantum efficiency as a function of wavelength.

Introduction

Use of CCDs for Precision Light Measurement

Charge-Coupled Devices (CCDs) have become the detector of choice for sensitive, highly precise measurement of light over the electromagnetic spectrum from the near-IR (<1.1 μm) to the x-ray band (up to 10 keV). Key advantages of CCDs over their predecessors (photographic emulsions and vacuum tube, electron beam readout devices such as Vidicons and SIT tubes) are high quantum efficiency, high linearity, large dynamic range, relatively uniform cosmetic response, low noise, and intrinsically digital image capture.

CCDs were initially designed as serial data storage media (an electronic analogy to the magnetic Bubble Memory units) in which charge packets were injected into linked capacitors to store data, and read back by moving the packets back out of the device. When it was found that charge packets could be directly induced in the capacitors by exposing them to light, the CCD as light sensor was born.

Physically, *CCD operation* consists of four critical stages. First, an incident light photon must be photoabsorbed in the sensitive portion of the CCD chip (called the *depletion region*). At optical and infrared wavelengths, the absorption results in a single electron being promoted into the conduction band (leaving a hole in the valence band); at shorter wavelengths, the photon has enough energy to make additional electrons via secondary ionizations by the photoelectron.

Second, the photon-induced electrons must be collected, via an electric field within the silicon, into localized regions near the front surface of the chip. The electric field is shaped by implanted dopants and by electric potentials applied to thin conducting strips (*gates*) that prevent the electrons from diffusing away. The resulting charge distribution corresponds to an electronic analog of the light intensity pattern shone on the CCD. The resolution of this pattern is governed by the size of the potential wells, which are designed to be periodic. Each well is called a *pixel* and corresponds to the minimum picture element detected by the CCD.

Third, after exposure is completed, the CCD charge pattern must be transferred out of the CCD. This is accomplished by modulating the potential applied to the CCD gates in such a way that no charge packets are mixed, but that each packet moves into the next pixel. The end pixel is transferred into a special pixel array called the *serial register*. Each movement of charge resulting from gate potential changes is called a clock cycle, and the serial register receives many clock cycles for each cycle of the full pixel array. The net result is a sequence of charge packets emerging from the serial register, each of which is directly proportional to the amount of light striking a particular location on the CCD.

Fourth, the emerging charges are converted into electric signals by a charge-sensitive preamplifier on the CCD chip. These signals are often digitized by electronics in the camera immediately outside the chip, but analog readouts that produce signals compatible with video standards are also used (the popular hand-held video cameras are examples of this). Research-grade camera readouts are able to measure the charge pulses with accuracies as good as one or two electrons rms, if the CCD and electronics are cooled.

Currently available CCDs carry out these steps so well that they are nearly the ideal detector for precision low light level applications, especially in astronomy. Such an ideal detector would have perfect quantum efficiency (i.e., convert every incident photon into detectable signal), no noise, unlimited dynamic range, linearity in response to incident intensity and position, and completely understandable characteristics.

CCDs have high quantum efficiency because photons interact via photoabsorption in the depletion layer, which directly results in one or more electrons promoted into the conduction band of the silicon lattice, and are very efficiently collected by the CCD. The main obstacles to perfect quantum efficiency are absorption of photons by the gate and insulator materials before they ever reach the depletion regions (or optically, by reflection off the front surfaces) or if the photon passes entirely through the depletion region without interacting.

There are many approaches to enhancing *CCD quantum efficiency* for various applications. In soft x-ray and ultraviolet wavelengths, the gate and insulator layers on the front of the CCD absorb too much light. To solve this, CCDs are built with thin gates or thinned substrates and back-side illumination. CCDs are also coated with phosphor coatings that down-convert ultraviolet light to longer wavelengths where the gate transmission is higher.

At hard x-ray and infrared wavelengths, too much light can pass through the depletion region without interacting at all. The depletion region is the part of the CCD pixel that is swept clean of free charges during the readout process. The depletion region gets deeper if higher purity silicon is used, and if higher voltage biases are applied during the readout.

Above 1.1 μm , photons do not have sufficient energy to promote electrons into the silicon conduction band, so other materials, such as germanium or a compound semiconductor such as InAs, InSb, or HgCdTe must be used.

CCD noise results from four major factors: (1) thermal background noise, (2) charge transfer imperfections, (3) charge-to-voltage amplification noise, and (4) cosmetic imperfections in the CCDs due to, for example, microscopic shorts in the insulating layers of the CCD. Factor (1) results from a “dark current” of thermally excited electrons that accumulate in the pixels and can be eliminated by cooling the CCD (typically to -60 to -120°C). Factor (2) results from traps that hold electrons long enough to shift them into following charge packets identified with other pixels. Factor (3) is a fundamental limit related to the temperature and capacitance of the output mode (kT/C), but it can be suppressed by signal processing techniques such as “correlated double sampling” to the equivalent of a few electrons (1–5 in state-of-the-art cameras). Factors (2) and (4) can be greatly reduced by improved manufacturing technique, especially scrupulous contamination control during the process.

CCD dynamic range is set by the maximum charge packet that can be stored in a pixel. Termed “full-well capacity,” this is set by the depth of the potential well. When the full-well capacity is exceeded, the image of a point source “blooms” as a result of charge leaking into surrounding pixels, and a trail of brighter pixels forms in the readout direction of the CCD due to charge incompletely transferring from pixel-to-pixel during a clock cycle. Modern CCDs have full-well capacities in excess of 10^5 electrons and can be designed even larger. (Note that larger full-well also requires larger output capacitance, so a trade-off is generally required between blooming and low noise.)

CCD linearity in intensity response and position response is very good because the conduction band in the CCD has so many states that the very small injected photocharge does not affect subsequent photon interactions. The position linearity results from the photolithography of the manufacturing process, which must be accurate to less than $1\ \mu\text{m}$. The primary limitation on linearity results from imperfect *charge transfer efficiency* (CTE) in the process of clocking charge packets from pixel to pixel. At readout rates below 100,000 pixels per second, CTE imperfections have four causes.

1. Design imperfections: errors in CCD design can leave potential minima that are incompletely drained during clocking.
2. Process-induced traps: random cosmetic defects, presumably due to imperfections in manufacturing.
3. Bulk traps: lattice defects or impurities that introduce local potential minima, which temporarily capture electrons long enough to remove them from the original charge packet, but re-emit them later.
4. Radiation-induced traps: similar to (3) but resulting from lattice defects caused by low-energy protons. This damage is most commonly seen by spacecraft CCD cameras.

CCD Operation and Data Reduction

In order to achieve ultimate *CCD performance* for a given goal, the CCD camera can be operated in special ways, and the postcamera data reduction can be optimized. Typical optical use of CCDs involves timed exposures, where the CCD pixels are exposed to light and the total charge integrated in pixels for a preselected time. At the conclusion of the integration, a shutter closes and the CCD is read out. As noise reduction limits the readout to roughly 100 kpixels/s, a large CCD (2048×2048 pixels) readout can take many seconds to complete.

To avoid the deadtime associated with the closed shutter, some CCDs are made with framestore regions. The framestore is a pixel array equal to the integration region which is permanently blocked by a cover from any additional light. The pixels containing the charge pattern resulting from the integration are very rapidly clocked into the framestore region (typically requiring much less than 1 s) and then slowly clocked out into the readout region without moving the integration pixels.

Operationally, CCD reduction requires calibration exposures. These include bias frames, which are readouts with the same integration time but no light striking the CCD, and flat field frames, which have a uniform illumination over the CCD. The bias frames are subtracted from the data frames to set the zero-point corresponding to zero incident radiation. (Note that CCDs will accumulate charge due to thermal electrons and low-level shorts in the gates, even if no light hits the CCD.) The flat field allows

correction for pixel-to-pixel sensitivity variations. Proper flat fielding can remove variations of arbitrary amplitude and spatial scale.

The CCD dark current bias can be reduced by cooling the CCD, or by operating it in an inverted phase mode. In inverted phase operation, the gate electrode is given a suitable negative bias that attracts hole carriers to the front surface of the CCD. These holes fill interface states at the Si–SiO₂ boundary between the conducting depletion region and the insulating layer under the gates. Suppression of these interface states dramatically lowers the dark current because the interface states are much more efficient at thermal electron promotion to the conduction band than the bulk material. Not all phases can be operated in inverted mode in a normal CCD because, without the restraining potentials provided by gates held at positive voltage, the pixel charge packets can intermingle. A special CCD called an MPP (multiphase pinned) device has extra implant doping that isolates the pixels even with all three phases inverted, yielding dark current so low that integration times up to minutes become possible in room-temperature MPP CCDs.

Other important uses of CCDs include cases where the CCD is continuously clocked, without any shutter. Suitable for high light level conditions, the effective integration time becomes the time to transfer a pixel charge across the source point spread function on the CCD. This allows sensitive timing of source intensity changes.

A similar technique is called *drift scanning*, where the rate of clocking of pixels equals the rate of motion of the target across the CCD. Such a condition is common in astronomy, where a fixed detector on the Earth sees slow motion of stars in the field of view due to the Earth's rotation.

Drifts and instabilities in the camera electronics can be corrected using a technique called “overclocking.” If the serial registers are clocked more times than there are physical pixels in the CCD, then the excess clocks will produce charge pulses corresponding to zero input light and zero dark current. The distribution of the overclock pulse is then a measure of the readnoise of the CCD chip-camera system, and the mean of the distribution sets the zero point of the energy to output voltage curve. Frequently, CCD cameras subtract the mean of the overclock pixels from all output values in a row (called “baseline restoration”).

CCD Signal-to-Noise Ratios (SNR)

To see how these characteristics of the CCD relate to measurement, it is instructive to study the SNR predicted for a given exposure time. In a single pixel illuminated by a source that contributes S_o counts (electrons) to the pixel, one also sees contributions from dark current (S_d) and background illumination (S_s , usually called the “sky” in astronomical usages), all in units of counts per pixel per second. The source contribution (S_o) can be expanded into the intensity of light from the source, I ; the quantum efficiency of the CCD, Q ; and the integration time, t ; to provide

$$S_o = I \times Q \times t \quad (56.17)$$

The camera readout contributes a randomly distributed but fixed Gaussian noise with variance N_r . The SNR of a particular pixel is then:

$$SNR = I \times Q \times t = (I \times Q \times t + N_r^2 + S_d + S_s)^{1/2} \quad (56.18)$$

If the light from a source is distributed over a number of pixels, n [as might arise from a star viewed through a telescope with a point spread function (PSF) covering n pixels], then if the integral of S_o over the PSF is C_o , and the integral of S_s over the pixels is C_s , then

$$SNR = C_o^{1/2} / (1 + C_s C_o + n + r^2 C_o)^{1/2} \quad (56.19)$$

Clearly, high Q and low r are desirable, and t should be chosen to make C_o greater than both C_s and r . It is worth noting that, in most optical applications (except for extremely faint sources), it is the

uncertainty in the flat fielding (i.e., the corrections made for pixel-to-pixel sensitivity variations and background) that ultimately limits the achievable SNR.

CCD Structure and Charge Transport

CCD structure and its potential profile under bias

A CCD is a semiconductor device operating under the principle that charges can be temporarily stored and transported along a string or array of MOS capacitors. The basic storage unit is called a pixel and is made up of several MOS capacitors. In almost all CCDs, charges are stored either directly at the oxide–semiconductor interface (surface-channel device), or deeper within an epitaxial layer (buried-channel device). Theoretically, a surface-channel CCD has a larger charge capacity, but it also is prone to noise arising from interface states at the boundary.

The CCD is operated by varying voltages applied to the surface electrodes. Typically, the CCD is kept for a long period in an integration state, where photon-induced electrons accumulate in the potential wells under the CCD pixels. After the integration finishes, the voltages are changed to transport the charge from one capacitor to the next. This sequence of moving charge packets by potential clocking is sometimes called “bucket-brigade” charge transfer.

The storage unit of the CCD is the MOS capacitor and it is possible to deplete, invert, or form a surface accumulation layer in the MOS capacitor by simply changing the surface potential. CCDs operate in the so-called “deep depletion” mode when the surface layers are fully depleted. For a buried-channel CCD with an n -type buried layer within a p -type epilayer, this would require the application of a positive bias to the surface electrodes. The equations governing the one-dimensional calculations of the potential distribution in the MOS capacitor are [1]:

$$\begin{aligned} \frac{d^2\psi}{dx^2} &= 0 & -d < x < 0 \\ \frac{d^2\psi}{dx^2} &= -q \cdot \frac{N_D}{\epsilon_s} & 0 < x < t \\ \frac{d^2\psi}{dx^2} &= q \cdot \frac{N_A}{\epsilon_s} & t < x < x_p \end{aligned} \tag{56.20}$$

where ψ is the potential, N_A is the substrate acceptor density, N_D is the donor density in the epilayer, x_p is the depletion edge in the p -type substrate, and ϵ_s is the semiconductor permittivity. Note also that d is the oxide thickness and the origin ($x = 0$) is located at the oxide–semiconductor boundary.

The boundary conditions will be:

$$\begin{aligned} \psi(x = -d) &= V_G & \left. \frac{d\psi}{dx} \right|_{x=t^-} &= \left. \frac{d\psi}{dx} \right|_{x=t^+} \\ \epsilon_{\text{ox}} \cdot \left. \frac{d\psi}{dx} \right|_{0^+} &= \epsilon_s \cdot \left. \frac{d\psi}{dx} \right|_{0^+} & \psi(x = t^-) &= \psi(x = t^+) \\ \psi(x = 0^-) &= \psi(x = 0^+) & \psi(x = t + x_p) &= 0 \end{aligned} \tag{56.21}$$

and the solutions are:

$$\begin{aligned} \psi &= V_G - E_{ox} \cdot (x + d) & -d < x < 0 \\ \psi &= \psi_{max} - q \cdot N_D \cdot (x - x_n)^2 / (2\epsilon_s) & 0 < x < t \\ \psi &= q \cdot N_A \cdot (x - t - x_p)^2 / (2\epsilon_s) & t < x < t + x_p \end{aligned} \quad (56.22)$$

where E_{ox} is the electric field in the oxide layer, V_G is the gate bias voltage, and x_n is the position of the potential maximum.

Figure 56.13 shows a typical potential profile across the MOS capacitor in a buried-channel CCD. Note the presence of a potential maximum, ψ_{max} , where the electrons will reside. It is given by:

$$\psi_{max} = \psi_f \cdot (1 + N_A/N_D) \quad (56.23)$$

where $\psi_f = q \cdot N_A \cdot x_p^2 / (2\epsilon_s)$. Since x_p increases linearly with N_D , the potential maximum ψ_{max} and hence the charge storage capability also increases for a heavily doped epilayer. The derivation of the potential profile in a surface-channel CCD will be similar, but with d set to zero.

Charge Transport

Charge transport in a CCD refers to the transfer of charges along the MOS capacitors (i.e., from one pixel to the next). There are several clocking schemes used, generally divided according to how many external voltage regions are applied per pixel, ranging from one (uni-phase) to four-phase.

Computation of charge transport in a CCD requires solving the two-dimensional Poisson equation with appropriate boundary conditions to obtain the potential distribution within the pixel for each separate phase within the clocking cycle. Numerical techniques using finite-difference or finite-element methods have been used. For charge transfer in an n -type epilayer, the electron flux, $F(x)$, is given by:

$$F(x) = n_s(x, t) \cdot v(E(x)) - D(E(x)) \cdot (n_s(x + \Delta x, t) - n_s(x, t)) = \Delta x \quad (56.24)$$

where $n_s(x, t)$ is the electron density, $E(x)$ is the electric field in the x -direction, $v(E(x))$ is the field-dependent velocity, and $D(E(x))$ is the electron diffusivity. Figure 56.14 shows the time evolution of charges along a CCD. Some “smoothing” of the output charge profile is often observed and, for high-

FIGURE 56.13 Potential profile across MOS capacitor.

FIGURE 56.14 Time evolution of charges along a CCD: (a) $t = 200$ ps; (b) $t = 400$ ps; (c) $t = 600$ ps.

speed devices, velocity saturation will be important. Computations of charge transfer are sometimes carried out using an equivalent circuit model for the CCD in a SPICE-type simulator. It has been shown to offer both faster computation time and the ability to include external support circuits into the model.

Charge transfer efficiency, η , is the key figure-of-merit in a CCD, at least comparable to quantum efficiency. A common technique to determine η is to measure the amplitude response of the CCD using a network analyzer. η is then related to the amplitude response of the output, G_V through the following relationship:

$$G_V = \exp\{-N_T \cdot (1 - \eta) \cdot [1 - \cos(2\pi f / f_c)]\} \quad (56.25)$$

where N_T is the number of transfers, f is the signal frequency, and f_c is the clock frequency. For the relatively mature Si CCD technology, charge transfer efficiency of 0.99999 can be easily achieved. Note, however, that this analysis applies to sinusoid illuminated scenes and test signals, but does not apply to delta function injections of charge that are infrequently transferred, as applies to the x-ray photon-counting case.

Input and Output Structures

The input structure of the CCD usually consists of a p - n junction and two or more input gates as shown in Figure 56.15. Initially, when the input voltage, V_{id} is pulsed low, charges will flow through the input (electrode) into the potential well created under the input gates G_1 and G_2 . When V_{id} returns to its equilibrium value, charges will be withdrawn except those residing in the potential well formed by the potential difference between G_1 and G_2 . Charge injection is now complete and a drop in the potential Φ_1 at the transfer gate will allow charges to enter into the first CCD pixel. The input charge, Q_{in} , is approximately given by:

$$Q_{in} = C_{ox} \cdot (V_{G1} - V_{G2}) \quad (56.26)$$

where C_{ox} is the oxide capacitance, and V_{G1} and V_{G2} refer to the voltage difference between G_1 and G_2 . In CCD sensors and detectors, signal input normally relies on the incident photons liberating charge within the depletion region (after traversing either the front gates [front-illuminated] or the back surface [back-illuminated]). Charges so created will be collected in the potential wells formed by the clock voltages.

Normally, the output structure of the CCD consists of a reset switch and a floating diffusion (FD) or floating gate (FG) amplifier. These are shown in Figure 56.16. During sampling, the output charge flows into the floating node and a voltage is developed across the output capacitance, which is a combination of the depletion capacitance of the floating node and the input gate capacitance of the source follower. In general, the voltage output, V_{sig} , can be expressed as:

$$V_{sig} = Q_{inj} \cdot A_v / C_{fd} \quad (56.27)$$

where Q_{inj} is the injected charge, A_v is the small-signal voltage gain of the output amplifier, and C_{fd} is the capacitance between the floating node and ground. Since both A_v and C_{fd} are sensitive to the output

FIGURE 56.15 Input structure of a CCD.

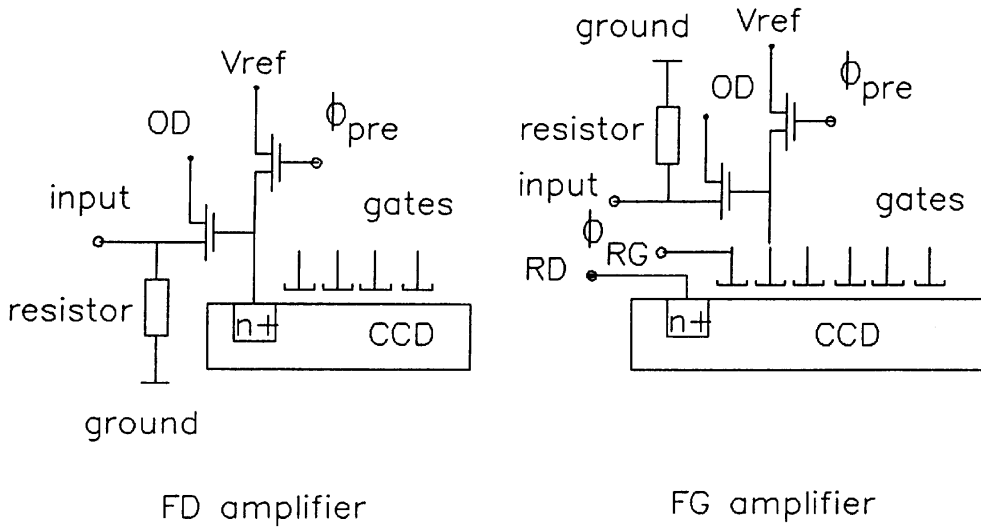

FIGURE 56.16 Output structures of a CCD.

charge and temperature, this type of output structure is not generally linear. Improvements in the output structure can be achieved using either a floating gate amplifier or Miller feedback at the output to reduce parasitic capacitances.

Noise in CCDs

CCD noise will degrade the SNR. The following are important noise sources in CCDs:

1. Thermal noise, or dark current, is due to thermally excited electrons that accumulate in the pixels during the integration. In applications where the clocking time is short compared to the integration time, the equivalent noise electron, n_{th} , is given by:

$$n_{th} = \sqrt{J_d \cdot A_E \cdot t_{int}} \quad (56.28)$$

where J_d is the leakage current density, A_E is the area of the transport electrode, and t_{int} is the integration time. A lowering of the operating temperature will normally reduce the leakage current density and hence the equivalent noise electron.

2. Bulk traps are the dominant noise sources for buried-channel CCDs and the equivalent noise electron from this source is:

$$n_{trap} = \sqrt{N_t \cdot V_{sig} \cdot N_t \cdot e^{-T_t/\tau_e} [1 - e^{-T_t/\tau_e}]} \quad (56.29)$$

where V_{sig} is the volume of the charge packet under the transfer electrode, N_t is the density of the bulk trap states, T_t is the transfer time, and τ_e is the electron emission time constant. It can be observed that the equivalent noise electron increases as the size of the charge packet increases, an indication that bulk traps do not generally affect the SNR in CCDs. In x-ray photon counting applications some effects of bulk trapping noise have been seen.

3. Both the input and output of a CCD involve charge storage across capacitors that will be affected by fluctuations in the circuit. The equivalent noise electron for this process is:

$$n_{inp} = \sqrt{kT \cdot C_{inp}} \quad n_{out} = \sqrt{kT \cdot C_{out}} \quad (56.30)$$

where kT is the thermal voltage and C_{inp} and C_{out} are the input and output capacitances. A special signal processing technique known as “correlated double sampling” can be used to reduce this kTC noise at the CCD output.

$1/f$ noise is also present in the output amplifier and is only significant at low frequencies. Methods to reduce $1/f$ noise include multiple sampling using distributed floating-gate amplifiers (DFGA) [2] and noise cancellation techniques using alternate gain inversion (AGI) [7].

4. The maximum SNR of a CCD is limited by the maximum amount of charge that can be stored in a pixel, divided by the equivalent noise electron. Expressed in decibels, it is:

$$\text{SNR} = 20 \log(Q_{\text{max}} = Q_{\text{noise}}) \quad (56.31)$$

The maximum charge is:

$$Q_{\text{max}} = C_e \cdot \Psi_{\text{BH}} \quad (56.32)$$

where C_e is the depletion capacitance associated with the electrode, and Ψ_{BH} is the depth of the potential well.

CCD Power Dissipation

CCD power dissipation is primarily linked to the charging and discharging of the gate capacitances. This power is mainly consumed by the clock driver and is given by:

$$P_{\text{clock}} = C_c \cdot V^2 \cdot f_c \quad (56.33)$$

where C_c is the clock line capacitance associated with the electrodes, V is the clock voltage, and f_c is the clock frequency. For $f_c = 100$ MHz and $V = 5$ V, typical values of P_{clock} are 50 μW per pixel.

In addition to P_{clock} , the on-chip power dissipation per pixel is approximately given by:

$$P_{\text{CCD}} \approx nq(f_c L)^2 / \mu_e + 2nqf_c(\Psi_{\text{BH}} - nq / (2C_e)) \quad (56.34)$$

where n is the number of electrons in a pixel, L is the pixel length, and μ_e is the electron mobility. The overall power dissipation in a CCD is therefore the sum of P_{clock} and P_{CCD} .

CCDs Applications to Light Sensing

Optical Imaging and Spectroscopy

The many fine properties of CCDs have made them the detector of choice for the recording and readout of images at both high and low light levels. The applications include (1) reconnaissance, both civilian and defensive, (2) scene and personnel monitoring, (3) robotics, and (4) astronomy. In astronomy, CCD cameras have found their way into almost all observatories in the world, both for direct readout of images and as the readout cameras for spectrographs.

Perhaps the most exacting application of CCDs has been to astronomy, a discipline in which the characteristics of the CCD need to be pushed to their limits in order to gain the optimum performance. As well as the attempt to optimize this performance in order to gain as much science as possible from the images, it has also been crucial to calibrate the devices as precisely as possible and to fully understand their behavior. In this sense, astronomy has been the “driver” for the scientific development of CCDs. Large-scale commercial applications, such as video recorders, monitoring cameras, etc., have driven the need for improved manufacturing yield, blemish-free operation, uniformity in performance, and reliability.

In order to illustrate the importance of CCDs to exacting scientific requirements, this section will focus largely on the applications to astronomy.

The early demonstration of the performance of a commercial CCD at the focus of a telescope quickly led to the realization of their potential for both space and ground-based astronomical cameras and instruments. Fortunately, this development in the early 1970s was just in time for the first major optical observatory in Earth orbit, the Hubble space telescope (HST). Perhaps the most spectacular application of CCDs to visible light imaging has been within the cameras on board this telescope, i.e., the wide field and planetary cameras built at the Jet Propulsion Laboratory. The CCDs in these cameras consisted of 800×800 pixel arrays, with each pixel of size $25 \mu\text{m}$. The first version of this camera contained eight thinned, back-illuminated devices that were more or less fully depleted. An accumulation layer at the back surface was achieved by flooding the devices with UV light from a lamp internal to the instrument. This accumulation layer allowed the collection of charge resulting from the photoelectric absorption of blue light, and accelerated the charge to the frontside potential wells. Furthermore, the devices were coated in a down-converting coronene phosphor that converted UV light into the yellow-green wavelength band, thus allowing a 20% efficiency in the UV. These devices thus had relatively high quantum efficiency from the UV through to about $1 \mu\text{m}$, vitally important for an instrument collecting photons from galaxies billions of light years away in the universe. As well as their high quantum efficiency, these devices had high charge transfer efficiency and relatively low readout noise at the time of their development. All of these characteristics have since been superseded—at first by an improved version of the camera installed in the HST in late 1993, and then in the Advanced Camera for Surveys, to be installed in 1999. These later instruments had larger format, higher quantum efficiency, and lower readout noise. During the 1980s, devices were developed with these large formats and with readout noise levels approaching one electron.

Starting with modest arrays of size on the order of a few hundred pixels in the 1970s, the devices that became available in the 1990s were as large as 4096 pixels square. As well as in space, these devices have been employed at the prime foci of the world's largest telescopes to give images covering more than 10 arc minutes on a side while still sampling the atmospheric-limited resolution (arcsecond or subarcsecond) adequately. Such devices, when exposed to the sky for up to an hour through a broadband filter, can produce images with tens of thousands of objects for statistical studies in astronomy.

Typical pixel readout rates for astronomical cameras are of the order of 50 kHz, taking tens of seconds for a full readout. Integration times for astronomical CCD cameras can vary from fractions of a second to tens of minutes or even times in excess of an hour, usually limited by the background noise induced by cosmic ray particles and their secondaries. These cosmic ray “events” can be removed by taking at least two frames of data and cross-comparing them. This is important even on the ground, where the radioactive background and muon-induced events total about one per cm^2 per minute; but the cosmic-ray background in space is about one per cm^2 per second, so that camera exposures are rarely longer than 10 to 20 min. Sophisticated computer algorithms have been developed in order to remove the effects of this background radiation.

Of special importance to applications in space research is the packaging of the devices. Contamination of the cold CCD surface by as much as a monolayer of a heavy molecule will effectively render the CCD useless in the vacuum-UV, for example. Careful attention must therefore be paid to the local instrument environment. The CCDs on the HST were in hermetically sealed packages, and the contamination problem was transferred to the lenses covering the CCD packages. In order to achieve optimum performance, the overall camera has to be designed to satisfy the exacting requirements of the CCD, from the point of view of thermal control and stability, absence of electronic interference, and rigorous attention to the elimination of water or heavy molecule contamination. For space application, it may also be advantageous to surround the CCD package with a cosmic-ray shield, such as the 1 cm (0.4 inch) of tantalum used in the CCD cameras on the HST and the Galileo mission to Jupiter. Such radiation shields have to be designed with caution, lest they introduce more secondary particles and induced radioactivity than the primary protons that they stop.

Finally, much effort is put into the processing of astronomical CCD data [24]. Special techniques have been developed to calibrate the pixel-to-pixel nonuniformity in quantum efficiency (a function of wavelength), both on large and small scales. With some effort, this nonuniformity can be calibrated to levels

below 1%. Although it may be easy to expose the CCD to a diffuse source such that there are at least 10,000 electrons per pixel, the corresponding flatfield calibration accuracy may be compromised at low light levels. For astronomical applications, especially in space, most of the pixels may receive only tens of electrons or fewer during an exposure. Low-level traps (including those caused by cosmic radiation) will then manifest themselves in the form of charge-transfer inefficiencies over localized areas or columns. It may be important to calibrate the CCD at the same exposure levels as those typically encountered during the science observation. One way of effecting this is to use hundreds or thousands of frames of data taken in different parts of the sky, and rejecting the astronomical objects in them. These “sky frames” can then be used to produce a “super sky-flat,” which is the average of the individual frames of data.

CCD X-ray Imaging Spectroscopy

Scientific applications such as astronomy have been responsible for driving improvements in CCD technology. In the x-ray domain, for example, CCDs are starting to be employed for medical radiography, where the digital imaging capability and high sensitivity allows for lower patient doses and online image processing. As high-resolution readout detectors of dispersive x-ray spectrometers, CCDs are becoming widely used in the new generation of high brilliance synchrotron beamlines. As spectrometers, they are also being considered in some applications as replacement for Si(Li) diodes, where the higher operating temperatures and improved resolution and efficiency down to x-ray energies below 1 keV leads to applications of interest to biological science and technology.

In contrast with optical imaging applications with many photons per charge packet, to measure x-ray spectral information directly with a CCD single photons per pixel per image frame are required. To use the CCD as a nondispersive x-ray spectrometer requires that the correspondence between the magnitude of the electron charge packet generated initially by the x-ray photon, and the signal measured at the CCD output, must be maintained. This places a very stringent requirement on the efficiency of charge transfer. However, even before the process of charge transfer is initiated, the physics of the charge collection may also degrade the energy measurement process.

The absorption process for a photon of energy E begins with the ejection of a photoelectron, of energy $E - E_B$, where E_B is the binding energy of the appropriate silicon atom electron shell. The range of the photoelectron may be only a fraction of 1 μm . In a few percent of cases, a silicon K shell fluorescence photon may be emitted, and this has a range of about 10 μm , so that there is a finite probability of the event energy splitting into more than one pixel.

Eventually, a proportion of the energy is converted to free electrons, the rest into phonons. The average energy to create an electron-hole pair is roughly constant at about 3.6 eV of incident photon energy per pair produced in silicon. If this free electron charge packet is created in the depletion layer of the CCD, it is promptly drifted under the influence of the electric field to the buried-channel collection site. During this drift time (t_d), the charge can laterally diffuse within a radius $\sim \sqrt{2Dt_d}$, where D is the diffusion constant. Except for the charge clouds originating deep in the depletion layer, this radius is small compared with the typical pixel size. If the charge is generated in a field-free layer *outside* the depleted volume, it will radially diffuse until a fraction recombines or reaches the depletion layer. The latter fraction then starts to drift with the same additional lateral drift as the depletion layer charge packets.

The pixel boundaries are loosely defined by the asymmetric fields created by electrode biasing schemes and surface channel stop implants, and not hard physical boundaries. Hence, any lateral spreading processes may allow some splitting of the initial charge packet between pixels. Furthermore, charge *loss* may be experienced either by the partial recombination of events when liberated deep below the depletion layer, or if the fraction of split charge is too low to be recognized against the device noise level.

In astronomical applications, in space-borne observatories, there is a continuous low-level background of charged particles. Rather than liberating point-like charge clouds, they liberate a population of signal electrons along their tracks throughout the silicon. They may be easily discriminated against x-rays if these tracks are highly skewed with respect to the silicon surface and cross many pixels. Also, if the track is long enough, the magnitude of total charge cloud generated may be large compared with the typical x-ray charge packet.

These features impose a requirement to perform event recognition and analysis. To perform this on-ground would require transmission of all pixel data, including empty pixels, which for megapixel CCD frames generated on second time scales is quite infeasible. Performing this recognition on-board first requires a comparison against some lower threshold. Selection of this level is critical—too high and some split charge may be neglected with a consequent degradation of energy resolution. Too low a threshold, and many spurious events will be counted. If there is a drift or change in the zero-energy signal upon which this threshold is applied, the energy scale may be misregistered, and/or the relative fraction of events selected at different x-ray energies may be unknowingly altered. Simulations show that for the potential energy resolution of CCDs, spectral analysis of cosmic plasmas will demand a calibration of relative detection efficiency versus energy to $\sim 3\%$. If the threshold value is set at about 4σ times the readout noise, this calibration may be degraded by as little as a single digital bit of a commonly used 12-bit ADC in the CCD readout electronics. Thus, the realtime digital processing of events is required to be fast and complex.

A further complication of the event splitting is that to avoid pile-up in CCD frames, the probability of having multiple events per pixel is made more stringent by requiring surrounding pixels to have no signal, and allow this recognition process. Typically, an event rate of 1 photon per 200 pixels per CCD frame is therefore imposed, but this places a rather low limit on attainable count rate performance. Especially with high-resolution focusing optics of observatories such as AXAF[5], this can be much lower than for many previous experiments. If the core of the point spread function of the mirror is not to be degraded by this effect, then special readout formats that reduce the imaged area, in order to accelerate frame readout times, must be employed.

Future Improvements to CCDs

Backside CCDs

The useful spectral range of conventional CCD detectors, although quite broad, is limited in part by the presence of the polysilicon gates on the front surface. As is illustrated in [Figure 56.17](#), photons with

FIGURE 56.17 Attenuation length in silicon in the soft x-ray through near-infrared spectral range. The polysilicon gates of front-illuminated devices, which are typically $\sim 0.4 \mu\text{m}$ thick, are strongly absorbing at wavelengths for which the attenuation length is less than the gate thickness, viz. wavelengths ($\sim 3 \text{ nm} < \lambda < \sim 400 \text{ nm}$). Thin-gate and back-illuminated CCDs, with much thinner dead layers, offer improved detection efficiency in the soft x-ray and UV portions of the spectrum. (From References 8 and 9.)

wavelengths in the range $\sim 3 \text{ nm} < \lambda < \sim 400 \text{ nm}$ have attenuation lengths in silicon less than the typical thickness of the gate structure ($\sim 0.4 \text{ }\mu\text{m}$). Photons in this spectral range are therefore absorbed before they can enter the photosensitive volume of the detector. For conventional CCDs, the detection efficiency is no more than a few percent in this band. If the gates can be made thinner by an order of magnitude, or avoided altogether, then the detection efficiency can be improved dramatically in both the very soft x-ray and the UV. Efforts following the former approach are described below. The latter strategy, which requires illumination of the back surface of the CCD (that is, the surface opposite the gates) is discussed here.

There are a number of techniques that can be used to produce back-illuminated devices [10–12], but they must all deal with two constraints: lateral diffusion of the photoelectrons before they are captured in the buried channel of a specific pixel and the tendency for photoelectrons to recombine at the back surface of the Si.

The lateral diffusion of electrons can lead to a loss of resolution of the CCD since they may cross the boundary between one pixel and another, leading to an erroneous assignment of the origin of the photon that created the electron. This problem is minimized by thinning the *back-illuminated CCD* to thicknesses that are on the order of the depletion depth of the Si, so the least drift occurs before the electron is captured in the potential well of the buried channel. This thinning is accomplished by a combination of methods, including mechanical grinding and polishing and wet etching. Handling of back-illuminated CCDs after thinning, however, is a problem since the remaining Si is between 10 and 100 μm thick, and is not strong enough to support rough handling, or even the intrinsic stresses arising from the initial fabrication of the CCD. To circumvent this problem, rim thinning or frame thinning can be used; in the first case, a rim several millimeters wide around the circumference of the wafer is protected during the thinning process, while in the latter, a region 1 or 2 mm wide around each device is protected.

Lateral diffusion can also be reduced by imposing an electric field through the thickness of the thinned membrane; but if this is done by imposing an electrode on the back surface, then the device will have a reduced QE (quantum efficiency) due to absorption in this layer. The presence of a depletion region in the CCD will also give rise to an electric field, which reduces the lateral diffusion of electrons; but if the desired depletion region is on the order of tens of micrometers, in order to image high-energy x-rays or IR photons, then the induced field will be small, due to the low doping levels in the silicon and Gauss' law.

Although the lateral spread of photoelectrons is a problem, the loss of carriers to recombination at the back surface presents a greater technical difficulty. The recombination velocity can be minimized by introducing a strong electric field at the back surface and by passivating this surface. There are several methods employed to generate this electric field: one is by implanting carriers (*p*-type for the case where photoelectrons are to be captured) and annealing the sample to activate these carriers [11], a second is to deposit a thin layer of metal with the appropriate work function difference (typically Pt or another transition metal) [10], while a third method is to grow a heavily doped epitaxial layer on the back surface [13]. In the implant method, strong electric fields can be generated and the annealing process can help to passivate the back surface, but high-temperature annealing of the wafer can present a problem if metallization is present, unless excimer laser annealing is employed [14]. Deposition of a thin metallic layer can lead to long-term instability of QE and does not appear to yield the highest QEs. Deposition of an epitaxial layer relies on the use of sophisticated equipment and surface cleaning methods.

In addition to introducing an electric field on the back surface, it is necessary to electrically passivate that surface to lower the electron recombination velocity. Again, there are several approaches. The flash gate technique is probably the simplest, relying on inserting the sample in a steam atmosphere, but it is not stable over time [10]. Another method is to grow a high-quality oxide on the back surface [11], but this requires the use of high temperatures, which could melt metalizations and allow any dopant layer to diffuse too deeply into the silicon.

Although the aim of the backside treatment process is always to maximize the fraction of charge collected from the vicinity of the back surface, there are subtle differences in requirements that depend on the application. In the UV ($100 \text{ nm} < \lambda < 400 \text{ nm}$), the extremely small attenuation lengths (see Figure 56.17) place a premium on nonnegligible ($>\sim 50\%$) charge collection efficiency very close to the back surface. Therefore, in UV sensors, the field in the immediate vicinity of the back surface is extremely

FIGURE 56.18 External quantum efficiency of back-illuminated CCD using an implanted and annealed back side. For comparison purposes, the external quantum efficiency of an ideal detector is shown, after modeling for the antireflection coating present on the back-illuminated detector.

important. Moreover, the real part of the index of refraction of silicon is quite high in the UV and optical bands, and Fresnel reflections limit the external detection efficiency that can be achieved. Thus, significant improvements in the UV response of back-illuminated CCDs have been obtained via the application of antireflection coatings as a part of the backside treatment process [12].

In the very soft x-ray range ($2 \text{ nm} < \lambda < 100 \text{ nm}$), the attenuation length can be larger by a factor of 10 than in the UV. Moreover, the range of the secondary photoelectrons is large enough to be comparable to the attenuation length [15], so the physics of the secondary ionization process becomes important. Thus, in the very soft x-ray regime, it is the average properties of the device over scales of a few hundred nanometers that determine performance. However, for spectroscopic applications, the theoretical limit of device performance cannot be reached unless the charge collection efficiency substantially exceeds ~90%. Thus, in the soft x-ray, one requires very high collection efficiency over a relatively large volume in the vicinity of the back surface.

Any backside fabrication techniques will probably require compromises to be made, but it is possible to achieve very high external QE in the UV, as shown in the accompanying Figure 56.18, and in the soft x-ray region where 77% QE has been achieved at 277 eV [16]. Further improvements are necessary to achieve good results in the vacuum UV and theoretical limits for energy resolution in the soft x-ray. These improvements are possible, but will probably depend on the continued development of sophisticated processing tools.

Thinned Gate CCDs

Recently, a new type of CCD was developed that was optimized for spectroscopy below 1 keV. This detector, called a thin gate CCD (or TGCCD), contained two novel features: floating gate output amplifiers (FGAs or “skippers”) and thin gates (electrodes) [2]. The goal was to develop a detector that had Fano-limited energy resolution with nonnegligible QE over the 200 eV to 1000 eV bandpass. This section briefly describes this detector and compares it with more conventional CCDs.

Most conventional CCDs use a floating diffusion amplifier (FDA) to read out the signal charge. The readnoise of the FDA has improved from several hundred electrons (rms) in the 1970s to less than 3 electrons in the last few years [3]. The energy resolution of CCDs over the entire soft x-ray bandpass is now limited by factors other than readnoise. It is desirable to push the readnoise down from a few

electrons to a fraction of an electron because it allows photons of lower energy to be detected in single-photon counting mode.

One method to further reduce the readnoise is to read out the same charge packet multiple times. The signal charge is destroyed when read out through an FDA. In the FGA, however, an insulating gate is placed between the charge transfer channel and the output node. Gates around the output node are used to read out and withdraw the signal charge multiple times. The readnoise is then reduced by the square root of the number of readouts. Effective readnoises of less than 1 electron have been demonstrated using the FGA [2,4], and photons of energy 66 eV (Al L_{α}) have been detected using the TGCCD. If the readnoise could be pushed to a fraction of an electron, it would be possible to detect optical photons in the single-photon counting mode.

Lower Readnoise

The other novel feature of the TGCCD is its electrode structure designed to maximize soft x-ray QE. Most conventional front-side illuminated CCDs have several hundred nanometers of $\text{SiO}_2/\text{Si}_3\text{N}_4$ insulator and Si electrode on the surface. These layers strongly limit the quantum efficiency of the device below 1 keV, but Fano-limited energy resolution is routinely achieved. The conventional solution to increase the low-energy QE has been to etch away the back surface of the device and illuminate it from behind (a back-side illuminated CCD). The difficulty with this technique is that the energy resolution is seriously degraded due to charge diffusion and poor charge collection.

The thin gate CCD is a front-side illuminated device with a unique gate structure that gives reasonable soft x-ray QE (0.20 at 277 eV), while retaining the good energy resolution of front-side illumination. The detector is a three-phase CCD. The first two phases (comprising only 1/3 of the active area of the device) are covered with 400 nm of polysilicon (or just poly) in the usual way. A third layer of poly is deposited on top of the first two and acts as a bus for a fourth (40-nm thick) layer of poly that defines the third clock phase. Two-thirds of the active area of the detector is therefore covered with only the insulator (100 nm of SiO_2 and Si_3N_4) and this fourth layer of poly. The measured energy resolution of this device is 34 eV at C K_{α} (277 eV). This is approximately a factor of 3 better than the best energy resolution obtained with the ACIS back-side illuminated CCDs [5]. Simulations show that an astrophysical spectrum obtained with TGCCD contains as much or more information than one obtained with a back-side illuminated CCD [6].

Radiation Damage

CCDs are often used in environments in which they are subject to ionizing radiation, and this radiation can degrade their performance. In particular, radiation damage plays an important role in the performance of most space-borne detectors. The Van Allen belts contain protons and electrons with energies of tens of MeV. These particles can produce damage by several mechanisms. Protons can generate vacancy-interstitial pairs in the Si lattice, which diffuse freely, even at cryogenic temperatures, and it is possible for the vacancy to form a complex with P atoms in the *n*-Si buried channel that traps electrons. The trap reduces CTE by preventing signal electrons from leaving the pixel during the clocking cycle. Electrons can also produce vacancies (although with much lower cross-section than the protons), but they can also create dangling bonds at the SiO_2 -Si interface above the buried channel, leading to a shift in operating voltage in the CCD and contributing to noise.

The P-V complexes remove electrons from a charge packet in the conduction band of silicon. In the worst-case limit, when the illumination levels are so low that each charge packet transferred encounters each trap in its empty trap state, the degradation of CTE is approximately $5 \times 10^{-7} \text{ rad}^{-1}$ (radiation doses are expressed here in total ionizing rads in Si, although it should be noted that the fraction of proton energy that goes into production of vacancy-interstitial pairs, the nonionizing energy loss, is about 1/2000 of the total ionizing dose [17].) This degradation is significant: if the device is subjected to 1000 rad yr^{-1} and there are 1000 transfers necessary to clock out the charge, then 40% of the charge packet would be lost due to proton-induced defects. At higher illumination levels, the traps greatly complicate the device response, particularly in single-photon counting applications. In this case, for example, the spectral response of the CCD becomes a function of the spatial distribution of the incident radiation.

This loss of CTE can be circumvented in several ways, including the use of increased shielding, a fat zero, annealing out the damage, implanting a narrow trough along the direction of transfer in the buried channel, or operating the device at a different (generally lower) temperature.

Relatively thick shielding, up to the equivalent 4 to 5 cm (1.6 to 2 inch) of aluminum, can provide significant attenuation (factors of several) of proton dose encountered in the radiation belts [18]. A fat zero is a uniform charge added to all the pixels of the CCD, usually induced by flooding the CCD with a low light level. Although a fat zero can reduce the CTE loss by filling the traps so they cannot be occupied by electrons from the charge packet of interest, they also add to the noise of the system. The P-V complex will dissociate at temperatures around 135° C [19], but the annealing is incomplete and may interfere with other requirements or constraints of the satellite mission. Using photolithography, a narrow trough or notch can be included in the buried channel parallel to the direction of transfer during fabrication, so charge packets are kept constrained and are less likely to interact with traps generated randomly across the buried channel [20]. It is not difficult to introduce a channel that is approximately 2 μm wide and can handle a charge packet of tens of thousands of electrons; this can decrease the CTE loss to 7×10^{-8} rad⁻¹ or less. Reducing the operating temperature slows the kinetics of trap emptying [21], so a single electron can be lost from the charge packet and fill the trap for the integration time of the frame. The effectiveness of this process depends on the clock speed and integration time, as well as the ability to operate the CCD at temperatures that approach -150° C, but CTE loss can be as low as 10^{-8} rad⁻¹ if troughs are included with low-temperature operation. Cosmic rays and electrons can also cause damage by displacing Si atoms from the lattice, but the flux of cosmic rays is much lower than protons in low Earth orbits and the electrons are much less effective in creating a vacancy. The approaches to hardening against proton damage will also be effective with these latter two particles.

The major effect of electrons on CCDs is to shift the flatband voltage of the CCDs and MOSFETs, but for doses around 1000 rads, this change is on the order of 10 mV. If further hardening of the gate oxide is desired, it can be accomplished using established methods [22]. The passage of electrons and other energetic charged particles through a device also creates free carriers that constitute an interfering signal. One electron-hole pair is created for each 3.65 eV absorbed in the Si, and charged particles can deposit charge packets of up to a full-well level and more, depending on the species, energy, and the active depth of the device. In astronomy, such events are an annoyance, even in terrestrial observatories, and are removed by comparing images of the same scene. In some applications, such as x-ray spectroscopy, these events are more serious because they can masquerade as desired signals unless careful analysis of the data is performed to exclude them. On the other hand, this sensitivity to charged particles can actually be used to advantage. The known conversion between particle energy deposition and liberated charge means that CCDs can be used as spectroscopic detectors, and such an application has been proposed for inertial-confinement fusion diagnostics [23].

Radiation hardening of CCDs has made rapid progress in the last few years, allowing devices to have much longer lives for scientific applications. Fabrication and operational changes have increased the hardness to displacement damage and the process requirements of high-quality ICs have led to a gate dielectric that is quite robust to ionizing radiation.

57.1 Introduction

As the name indicates, densitometry is the measurement of optical density (O.D.). Optical density, in turn, can be broadly defined as a measure of the attenuation of radiant flux by some sort of optical element that can be transmitting, reflecting, or both. Densitometry is most widely applied in photographic science, and measurements in this field are covered by a four-part ANSI/ISO standard [1]. The treatment here follows that document. The measurement of transmission and reflection from the standpoint of optics has been discussed by Palmer [2]. This chapter uses the single word density, without the adjective, and uses the words “light” and “flux” interchangeably (although density can be measured in the UV and IR also, of course).

It turns out that, in practice, the measured density of a given sample can be affected significantly both by the design of the equipment and the nature of the sample. Therefore, the first rule of practical densitometry is that the sample must be measured in a way that is meaningful with respect to its intended use.

57.2 Monochrome Transmission Density

It is convenient to start by discussing transmitting samples, without the color aspect. Such samples can be either black-and-white photographic films or filter layers of various sorts. If light falls on such an element, a fraction of the flux is reflected from the first surface. The remainder penetrates the surface, and a part of this flux is absorbed. What is neither reflected nor absorbed exits the layer, as shown in [Figure 57.1](#). Let these fractions be denoted, r , a , and t , where lower-case t indicates internal transmittance. If the element is in air, reflection can occur at the rear surface also, but this can be neglected. By the conservation of energy, one obtains

$$r + a + t = 1 \tag{57.1}$$

FIGURE 57.1 Cross-section of emulsion layer showing (A) reflection, (B) absorption, (C), diffuse transmission, and (D) specular transmission.

The fractions r and t can be measured independently by spectrophotographic techniques, so that a is readily determined. This fraction is termed the absorbance of the layer, and its measurement is also discussed by Palmer [2].

Some applications require the measurement of absorbance, but in most practical work, what is important is the fraction of the incident light that exits the element, regardless of where attenuation takes place. Therefore, transmittance is defined by:

$$T = \frac{\Phi_e}{\Phi_i} \tag{57.2}$$

where e and i refer to emergent and incident flux, respectively. Note that all losses are lumped together. In silver halide photographic layers, the first-surface reflection is usually small; in thin-film filters, a significant proportion of the total loss may occur by reflection. Following Hurter and Driffield [3], the English pioneers of densitometry, one can define the transmission density D

$$D = -\log_{10} T = \log_{10} \frac{1}{T} \tag{57.3}$$

Density is therefore a nonlinear dimensionless quantity ≥ 0 . McCamy has published an extensive review of densitometry and sensitometry [4].

The operation of a practical densitometer can be discussed with reference to [Figure 57.2](#). The system consists of a light source, an aperture to define the area being measured, a sensor, logging circuitry, and a suitable readout display. In many instruments, the output is fed to a computer.

FIGURE 57.2 Schematic of transmission densitometer.

To measure transmittance/density, a reading is first taken with no sample over the aperture. This reading is a measure of the incoming light Φ_i . A second reading with the sample in place then determines Φ_e . It should be clearly understood that what the system actually does is to sense the flux passing through the aperture in the two cases, and then displays the negative logarithm of the ratio. This fact explains some of its operating characteristics. Starting from this basis, for example, McCamy [5] has treated measurement errors for the case when the sample is not uniform (“wedged”) over the aperture.

The basic procedure also means that any source having enough power to operate the sensor can be used, and filters and apertures can readily be interchanged; it is only necessary to “zero” the instrument before making a measurement. The measuring aperture is usually of the order of 1 mm in diameter. If the area of this aperture is reduced to, say, 0.1 mm², the device becomes a microdensitometer. Such instruments present special problems not discussed here but treated in the literature [6].

Now consider the complications introduced by the nature of samples, especially photographic samples. Developed black-and-white photographic layers consist of discrete grains of silver metal dispersed in a thin layer of gelatin. Such grains act as scatterers, which means that some of the photons exiting the layer will not be traveling in their original directions. Such photons are identified by “C” in Figure 57.1. Clearly, the measured transmittance/density will depend on how much of this scattered light reaches the sensor. The effect of scattering can be quite large, and therefore in order to obtain values that are both reproducible and meaningful it is necessary to control what is termed the “geometry” of the system, i.e., the angular subtenses of the influx and efflux beams at the sample.

In Figure 57.3, Θ_i and Θ_e are these half-angles, respectively, referred to the normal to the element surface. The current standard [1b] prescribes two configurations, the first of which is as follows: $\Theta_i = 5^\circ$; $\Theta_e = 90^\circ$. The reverse of this configuration, i.e. $\Theta_i = 90^\circ$; $\Theta_e \leq 5^\circ$, yields the same density readings and is also permitted by the standard. This case is termed “diffuse density” and is the most important practical case because most commercial densitometers conform to this mode. Essentially, all the light exiting the sample, whatever its direction, reaches the sensor and is evaluated. This configuration simulates the case of contact printing a photographic negative, or of viewing a transparency on a diffuse illuminator. The practical construction of such an instrument is described below.

The second case occurs when the sample is illuminated, and the emergent flux collected, by lenses of finite aperture. In principle, in this case, the angles Θ_i and Θ_e can vary between, say, 5° and 90° and may differ from one another, but the standard specifies two sets of optics with matched apertures of $f/1.6$ and $f/4.5$. These relative apertures are representative of motion picture projectors and microfilm readers, respectively. The corresponding half-angles are 18.2° and 6.4° . (For a lens in air, $f/\text{no.} = 1/(2\sin\Theta)$, where Θ is the half-angle shown in Figure 57.3.) This case is termed “projection” density.

It is useful to define a ratio

$$Q' = \text{Projection density/diffuse density} \tag{57.4}$$

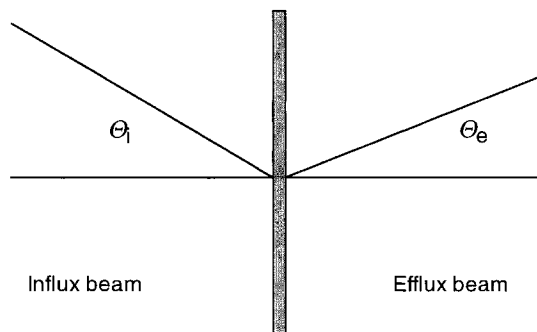

FIGURE 57.3 Angular subtenses of influx and efflux beams at sample.

which has been termed the “effective Callier coefficient.” As would be expected, projection density is greater than diffuse density for a given sample so that $Q' = 1$. The exact ratio between the two densities depends on the scattering characteristics of the sample and the f -numbers involved. Only limited information on Q' has appeared in the literature [7] but, as Figure 57.4 shows, this parameter behaves as might be expected.

The dependence of the effective density on aperture shown in Figure 57.4 may be important in practice. Amateur photographers are aware that a B&W negative usually produces a more contrasty print in a condenser enlarger than it does in a diffuser enlarger, and this behavior can easily be deduced from Eq. (57.4). It may also be important in microdensitometry, since these instruments measure a projection density and a wide range of apertures may be encountered in various instruments. In such cases it is usually recommended that the data be reduced to diffuse density. This is easily done by measuring a sufficiently large sample in both projection and diffuse densitometers. It might be remarked that the scattering characteristics of individual films can vary significantly, and Q' should be measured for the samples at hand. Except for very low densities, Q' is relatively unchanged as the diffuse density varies.

For completeness, it is noted that earlier editions of density standards listed two other forms of density. The first of these was the case of angle $\Theta_i = \text{angle } \Theta_e \leq 5^\circ$. This case was termed “specular density” and was intended to simulate the use of the attenuating element in a collimated beam. The second case was the case of angle $\Theta_i = \text{angle } \Theta_e = 90^\circ$. This type of density was termed “doubly diffuse,” and was intended to simulate the use of a negative in certain contact printers. Neither of these densities is important in modern practice; discussions of them can be found in the literature. [8].

In a color film, the “grains” are actually tiny volumes of dyed gelatin. Since the index of refraction of such a “grain” is only slightly different from the surround, it does not act as a scatterer. Thus, the density differences found on color films as a function of densitometer geometry are usually negligible and often ignored in practice.

In recent years, the photographic industry has introduced a new type of grain, the “tabular” grain, whose thickness is much smaller than the dimensions in the plane parallel to the coating surface. It has been demonstrated that, in the undeveloped state, these grains scatter light significantly less than the older “3-D” types of grains. No studies of developed T-grains have appeared in the literature, but it seems possible that developed B&W layers consisting of T-grains may scatter less than the traditional types of layers, thus reducing the sensitivity of density measurement to instrument geometry. (The data of Figure 57.4 were obtained with “3-D” grains.)

One can now turn to the optical configuration of a practical diffuse densitometer. From an optical standpoint, a good way to collect all the flux exiting the sample would be to use an integrating sphere,

FIGURE 57.4 Variation of the effective Callier Q' -factor with the f -numbers of the influx and efflux beams, which were matched.

and instruments have been built using such spheres. However, in an actual contact-printing case there will be some light reflected back to the negative from the paper surface. Any retroreflection from an integrating sphere will of course be quite different from that coming from a paper surface. The better to simulate the contact-printing case, the present ANSI/ISO standard specifies that, in diffuse densitometers, the emulsion side of the sample shall be in contact with opal glass, which both acts as the diffuser and provides the desired back reflection. The optics of a diffuse densitometer are shown in Figure 57.5.

In the system shown, the sample is illuminated by diffuse light, which is the reverse of what is shown in Figure 57.3; however, as noted, diffuse density optics are reversible. Weaver studied the differences between opal-glass and integrating-sphere densities and found that because of the interreflections, the values were slightly lower in the opal-glass case [9]. The difference was ~0.04 density unit for very low densities, decreasing to 0.01 to 0.02 for samples whose densities were between 2.0 and 3.0. The opal-glass construction was also adopted in the standard because such instruments are easier to build and maintain. Care must be taken, however, to ensure that the diffuser meets the standard's specifications.

In actual operations, it is too time-consuming to zero the instrument before each reading. Likewise, the fraction Φ_c/Φ_i is rarely calculated specifically; the instrument simply provides a reading based on the amount of flux reaching the sensor. Because of the possibility of electronic drift however, it is advisable to zero the instrument periodically, unless it is known to be dependably stable. Likewise, the readings produced for some accurately known calibration sample of high density should be checked, a procedure known as "sloping" the instrument. Standard samples are available for this purpose; see the Appendix.

57.3 Monochrome Reflection Density

By definition, the reflectance factor

$$R = \frac{\Phi_r}{\Phi_o} \tag{57.5}$$

where Φ_r is the flux returned to the sensor from the sample, and Φ_o is the flux returned by a "perfectly reflecting, perfectly diffusing material located in place of the specimen" [1d]. Reflection density is then

$$D_R = -\log_{10} R = \log_{10} \frac{1}{R} \tag{57.6}$$

The optical configuration specified in the standard is shown in Figure 57.6. With reference to the normal to the specimen surface, one beam subtends an angle of $0 \pm 5^\circ$ and the other an angle of $45^\circ \pm 5^\circ$. Also, the 45° beam is annular. As in the case of transmission optics, the influx and efflux beams are interchangeable. When the influx beam is at 45° , the system is termed "45/0"; when the efflux beam is at 45° , the designation is "0/45." The angle between the two beams was selected to avoid the specular reflection from the surface. The 45° beam is made annular to minimize the effects of any texture pattern that might be embossed on the sample surface. The standard also specifies that when measured, samples

FIGURE 57.5 Optical system for measuring ISO diffuse density.

FIGURE 57.6 Annular geometry for measurement of reflection density.

shall be backed by a black diffusing material having a reflection density not less than 1.5. This procedure is specified to improve reproducibility, especially for thin samples.

It will be obvious that a reflection densitometer cannot be “zeroed” by taking a reading with no sample in place. Instead, as prescribed by the Standard [1d], calibration samples that have been measured on other primary instruments are used both to zero and slope the densitometer. Formerly, coatings of MgO_2 or BaSO_4 were used as reference “whites,” but these layers are difficult to use. An ASTM standard [10] discusses the preparation of reference whites from pressed powders. For routine work, “plaques” consisting of stove enamel of various gray levels on a metal substrate are widely used. These plaques are very durable, but their physical form is quite different from actual paper samples. Photographic paper strips that have been calibrated in primary instruments can also be used. Physically, these strips are exactly like the samples to be read, but they are very easily damaged and must be used with care. Any scratch in the surface can cause a specular reflection to reach the sensor, which will produce a false reading.

Actually, the reflection of light from a photographic paper is more complicated than might appear at first glance. A typical B&W paper is shown in cross section in Figure 57.7. As with film samples, the emulsion layer consists of Ag grains suspended in gelatin. The support is a diffuse reflector. It turns out that reflection to the sensor occurs in three ways, as sketched. (The specular reflection is omitted in Figure 57.7.) Note that the component r_2 traverses the emulsion layer twice and r_3 at least four times, and that r_1 does not traverse the layer. For low densities, all three components contribute to the reflection reading. As the population of grains in the emulsion layer grows, the multiply-reflected beam r_3 rapidly becomes negligible. With continued increases in the grain population, the component r_2 also reduces to insignificance, and only the r_1 component remains. This component, being a surface reflection, remains essentially constant at about $0.005I_0$.

The mechanism described above can be confirmed by measuring the densities of a test strip by transmission and then cementing the strip to a diffuse reflector and measuring the same densities by reflection. The results of such an experiment are shown in Figure 57.8. This curve has three regions, as expected. In the first region, the slope is greater than 2, corresponding to the rapid loss of the r_3 component. In region 2, $\Delta D_R = 2\Delta D_T$; in this region, most of the photons reaching the sensor are those that have traversed the layer twice. Finally, in the third region of the curve, the r_2 component has become negligible, and only the surface component r_1 remains significant. Since, as noted, this component $\sim 0.005I_0$, the maximum reflection density attainable in a photographic paper should be about 2.0 to 2.3,

FIGURE 57.7 Cross-section of photographic paper showing different reflection paths for influx beam: r_1 , surface reflection; r_2 , direct reflection from support to sensor; and r_3 , one or more internal reflections before reaching sensor.

and this is found to be the case for actual papers. (We have assumed a glossy paper. If the paper surface is textured, as it is in some products, specular reflections may be directed to the sensor from microareas and the maximum density attainable on the sample will drop, in some cases significantly.) The curve of Figure 57.8 also becomes very important in color reflection work, as is discussed below.

57.4 Color Transmission Densitometry

So far, we have assumed either that the measuring beam was monochromatic or that the sample was neutral, i.e., that transmittance or reflectance was constant across the spectrum of interest. Actually, the assumption of neutrality is reasonable for many B&W materials. However, of course, the densitometry of color images is extremely important, and this aspect is discussed below.

FIGURE 57.8 Densities measured on a film sample, both by transmission and after cementing the emulsion side to a diffusing reflector.

Before doing so, however, it will be useful to make a brief digression into the structure of photographic color materials [11]. Although an oversimplification, we can consider such materials to be three separate films coated one over the other on a single support. From the top down, the spectral sensitivities of these three layers are adjusted to record the blue, green, and red regions of the visible spectrum, respectively. In accordance with the principles of subtractive color reproduction, the images recorded in these layers are formed of yellow, magenta, and cyan dyes (again from the top down). The problem is to densitometer these dyes. As before, we start with transmitting samples. Referring back to Figure 57.2, for any wavelength λ , the reading of the instrument with no sample in place will be

$$KS_{\lambda}s_{\lambda}F_{\lambda} = KJ_{\lambda} \quad (57.7)$$

where K = proportionality constant, S_{λ} = spectral power of the influx beam at λ , s_{λ} = relative spectral sensitivity of the receiver at λ , and F_{λ} = transmittance of any filters in the beam at λ . (The transmission of the instrument optics may be significant, but this can be included with S_{λ} , since it is a fixed characteristic of the device.) The product J is termed the “response” or the “spectral product” of the instrument.

If a sample whose transmission at wavelength λ is T_{λ} is now placed over the aperture, the reading will be

$$KS_{\lambda}s_{\lambda}F_{\lambda}T_{\lambda} = KJ_{\lambda}T_{\lambda} \quad (57.8)$$

and the measured transmittance reduces to T_{λ} , as it should. Thus, in the monochromatic case, the measured value is independent of the system response. When the influx beam contains two discrete wavelengths, the no-sample reading becomes

$$K(J_1 + J_2) \quad (57.9)$$

and with the sample in place it will be

$$K(J_1T_1 + J_2T_2) \quad (57.10)$$

The measured transmittance

$$T = \frac{J_1T_1 + J_2T_2}{J_1 + J_2} \quad (57.11)$$

Note that when the sample is neutral, Equation 57.11 again reduces to the case where the transmittance is independent of the instrument response. But when the sample is not neutral, Equation 57.11 can no longer be simplified. In other words, in the general case the transmittance/density values depend on the system response as well as on the sample.

For continuous bands of radiation, Eq.(9) becomes

$$T = \frac{\int J_{\lambda}T_{\lambda}d\lambda}{\int J_{\lambda}d\lambda} \quad (57.12)$$

and

$$D = -\log_{10} \left[\frac{\int J_{\lambda}T_{\lambda}d\lambda}{\int J_{\lambda}d\lambda} \right] = \log_{10} \left[\frac{\int J_{\lambda}d\lambda}{\int J_{\lambda}T_{\lambda}d\lambda} \right] \quad (57.13)$$

The integration limits are set by the distributions.

From the above analysis, it is clear that in order to obtain meaningful density values, the spectral characteristics of the densitometer must be made equal to those of the receiver that will “view” the sample in actual use. Furthermore, of course, the actual receiver will vary from application to application. The densitometer characteristics are set by inserting appropriate filters in the beam. A number of spectral distributions are specified in Reference 1c as follows:

1. For reflection densitometry, the influx spectrum shall be ICI Illuminant A, which is essentially 2856 K.
2. For transmission densitometry the influx spectrum shall be Illuminant A modified by an infrared absorbing filter, as tabulated in the standard.
3. For samples to be viewed by an observer, the spectral characteristic of the system shall match the relative luminosity function $V(\lambda)$. This case is termed “visual” density.
4. For color negative films, a set of three distributions in the red, green, and blue regions of the spectrum is specified. This set is identified Status M, and approximates the spectral sensitivities of the three layers of color print materials.
5. For measuring red, blue, and green densities of color materials other than color negatives, a set of three responses identified Status A is provided.
6. To evaluate color images to be used in graphic arts processes, two sets of distributions are specified and are identified as Status T and Status E.
7. In the microfilm industry, prints are often made onto diazo or vesicular films. A narrow distribution centered at 400 nm is specified for this application, and the resulting densities are termed ISO printing densities Type 1.
8. A spectral distribution covering the range $\lambda \approx 360$ to 540 nm is provided for measuring samples to be printed onto B&W photographic papers. Such densities are designated ISO printing densities Type 2.
9. Status I response consists of three passbands centered at 420, 535, and 625 nm ± 5 nm. This set is used in evaluating graphic arts materials such as process inks on paper.
10. A narrowband response centered at 800 nm ± 20 nm is provided for measuring effective densities to S-1 photosurfaces, such as those used in optical sound systems. Densities measured with this response are identified “ISO type 3.”

These responses are shown in [Figures 57.9a–e](#), which are reproduced from the current standard.

The next problem in color densitometry stems from the fact that the three layers are superimposed and from the nature of the dyes. The spectrophotometer curves for a typical dye set are shown in [Figure 57.10](#). In this figure, the lower three curves refer to the dyes measured individually, while the upper curve shows the result of superimposing them. The values for the individual dyes are termed “spectral analytical densities,” and those for the tri-pack are termed “spectral integral densities.” Since superimposed densities may be considered to add, at any wavelength the spectral integral value is the sum of the three analytical values. Note that all three of the individual dyes absorb light outside the spectral regions in which they are supposed to work.

This unwanted absorption can cause problems in color reproduction and, more to the point for this chapter, in densitometry, because straightforward measurements of a real film at any wavelengths yield integral values. In many cases, these integral values are required. In the manufacture and processing of films, however, it may become necessary to determine the densities in an individual layer. It is not sufficient to coat and measure a layer by itself, since layers coated in a tri-pack may respond differently from the same layers operated singly.

This problem is solved by taking advantage of two rules called the “additivity rule” and the “proportionality rule.” The first of these is merely the rule that densities add. The proportionality rule is an extension of Beer’s law. Consider an element, such as a glass cell or a layer of a color film, containing a dye whose concentration can be varied. Beer’s law states that

FIGURE 57.9a Spectral products for ISO density and relative spectral power distributions for influxes. (continues)

$$T_{\lambda} = e^{-\beta_{\lambda}c} \quad (57.14)$$

where c is the dye concentration and β_{λ} is the extinction coefficient at wavelength λ . The coefficient β varies with wavelength, of course, but will be constant at a given wavelength (unless changes in dye concentration produce chemical reactions.) Strictly speaking, Beer's law applies to the internal transmittance, but in the case of photographic layers, the surface reflectance is negligible. From Equation 57.14, it follows that

$$\ln T_{\lambda} = -\beta_{\lambda}c \quad (57.15)$$

and therefore,

$$D_{\lambda} = 0.434\beta_{\lambda}c \quad (57.16)$$

Consider now the density at two wavelengths for any given dye sample. Clearly,

$$\frac{D_{\lambda_1}}{D_{\lambda_2}} = \frac{\beta_{\lambda_1}}{\beta_{\lambda_2}} \quad (57.17)$$

FIGURE 57.9b Spectral products for type 1 and 2 densities. (continues)

FIGURE 57.9c Spectral products for Status A and M densities. (continues)

FIGURE 57.9d Spectral products for Status T densities. (continues)

FIGURE 57.9e Spectral products for Status E and I densities.

FIGURE 57.10 Spectral density distributions of the C, M, and Y components as functions of wavelength for a hypothetical color film, and of the composite absorber (N).

Thus, for a given dye sample, the ratio of the densities at any two wavelengths is fixed regardless of dye concentration (i.e., assuming Beer's law holds), and this is a statement of the proportionality rule.

As noted, straightforward density measurements on a real sample yield integral densities. The proportionality rule can be used to derive analytical densities in the following manner [12]. Assume spectral densities for simplicity. With reference to Figure 57.10, we select three wavelengths at or near the peak absorbances of the three dyes. Consider first the blue wavelength. By the additivity rule, the blue integral density is

$$D_b = Y_b + M_b + C_b \quad (57.18)$$

where Y_b , M_b , and C_b are the blue analytical densities of the yellow, magenta, and cyan dyes, respectively. But by the proportionality rule, $M_b/M_g = \text{constant}$, where M_g is the analytical density of the magenta dye measured at the peak wavelength in the green. The value of this ratio is readily determined from a spectrophotometric curve of the dye. Denoting such ratios a_n , for measurements at the three peak wavelengths we have

$$\begin{aligned} D_b &= Y_b + a_1 M_g + a_2 C_r \\ D_g &= a_3 Y_b + M_g + a_4 C_r \\ D_r &= a_5 Y_b + a_6 M_g + C_r \end{aligned} \quad (57.19)$$

This constitutes a set of three equations with three unknowns. The solution has the form

$$\begin{aligned} Y_b &= b_1 D_b + b_2 D_g + b_3 D_r \\ M_g &= b_4 D_b + b_5 D_g + b_6 D_r \\ C_r &= b_7 D_b + b_8 D_g + b_9 D_r \end{aligned} \quad (57.20)$$

where Y_b , M_g , and C_r are the desired values of the three analytical densities. The b -coefficients are algebraic combinations of the a -coefficients, which can be reduced to numerical values since the a -coefficients are known. In practical work, the determination of the a -coefficients is usually done using data for a number of different dye density levels. The off-peak density for each level is plotted against the peak density, giving a straight line whose slope is a good measure of the a -coefficient. Thus, for example, the coefficient a_1 in Equation 57.14 would be found by plotting M_b vs. M_g for several levels. The values of the coefficients can also be found by doing narrow-band densitometry on the samples instead of spectrophotometry.

So far, we have been assuming spectral densities. By the first law of densitometry, however, any sample should be measured with a system whose spectral response is equal to that used in actual practice—in other words, color negative samples should be measured with the Status M filters described before, etc. However, the analysis described above works satisfactorily with the status filters, which are relatively narrow-band, and much practical densitometry is performed in this manner.

Finally, because of its practical importance, we must introduce one more type of color density: the “equivalent neutral density,” or END. END is defined as the neutral density that a given dye deposit—either yellow, magenta, or cyan—will produce when it is combined with the correct amounts of the other two dyes, whatever those amounts may be. It is important in practical film building, because one of the most important properties of a color film is its ability to produce a neutral as a neutral—in other words, to image a gray object as a gray that shows no residual tint of another color. Such a film is said to be “balanced,” and good balance is considered extremely important by discriminating users. When the ENDS of the three layers of a color film are equal, the image will indeed be balanced, and color film densitometry may be done in terms of ENDS. The END is a form of analytical density because it is a property of an individual layer. Originally, ENDS were measured in a special densitometer, but they are now calculated from the normal analytical densities by an equation of the form

$$\text{END} = m[\text{analytical spectral density}] + K \quad (57.21)$$

where the constants m and K are determined by comparing the visual densities of satisfactory neutral images with the corresponding analytical spectral densities. In some cases, a second-order equation has been found to yield better results [12b].

57.5 Color Reflection Densitometry

Color reflection densitometry follows the general principles set forth above for the B&W reflection case. Since color prints are for the most part intended to be viewed by a human observer, in many cases a visual integral density provides the needed information. The film builder or process controller, however, may need information about the analytical densities of his layers, and here the approach used for transmitting samples does not work. The reason it fails is that, for such samples, Beer’s law fails, as is shown by the curve of Figure 57.8. If the law held, the reflection density would be proportional to the dye concentration (see Equation 57.11).

Pinney and Vogelsong [13] have described a method of obtaining reflection analytical densities in such cases. The method involves the empirical determination of a calibration curve similar to Figure 57.8 for the material at hand, relating the reflection densities of a dye deposit to the transmission densities. The reflection integral densities of the sample are then measured and converted to transmission densities. The analytical values for these transmission densities are calculated using the method described above for such samples. Finally, the derived transmission values are converted back to reflection analyticals by going through the calibration curve in the reverse direction.

One last comment on the densitometry of color print papers should be added. In the commercial production of color prints, it may be extremely important to measure chemical stain in what should be the white areas of the picture. The passbands of the Status A filters are not well placed to monitor such stain, and it may be necessary to make additional measurements.

57.6 Densitometry of Halftone Patterns

Halftone patterns are used in the printing industry to reproduce continuous-tone images using two levels of ink: either ink or no ink. Various gray levels are produced by printing a pattern of repetitive “dots” too small to be resolved by the unaided eye. Essentially, the size of the dots is varied to produce a gray scale. Halftone patterns to be measured may be transmitting or reflecting; monochrome or color. A number of standards for densitometry in the graphic arts have been approved or are under development [14]. These standards provide much practical guidance, and are consistent with ISO-5. Densitometry in this field is an example of the basic mechanism by which the instrument operates—comparing the flux reaching the sensor with and without the sample in place. When the sample is a halftone, the flux reaching the sensor depends on the fractions of the area that are dense and clear. Adopting the notation of Ref. 13b and assuming a transmitting sample, the measured density will be

$$D_t = -\log_{10}\bar{T} = -\log_{10}[fT_s + (1-f)T_b] \quad (57.22)$$

where D_t = measured density of pattern, \bar{T} = average pattern transmittance, f = fraction of pattern area that is dense, T_s = transmittance of “solid” areas (essentially equal to dot density), and T_b = transmittance of clear areas.

It is interesting to calculate the measured density of a halftone pattern half of which is perfectly dense ($D = \infty$; $T = 0$) and half of which is perfectly clear ($D = 0$; $T = 1$). The calculated value for $D \approx 0.3$; and this value will indeed be found if such a pattern is densitometered.

If D_p , T_s , and T_b are known, Equation 57.22 provides an easy way to determine the fractional area covered by the pattern dots with an ordinary densitometer, and this is often done in graphic arts work. In practical work, T_s and T_b are measured in terms of density also, and this can be done satisfactorily on large areas. Since by definition $T = 10^{-D}$, the solution of Equation 57.22 for f can be written

$$f = \frac{1 - 10^{-(D_t - D_b)}}{1 - 10^{-(D_s - D_b)}} \quad (57.23)$$

In this form, the equation is known as the Murray-Davies equation.

57.7 Summary

A densitometer measures the flux reaching the sensor with a sample in place, and calculates the ratio of this value to that obtained either with no sample in place (in the transmission case) or with a reference white in place (in the reflection case). The instrument then displays the negative log of this value.

The observed reading may depend significantly on the characteristics of the instrument, i.e., on the

1. angular substance of the influx beam,
2. angular substance of the efflux beam,
3. spectral power distribution of the influx beam, and
4. spectral sensitivity of the receiver.

For a complete specification of the density in a given case, these four parameters should be indicated. ISO 5.1. (Ref.1a) provides a standardized notation.

58.1 Introduction

Imagine how dull a world without color would be. Until the 1960s, many products were available in only a limited variety of colors. Consumers demand a variety of colors, and the materials available today allow manufacturers to meet those demands.

For many centuries, color was controlled by master color matchers adjusting the color of their products visually in natural daylight. It was about the 1950s when color measuring instruments began to make a significant impact in the manufacturing process, and by the 1970s they were commonly used in most industries. Color measuring instruments are used mostly for quality control but also for computerized color matching systems, process control, evaluation of raw materials, and as an aid to solving color problems.

While it is common to speak of a red car or a red light, color is a perception—not an intrinsic property of the object or the light. Color perception is influenced by the light source, the [reflectance](#) or transmittance properties of the object, the eye, and the brain. Color is one aspect of appearance. Gloss and texture are other aspects.

Color perception is three dimensional, i.e., three terms are needed to describe a color. Hue, lightness (sometimes called value), and **chroma** are one set of terms often used to describe color. Hue distinguishes blue from green from yellow, etc. Lightness distinguishes light colors from dark colors—for example, a light blue fabric from a dark blue fabric. Chroma, the most difficult of the three terms to understand, describes how different a color is from gray—for example, distinguishing a pastel green from a bright green. If the two greens are of the same hue (one is neither yellower nor bluer than the other) and have the same lightness, then the pastel green would be described as having a low chroma and the bright green as having a high chroma. [Figure 58.1](#) is a diagram illustrating the three dimensions of color.

Daylight, fluorescent lamps, and incandescent lamps are widely used light sources for color evaluation. The perceived color of an object changes as the light changes. The human visual systems attempt to compensate for the change in light source and hold the color constant. Light booths provide standardized and controlled light sources for the visual evaluation of color. Most light booths contain a simulated daylight lamp, a cool white fluorescent lamp, an incandescent lamp, and an ultraviolet lamp for detecting fluorescence. By use of a switch, a light booth can be used to examine how the perception of a colored material changes with different light sources.

Two objects may appear the same when viewed under one light source, but different when viewed under another light source. This effect, called metamerism, is one of the major industrial problems for color matching. [Metamerism](#) usually occurs when attempts are made to produce objects that are the same color but made out of different materials, such as trying to match the dyed textile interior of a car with paint on the exterior and the plastic on the dashboard.

[Colorimetry](#), the measurement of color, attempts to quantify the perception of color. The Commission Internationale de l'Éclairage ([International Commission on Illumination, or CIE](#)) is a voluntary organization of scientists and engineers from all over the world who are interested in light and color. The recommendations constituting modern colorimetry were first published by the CIE in 1931 and have been regularly updated since then [1].

Electromagnetic radiation (x-rays, gamma rays, light, and radio waves) irradiates the Earth constantly. Visible light is the name given to the electromagnetic radiation that the human eye perceives. The wavelength of visible light ranges from about 380 nm to about 780 nm. Sunlight is a mixture of all the wavelengths of light. Water vapor can spatially separate the light into its various wavelengths—the rainbow. Prisms and diffraction gratings can also spatially separate light into its component wavelengths.

FIGURE 58.1 The three dimensions of color.

Light sources can be described numerically by their spectral power distribution, the relative amount of power the source emits at each wavelength of interest. A light source may emit power at wavelengths below (ultraviolet “light”) or above (infrared “light”) those of visible light. Ultraviolet radiation is important to colorimetry because it can cause fluorescence. Infrared radiation is the basis of “heat lamps” but is not important in colorimetry. Spectroradiometers measure the spectral power distribution of light sources.

Illuminants and sources are sometimes confused. Sources are actual physical entities that produce visible radiation, whereas an illuminant may only be a numerical table of values of a spectral power distribution. Initially, the CIE recommended three light sources for colorimetry in 1931. Source A, which is still in use, is an incandescent, tungsten filament light. An illuminant is the spectral power distribution of a light source. Thus, Illuminant A is the spectral power distribution of Source A. An illuminant may be defined, even when a source for that illuminant does not exist. Examples of illuminants without sources are the D series of illuminants recommended by the CIE. The D illuminants represent various phases of daylight. Illuminant D65 represents average daylight and is the most common illuminant used in colorimetry. No sources were recommended for the D series of illuminants.

Fluorescent lights have great commercial importance. Cool white fluorescent lamps are the most common light sources in offices in the United States. There are a variety of other types of fluorescent lamps used in stores and offices. The CIE also recommended a series of illuminants to represent fluorescent lamps. F2 represents cool white fluorescent lamps. [Figure 58.2](#) shows the spectral power distributions of Illuminants A, D65, and F2.

Color vision and perception is complex and has been extensively studied. Ninety-two percent of men and 99.5 percent of women have “normal” color vision. The eye’s lens focuses images on the light-sensitive retina. Rod cells make up the majority of the retina and are sensitive to low levels of illumination (night vision). Cone cells provide color vision and are located in a small area of the retina called the *foveal pit*. There are three types of cone cells. One type of cone cell has peak sensitivity to blue light, one type to green light, and one type to red light. Signals from the cone cells are transmitted to the brain where they are processed into color perceptions.

Color perception is an extremely complex phenomenon. For example, the background on which a material is viewed can have a major effect on the perceived color of that material. The ambient light to which the eye becomes adapted also influences the color of materials. Basic colorimetry, the topic of this chapter, provides the rather simple concept of dealing with the measurement of single independent colors. Most of industrial color control is adequately described using basic colorimetry. Advanced colorimetry attempts to use physical measurements to describe the perceived color of a material when viewed in a complex scene.

All colors are perceived by stimulating combinations of the three cones. Computer monitors and color television tubes produce colors by lighting combinations of red, green and blue phosphors. In 1931 when

FIGURE 58.2 The spectral power distribution of CIE Standard Illuminants A, D65, and F2.

FIGURE 58.3 The spectral reflectance curve of a printed yellow ink.

the CIE was developing the system for modern colorimetry, they transformed the data from real experiments that had human observers match each wavelength of visible light with combinations of red, green and blue lights, to three mathematical imaginary “lights” labeled X, Y, and Z. All colors can be matched by varying amounts of X, Y, and Z. The amounts of each X, Y, and Z imaginary light that must be mixed together to match a color are called the tristimulus values (see “The CIE Standard Observers,” page 58-6).

Most objects absorb, transmit, or reflect (scatter) light. Transparent objects absorb and transmit light. Opaque objects absorb and reflect light. Light sources emit light. Fluorescent objects absorb, reflect, and emit light. Translucent or hazy objects absorb, transmit, and scatter light. Measuring the color of fluorescent, translucent, and hazy objects is difficult and will be covered in later sections.

Objects are characterized by the amount of light they reflect or transmit at each wavelength of interest. Most spectrophotometers measure [reflectance factors](#) rather than reflectance. Reflectance is the amount of light reflected from an object compared to the amount of light illuminating that object. The reflectance factor is the amount of light reflected from an object compared to the amount of light reflected from a perfect diffuser under the same conditions. A perfect diffuser is a theoretical material that diffusely reflects 100 percent of the light incident upon it. The term reflectance is often used in a general sense, or as an abbreviation for, reflectance factor. Such usage may be assumed unless the term reflectance is specifically required by the context [49]. Spectrophotometers designed for color measurement usually measure reflectance or transmittance at 10- or 20-nm intervals throughout the visible spectrum.

When the reflectance or transmittance of an object is low, the object absorbs most of the incident light; when it is high, the object reflects or transmits most of the incident light. [Figure 58.3](#) shows the reflectance curve of a printed yellow ink. Note that the yellow ink absorbs light in the blue portion

FIGURE 58.4 The spectral reflectance curve of a green transparent plastic.

of the spectrum and reflects light in the yellow and red portions of the spectrum. A green plastic (Figure 58.4) absorbs light in the blue and red portions of the spectrum and transmits light in the green portion.

The tristimulus values of an object can be calculated by combining the reflectance or transmittance of the object with the spectral power distribution of an illuminant and the color matching functions of a Standard Observer. The yellow ink's tristimulus values for Illuminant D65 and the 10 Degree Standard Observer are $X = 66.62$, $Y = 69.72$, and $Z = 7.03$. Those for the green plastic are $X = 21.03$, $Y = 39.40$, and $Z = 24.06$. An object's tristimulus values will change with the illuminant. For example, the tristimulus values for the yellow object for Illuminant A and the 10 Degree Standard Observer are $X = 91.15$, $Y = 77.83$, and $Z = 2.80$.

Pairs of objects are said to match when their tristimulus values are the same. However, since the calculation of the tristimulus values included the source and observer as well as the object, when one of these changes, the objects may no longer match, i.e., they may have different tristimulus values. Metameric colored objects have the same tristimulus values for the illuminant under which they match but different tristimulus values for illuminants where they do not match.

Color measurements are most often made to determine quantitatively whether or not the colors of two objects or batches of material are the same. But what happens when they do not match? Color difference equations were developed to quantify the difference. Starting with the objects' tristimulus values, a color difference equation will calculate the total color difference, ΔE or DE , and its component parts—the differences in lightness (ΔL or DL), chroma (ΔC or DC) and hue (ΔH or DH) or the differences in lightness, yellowness-blueness (Δb or Db) and redness-greenness (Δa or Da). Numerical color differ-

ences may be used for setting tolerances for quality control applications, to answer the question: is the match close enough?

58.2 Standardized Light Sources

Color Temperature

Light sources may be described by their color temperature. A block of carbon would look completely black when its temperature was at absolute zero, 0 K. When the carbon block is heated to about 2850 K, it looks yellow—about the same color as an incandescent light bulb. Heat the block to 5000 K, and it looks whitish. At 7500 K, the block would have the bluish color of north sky daylight. A full (blackbody) radiator is a theoretically perfect emitter and absorber of radiation that changes color like the carbon block just described. The color temperature of a light source is the temperature of a full radiator that has the same color as the light source. When a light source does not exactly match the color of a full radiator, the correlated color temperature is used to describe the light source. The correlated color temperature is the temperature of a full radiator whose color is closest to the source.

Daylight varies during the day—redder in the morning and evening and bluer at noon. Average daylight (diffuse skylight without direct sunlight) has a color temperature of 6500 K. North sky daylight is preferred by many people for the visual evaluation of color and has a color temperature of 7500 K.

CIE Recommendations

Source A has a color temperature of 2856 K. The CIE recommended daylight illuminants are referred to by the prefix D, followed by the first two digits of their color temperature. Thus, CIE Illuminant D65 has a color temperature of 6500 K. Illuminant D50 has a color temperature of 5000 K and is preferred by the graphic arts community. Illuminant D75 would be used for north sky daylight having a color temperature of 7500 K. Illuminant F2 has a color temperature of about 4100 K.

58.3 The CIE Standard Observers

The CIE adopted two Standard Observers based on color matching experiments. The CIE 2 Degree Standard Observer was recommended in 1931, and the CIE 10 Degree Standard Observer was recommended in 1964.

In the CIE experiments, observers having normal color vision matched spectrum colors with combinations of red, green, and blue light. [Figure 58.5](#) illustrates the experimental setup used in the Standard

FIGURE 58.5 Experimental field of view for determining the CIE Standard Observers.

Observer experiments. One-half of a circular field was illuminated with the spectrum color, while the other half was illuminated with a mixture of red, green, and blue lights. The observer adjusted the amounts of red, green, and blue until the mixture matched the spectrum color. Unfortunately, not all of the spectrum colors could be matched with combinations of the red, green, and blue lights used in the experiment. In those cases, one of the lights had to be moved so that it illuminated the test field. By “diluting” the spectrum color with one of the lights, the resultant color could be matched with the remaining two lights. The amount of light used to dilute the spectrum color was considered to be a negative amount. To avoid having color matching functions with negative amounts of light, three “imaginary” lights (X, Y, and Z) were created by performing a mathematical transformation. Color matching functions are the amounts of X, Y, and Z required to match the colors of the spectrum and are used in the calculation of tristimulus values. Figure 58.6 shows the color matching functions, $(\bar{x}, \bar{y}, \text{ and } \bar{z})$ for the 10 Degree Standard Observer.

In the first experiments, the circular field viewed was projected on the foveal pit and subtended a solid angle of 2°. This is about the size of a dime held at arm’s length. The 2 Degree Standard Observer developed from these experiments is very useful when viewing small fields, such as the signal lights of ships or small colored chips. Industrial color matchers view larger fields, such as two 5 × 12-inch panels. The 10 Degree Standard Observer should be used when viewing larger fields. Observers for those experiments viewed a 10° visual field, which is about the size of a fist held at arm’s length.

The standard observers represent combinations of the color matching functions of a number of observers. Standard observer color matching experiments are tedious and difficult to do. Few people can do them with reproducibility. An individual’s color matching functions are likely to vary from that of a CIE Standard Observer. Although these differences do not generally present a problem, they can affect the evaluation of metameric samples.

58.4 Calculating Tristimulus Values

Tristimulus values for a reflecting samples are calculated from the following equations:

$$X = k \int_{380}^{780} R_{\lambda} S_{\lambda} \bar{x}_{\lambda} d\lambda \cong k \sum_{380}^{780} R_{\lambda} S_{\lambda} \bar{x}_{\lambda} \Delta\lambda \tag{58.1}$$

$$Y = k \int_{380}^{780} R_{\lambda} S_{\lambda} \bar{y}_{\lambda} d\lambda \cong k \sum_{380}^{780} R_{\lambda} S_{\lambda} \bar{y}_{\lambda} \Delta\lambda \tag{58.2}$$

FIGURE 58.6 The color matching functions for the CIE 10 Degree Standard Observer.

$$Z = k \int_{380}^{780} R_{\lambda} S_{\lambda} \bar{z}_{\lambda} d\lambda \cong k \sum_{380}^{780} R_{\lambda} S_{\lambda} \bar{z}_{\lambda} \Delta\lambda \quad (58.3)$$

$$k = \frac{100}{\int_{380}^{780} S_{\lambda} \bar{y}_{\lambda} d\lambda} \cong \frac{100}{\sum_{380}^{780} S_{\lambda} \bar{y}_{\lambda} \Delta\lambda} \quad (58.4)$$

in which S_{λ} is the relative spectral power distribution of the illuminant at wavelength λ , R_{λ} is the reflectance factor of the sample at wavelength λ , and \bar{x}_{λ} , \bar{y}_{λ} , and \bar{z}_{λ} are the color matching functions of the observer at wavelength λ . For transmitting objects, substitute the transmission factor, T_{λ} , of the sample at wavelength λ for the reflectance factor. The factor k normalizes Y so that it will equal 100.00 for a perfect reflector or transmitter, i.e., R_{λ} or T_{λ} is 100.00 at all wavelengths of interest. The summations in the above equations are only valid if the reflectance or transmittance of the sample is measured at wavelength intervals of 1 nm or 5 nm from 380 to 780 nm.

Many commercial spectrophotometers measure wavelength intervals of 10 or 20 nm. To accurately calculate tristimulus values of samples measured with those instruments, the following equations should be used:

$$X = \sum W_{x\lambda} R_{\lambda} \quad (58.5)$$

$$Y = \sum W_{y\lambda} R_{\lambda} \quad (58.6)$$

$$Z = \sum W_{z\lambda} R_{\lambda} \quad (58.7)$$

in which $W_{x\lambda}$, $W_{y\lambda}$, and $W_{z\lambda}$ are weighting factors designed for 10 and 20 nm wavelength intervals. T_{λ} can be substituted for R_{λ} for transmitting samples. Although a number of weighting factors have been developed over the years [2–7], those recommended by ASTM in E 308 Standard Practice for Computing the Colors of Objects by Using the CIE System [7] are recommended.

Tristimulus values for a light source can be calculated easily from measurements taken at 1 or 5 nm intervals from the following equations:

$$X = \frac{k_m}{\sum \bar{y}_{\lambda}} \sum S_{\lambda} \bar{x}_{\lambda} \quad (58.8)$$

$$Y = \frac{k_m}{\sum \bar{y}_{\lambda}} \sum S_{\lambda} \bar{y}_{\lambda} \quad (58.9)$$

$$Z = \frac{k_m}{\sum \bar{y}_{\lambda}} \sum S_{\lambda} \bar{z}_{\lambda} \quad (58.10)$$

in which S_{λ} is the relative spectral power of the light source at wavelength λ , k_m is the maximum spectral luminous efficacy function (683 lm W⁻¹), and \bar{x}_{λ} , \bar{y}_{λ} , and \bar{z}_{λ} are the color matching functions for the standard observer.

58.5 Reflectance Measurements

Specular and Diffuse Reflectance

Specular (sometimes called *regular*) reflection is the mirror-like reflection from an object. If you shine a beam of light on a mirror, it will be entirely reflected at the same angle on the opposite side of a normal

plane to the mirror's surface. However, if you shine a beam of light on a pellet of compressed barium sulfate (BaSO_4) powder, it will enter the surface, be scattered a number of times, and exit the pellet in many directions. This is called diffuse reflection. Glossy and semiglossy materials contain a combination of specular and diffuse reflection as shown in Fig. 58.7. Observers usually discount the specular reflection when visually evaluating the color of a material.

Illuminating and Viewing Geometries for Reflectance

Instruments designed for measuring the color of reflecting objects consist of an illuminator, a sample holder, and a receiver. The CIE has recommended four illuminating and viewing geometries for making reflectance measurements.

Bidirectional geometries illuminate the sample with a narrow beam of light and view the sample with a receiver having a narrow entrance field. In the most commonly used bidirectional geometry, the sample is illuminated at a 45° angle ($\pm 2^\circ$) from the sample's normal and viewed along the sample's normal ($\pm 10^\circ$). The other recommended geometry illuminates the sample along its normal and views the sample at 45° from its normal. Bidirectional geometries measure only diffuse reflection and can be sensitive to the surface texture of the sample. The two bidirectional geometries produce equivalent results [8, 9].

In the most common diffuse geometry, the illuminator includes an integrating sphere. An integrating sphere is a hollow metal sphere coated with a highly reflecting white coating with openings for the light source, the sample, and the receiver. The instrument's light source projects a beam of light onto the integrating sphere's wall. The light is reflected many times by the sphere's wall, and the sample is illuminated from all angles. When measuring in the diffuse/normal mode, $d/0$, the receiver views the sample along its normal. When the receiver is positioned in this manner, the specular reflection is directed back towards the light source and is not measured.

For some applications, it is useful to remove the specular reflection off of the sample's surface from the reflection of the light that is reflected back from the interior of the sample. This can be done by moving the receiver 6 or 8° from the sample's normal as shown in Fig. 58.8. A specular inclusion port is placed at the equal angle on the opposite side of the sample's normal. By placing a white plug having the same reflectance as the sphere wall in the port, the specular reflection can be included in the measurement. By using a light trap at the specular inclusion port, some or all of the specular reflection can be excluded from the measurement. The narrower the specular reflection peak, i.e., the glossier the material, the more specular reflection is excluded. Specular included measurements are normally abbreviated SCI, while specular excluded measurements are abbreviated SCE. This geometry is referred to as diffuse/near-normal but still abbreviated $d/0$. When the specular reflection is included, this geometry is sometimes referred to as total/normal, $t/0$.

FIGURE 58.7 A semiglossy material showing a combination of specular and diffuse reflection.

The last of the CIE recommended illuminating and viewing geometries is the normal/diffuse or near-normal/diffuse, $0/d$ and $0/t$. This is the reverse of the $d/0$ geometry. The illuminator illuminates the sample along its normal, or slightly off of its normal. For this geometry, the integrating sphere is part of the receiver. Light reflected from the sample is captured by the integrating sphere and the remaining optics of the receiver views the sphere wall. The two diffuse geometries produce equivalent results [8, 9].

Monochromatic and Polychromatic Illumination

An instrument's illuminator may illuminate the sample with either a narrow band of wavelengths, 1 to 10 nm wide, called monochromatic illumination, or a wide band of wavelengths, usually simulating a daylight illuminant and called polychromatic illumination. For nonfluorescent samples, either illumination method can be used with equivalent results. However, for fluorescent samples, only polychromatic illumination can produce valid results.

Sample Texture and Bidirectional Geometries

Bidirectional illuminating and viewing geometries can be very sensitive to surface texture and any polarization of reflected light. Keeping the illuminator and receiver in the same plane maximizes this sensitivity. To reduce or eliminate this sensitivity, circumferential or annular illumination (or receiving) can be used. When an illuminator provides light (or the receiver possesses responsivity) at many points distributed uniformly around a 45° cone centered at the sample's normal, we refer to circumferential illumination (or viewing). When the illuminator provides light continuously and uniformly around the cone, we refer to annular illumination (or viewing).

Which Illuminating and Viewing Geometry Is Best?

"Which illuminating and viewing geometry is best for color measurement?" is a difficult question to answer [9–12]. For matte samples, all of the geometries produce equivalent results. For high-gloss samples, the diffuse geometries with the specular reflection excluded provide measurements very close to the bidirectional geometries. For semigloss samples, the problem becomes more complex. The two bidirectional geometries are similar to the way a person evaluates color visually and are often thought

FIGURE 58.8 The diffuse/normal illuminating/viewing geometry with the ability to include or exclude the specular surface reflection.

to agree better with visual evaluation. On the other hand, the diffuse geometries measured with the specular reflection included minimize the effect of the sample's texture and gloss and are quite useful for computerized color matching. Rather than purchasing multiple instruments, most users select the geometry most suited to their major needs and compromise on other measurements.

Spectrophotometers

Spectrophotometers are used to measure an object's reflection characteristics throughout the visible spectrum. Double-beam spectrophotometers monitor a reference standard to compensate dynamically for fluctuations in source output, detector response, and atmospheric absorption to increase the instrument's stability [13]. Improvements in electronics and optics have allowed single-beam spectrophotometers to achieve the stability of double-beam instruments [14]. Single-beam instruments with an integrating sphere require a correction for the reduction of sphere efficiency caused by sample absorption [14].

Reflectance measurements are referred to as if they take place at a single wavelength. In actuality, a spectrophotometer has a finite spectral bandwidth or bandpass centered about that wavelength. Some instruments will have a bandpass as narrow as 1 nm, while others may exceed 20 nm. Bandpass is important because it influences the color measurement. The extent of this influence depends on the sample being measured [15, 16]. The spectral bandpass should be equal to the wavelength increment used in the calculation of tristimulus values to obtain the best color measurement results [17].

Spectrophotometers must be standardized before making reflectance factor measurements. The high point of the measurement scale is set by measuring a white standard of known reflectance factor [18]. The zero point is set by measuring a light trap or a black calibration standard. Single-beam, integrating sphere spectrophotometers may also require a sphere wall calibration, which is often done with a gray standard.

Some spectrophotometers allow the user to vary the size of the area measured. For most applications, the largest area possible should be measured. A number of documentary standards exist for making and reporting reflectance measurements [9, 17, 19-25].

Colorimeters and Spectrocolorimeters

Colorimeters were developed in the 1920s to 1930s as a less expensive alternative to spectrophotometers for quality control and color difference applications. They are simple to use and directly measure a sample's tristimulus values or related color coordinates. Three or four filters modify the light source and attempt to duplicate a Standard Illuminant/Standard Observer combination. Because of the difficulty in matching the CIE Illuminant and Standard Observer functions, they are less accurate than spectrophotometers for determining a sample's tristimulus values. Colorimeters determine the color difference between two samples more accurately than they determine tristimulus values, and they are often called color-difference meters. Since only one Standard Illuminant/Standard Observer combination is usually possible, colorimeters cannot be used to determine metamerism. Standards also exist for making colorimeter measurements [24–26].

A new class of instruments, spectrocolorimeters, began to appear in the 1980s. Spectrocolorimeters are spectrophotometers that only output tristimulus values or related color coordinates. They are less expensive and often have fewer options (such as variable area of view) than fully functional spectrophotometers. However, because they are spectrophotometers, they are capable of measuring metamerism.

Sample Preparation

Accurate color measurement is often dependent on sample preparation. Ideally, a sample for reflectance measurement is flat, has a uniform gloss and texture, is opaque, and is nondirectional. Always strive for sample preparation techniques that are reproducible. Consult standard test methods [24], standard practices [19, 27–29], books and articles [30–33] for help and advice on sample preparation.

58.6 Transmittance Measurement

Regular and Diffuse Transmittance

When a beam of light passes through a “transparent” material along its normal, the intensity of the beam will be decreased by absorption, but the direction of the beam will be unchanged. This is called regular transmittance. When a beam of light passes through a hazy or translucent material along its normal, the material scatters light and spreads the beam. This is called diffuse transmittance.

Illuminating and Viewing Geometries for Transmittance

The CIE has recommended three illuminating and viewing geometries for transmittance measurements. [1] Most transmittance measurements are made with spectrophotometers designed for analytical chemistry applications that use a normal/normal, 0/0, geometry. The illuminator directs the incident beam along the sample’s normal, and the receiver views the sample along its normal. Only regular transmittance can be measured accurately using this geometry.

Regular and diffuse transmittance can be measured using the normal/diffuse, 0/d, geometries (or the equivalent diffuse/normal, d/0), which the CIE also recommended for reflectance measurements. Regular transmittance is measured by keeping the sample as far away as possible from the integrating sphere, whereas diffuse transmittance is measured by placing the sample in contact with the sphere. Instruments designed specifically for transmittance measurements would have only a sample or illuminator port and a receiver port. Instruments designed for reflectance measurements can be used for making transmittance measurements by placing a white material in the sample port and using the specular included mode of measurement. The illuminator or receiver port would then serve as the sample port.

The third geometry recommended by the CIE, diffuse/diffuse, d/d, is not often used for industrial color measurement. One integrating sphere is used to illuminate the sample, and a second integrating sphere is used to view the sample.

The two bidirectional reflectance geometries (45/0 and 0/45) have also been used for making regular transmittance measurements.

Monochromatic and Polychromatic Illumination

Instruments for measuring transmittance may have either monochromatic or polychromatic illumination. The transmittance of nonfluorescent samples can be measured using either type of illumination, but fluorescent samples can only be measured using polychromatic illumination.

Standardizing Instruments for Transmittance Measurements

Three techniques exist for setting the high end of the measurement scale, a transmittance factor of 1.0. Each technique produces different results, so it is important to document the method used.

Setting the instrument to read a transmittance factor of 1.0 with no sample in the sample compartment is the easiest technique. The transmittance measurements will then be relative to air. This technique is often used when solid samples are being measured.

Transmittance measurements of solid materials may also be made relative to a clear blank of similar material. To make these measurements, the clear blank is placed in the sample compartment before the instrument is standardized.

When liquids are to be measured, a holder containing solvent or nonabsorbing liquid of the same refractive index as the liquid to be measured should be placed in the sample compartment before standardizing the instrument. This eliminates any effects of the holder’s transmittance.

Sample Preparation

Ideal samples will be flat with parallel sides. Liquid sample holders should be made from optical glass. Because transmittance will change with sample thickness and the concentration of colorant, it is impor-

tant that sample holders and blanks used for standardization have the same path length or thickness as the sample. When two different samples must be compared, they should be prepared using the same technique and have the same thickness.

It is extremely difficult to measure the transmittance of curved materials because the curvature of the object may act as a lens and deflect the incident light away from the receiver. If the curvature is not too great, it may be possible to make a diffuse transmittance measurement.

58.7 Color Difference Calculations

A number of equations have been developed over the years for calculating the color difference between two objects [1, 10, 24, 30, 34, 35, 36]. One of the most common equations is the CIELAB recommended by the CIE in 1976 [1].

First the CIELAB coordinates, L^* (lightness), a^* , b^* , C^*_{ab} (chroma) and h_{ab} (hue angle) are calculated with Equations 58.11 through 58.15.

$$L^* = 116 f(Y/Y_n) - 16 \quad (58.11)$$

$$a^* = 500 [f(X/X_n) - f(Y/Y_n)] \quad (58.12)$$

$$b^* = 200 [f(Y/Y_n) - f(Z/Z_n)] \quad (58.13)$$

$$C^*_{ab} = [a^{*2} + b^{*2}]^{1/2} \quad (58.14)$$

$$h_{ab} = \arctan[b^*/a^*] \quad (58.15)$$

in which X , Y , and Z are tristimulus values and the subscript n refers to the tristimulus values of the perfect diffuser for the given illuminant and standard observer; $f(X/X_n) = (X/X_n)^{1/3}$ for values of (X/X_n) greater than 0.008856 and $f(X/X_n) = 7.787(X/X_n) + 16/116$ for values of (X/X_n) equal to or less than 0.008856; and the same with Y and Z replacing X in turn. The hue angle is 0° along the $+a^*$ axis, 90° along the $+b^*$ axis, 180° along the $-a^*$ axis, and 270° along the $-b^*$ axis.

The total color difference, ΔE^*_{ab} , and its components—the lightness difference, ΔL^* , the chroma difference, ΔC^*_{ab} , and the hue difference, ΔH^*_{ab} —are calculated using Equations 58.16 through 58.21.

$$\Delta L^* = L^*_{\text{trial}} - L^*_{\text{standard}} \quad (58.16)$$

$$\Delta a^* = a^*_{\text{trial}} - a^*_{\text{standard}} \quad (58.17)$$

$$\Delta b^* = b^*_{\text{trial}} - b^*_{\text{standard}} \quad (58.18)$$

$$\Delta E^*_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2} \quad (58.19)$$

$$\Delta C^*_{ab} = C^*_{ab \text{ trial}} - C^*_{ab \text{ standard}} \quad (58.20)$$

$$\Delta H^*_{ab} = [(\Delta E^*_{ab})^2 - (\Delta L^*)^2 - (\Delta C^*_{ab})^2]^{1/2} \quad (58.21)$$

A negative value of ΔL^* means the trial is darker than the standard, and a negative value of ΔC^*_{ab} means the trial has a lower chroma than the standard. When the hue angle, h_{ab} of the trial is greater than that of the standard, the sign of ΔH^*_{ab} is positive, and vice-versa. The total color difference and its components can then be used in setting color tolerances [19, 37].

Researchers have been making modifications to the CIELAB color difference equation in an attempt to have the color difference more closely correlate with visually observed color differences. The $\text{CMC}(l:c)$ color difference equation [50–52] has gained great acceptance in the textile industry and is being tested

in other areas. Starting with the CIELAB color differences, the CMC(l:c) color differences are calculated with Equations 58.22 through 58.28.

$$\Delta E = \left[\left(\frac{\Delta L^*}{l S_L} \right)^2 + \left(\frac{\Delta C_{ab}^*}{c S_C} \right)^2 + \left(\frac{\Delta H_{ab}^*}{S_H} \right)^2 \right]^{1/2} \quad (58.22)$$

$$S_L = \frac{0.040975 L^*}{1 + 0.01765 L^*} \quad (58.23)$$

unless $L^* < 16$, in which case $S_L = 0.511$,

$$S_C = \frac{0.0638 C_{ab}^*}{1 + 0.0131 C_{ab}^*} + 0.638 \quad (58.24)$$

$$S_H = (FT + 1 - F) S_C \quad (58.25)$$

$$F = \left(\frac{(C_{ab}^*)^4}{(C_{ab}^*)^4 + 1900} \right)^{1/2} \quad (58.26)$$

$$T = 0.36 + \text{abs}[0.4 \cos(35 + h_{ab})] \quad (58.27)$$

unless h is between 164° and 345° when

$$T = 0.56 + \text{abs}[0.2 \cos(168 + h_{ab})] \quad (58.28)$$

in which the notation “abs” indicates the absolute (i.e., positive,) value of the term inside the square brackets. When $l = c = 1$, the formula quantifies the perceptibility of color differences. Optimum values of l and c for quantifying the acceptability of a color match must be determined for the material being measured. The textile industry has found the optimum values to be $l = 2$ and $c = 1$ [51].

In 1994, the CIE recommended a new color difference equation, CIE94 [36], which is similar to the CMC equation. CIE94 color differences are calculated using Equations 58.29 through 58.33. The perceived color-difference, ΔV , is related to the measured color difference through an overall sensitivity factor, k_E .

$$\Delta V = \frac{1}{k_E} \Delta E_{94}^* \quad (58.29)$$

$$\Delta E_{94}^* = \left[\left(\frac{\Delta L^*}{k_L S_L} \right)^2 + \left(\frac{\Delta C_{ab}^*}{k_C S_C} \right)^2 + \left(\frac{\Delta H_{ab}^*}{k_H S_H} \right)^2 \right]^{1/2} \quad (58.30)$$

$$S_L = 1 \quad (58.31)$$

$$S_C = 1 + 0.045 C_{ab}^* \quad (58.32)$$

$$S_H = 1 + 0.015 C_{ab}^* \quad (58.33)$$

The overall sensitivity factor, k_E , is used to account for variation in the illuminating and viewing conditions. A person in the textile industry who is using CMC(2:1) and would like to compare the results with CIE94 would set $k_L = 2$ and $k_C = k_H = 1$, i.e., CIE94(2:1:1).

The improvement in correlating with visual assessments of color difference could result in either the CMC($l:c$) or the CIE94 replacing the CIELAB color difference equation. Hunter and Harold [30] detail many of the older color difference equations, many of which are still in use. A history of the development of color metrics was written by Richter [53].

58.8 Special Cases

Fluorescent Samples

Fluorescent materials not only reflect light but also emit light. Light absorbed at some wavelengths is emitted at longer wavelengths. The amount of light emitted depends on the intensity and the spectral power distribution of the source. Because of the emission of light, spectrophotometers that illuminate a fluorescent material with monochromatic light cannot be used, because the light emitted at the longer wavelengths will be measured as if it had been reflected from the material. Reflectance measurements of the material illuminated by polychromatic light will include the emitted light at the proper wavelengths. If the instrument's light source is a good representation of the illuminant, the measurement will be indicative of the observed color. Techniques have been recommended by the CIE for assessing the quality of daylight simulators [55]. Measured reflectance factors at the wavelengths of emittance may be greater than 1.0. Special fluorescent calibration standards must be used to accurately measure these materials [38]. The 45/0 or 0/45 bidirectional geometries are recommended for measuring fluorescent materials [39, 40].

The complete analysis of a fluorescent material requires that the emittance be separated from the reflectance. Spectrofluorimeters were designed to analyze fluorescent samples. These instruments illuminate the sample with monochromatic light. Reflected and emitted rays pass through a second monochromator to isolate the receiver wavelengths. By viewing the sample at the same wavelength as it is illuminated, the true reflectance of the sample can be determined. Either the excitation spectra or the emittance spectra can be studied by setting each monochromator at different wavelengths. Techniques have also been developed to correct spectrophotometric measurements of fluorescent samples [54, 56].

Metallic and Pearlescent Samples

Materials that contain metallic and/or pearlescent pigments are goniochromatic, i.e., they change color with the illuminating and viewing geometry. Goniospectrophotometers are needed to measure these materials. A goniospectrophotometer illuminates (or views) the sample at a fixed angle, usually 45°, and views (or illuminates) the sample at three or more angles. The position of the receivers (or illuminators) is described by the aspecular angle, the viewing angle measured from the direction of the specular reflectance, which is equal and opposite the angle of illumination. In a goniospectrophotometer that illuminates the sample at 45° and views at three angles, one of the viewing angles would be near the specular reflection at about 25°, the second at the CIE recommended bidirectional angle of 0° and the third would be far away from the specular reflectance at about 70°.

Goniospectrophotometry is still in its infancy and the CIE recommendations and ASTM standards for making these measurements are still under development.

Retroreflecting Samples

Highway signs and high visibility clothing are examples of retroreflectors. Light shining on a retroreflector is returned in directions very close to the illumination angle. Most retroreflectance measurements are made in connection with highway safety. There are only a few specially built instruments for measuring retroreflection. A projector is usually used to illuminate the sample, and a teleradiometer or a radiometric

telecolorimeter is used to view the sample. Tristimulus values can be calculated from the retroreflectance factors. Standard practices and test methods exist for specifying the illuminating and viewing geometries and making retroreflectance measurements [41–45].

Lamps, Light Sources, and Displays

Spectral radiometers and radiometric colorimeters were designed to measure lamps, light sources, and displays. These instruments are similar to spectrophotometers and colorimeters but do not need an illuminator, because the sample being measured emits light.

Lamps and light sources can either be measured directly or by measuring the reflectance of a stable white reflecting surface being illuminated by the lamp or light source. To measure televisions, computer monitors, and other similar devices, the emitted light must usually be imaged directly on the optics of the spectral radiometer or radiometric colorimeter [46, 47].

Hazy and Translucent Materials

Hazy and translucent materials are measured by placing them in contact with an integrating sphere and measuring their diffuse transmittance. A haze index can be calculated from four diffuse transmittance measurements on a reflecting spectrophotometer [48]. Two of the measurements are made with a white material in the reflectance sample port, and two measurements are made with a light trap in the port. Special instruments called *hazemeters* were designed to make haze measurements.

58.9 Instrument Manufacturers

Costs of color measuring instruments vary significantly. The more accurate instruments with the best repeatability and reproducibility can be expected to cost more. [Table 58.1](#) lists the price ranges for various types of color measuring instruments. There is a classification in the table called spectral analyzers. Although these instruments may provide information that makes them appear to be colorimeters or spectrophotometers, they use measurement techniques not traditionally associated with those instruments. For example, several use LEDs instead of more traditional light sources. Since the instruments vary so widely in capability, the purchaser must ensure that a particular instrument has the capability to make the measurements desired with sufficient accuracy, repeatability, and reproducibility.

TABLE 58.1 Color Measuring Instruments and Their Costs

Instrument type	Price range in US \$
Colorimeters	4,000–15,000
Goniospectrophotometers	12,500–30,000
Hazemeters	13,000–15,000
Radiometric Colorimeters	2,000–10,000
Retroreflectometers	3,500–15,000
Spectral Analyzers	1,500–2,500
Spectrofluorimeters	30,000–40,000
Spectrophotometers	2,500–20,000
Spectroradiometers	2,500–40,000

[Table 58.2](#) provides contact information for a number of manufacturers of color measuring instruments. The manufacturers listed in this table design instruments specifically for color measurement. Thus, manufacturers of analytical spectrophotometers are excluded even if their instruments have color measuring capabilities. The table is also limited to manufacturers with a major presence in the U.S.

58.10 Defining Terms

For a more extensive collection of terms relating to color and appearance, the reader should refer to ASTM E 284 Standard Terminology of Appearance [49].

Chroma: Attribute of color used to indicate the degree of departure of the color from a gray of the same lightness.

CIE: The abbreviation for the French title of the International Commission on Illumination, Commission Internationale de l'Éclairage.

CIE standard observers: The ideal colorimetric observer data adopted by the CIE to represent the response of the average human eye, when light-adapted, to an equal-energy spectrum. The standard observer adopted in 1931 was developed from data obtained with a 2° field of vision and is commonly called the "2° standard observer." The standard observer adopted in 1964 was developed from data obtained with a 10° annular field of vision and is commonly called the "10° standard observer."

CIE tristimulus values: Amounts of the three mathematical lights necessary in a three-color additive mixture required for matching a color in the CIE System. They are designated X, Y, and Z. The illuminant and standard observer color matching functions must be designated.

colorimetry: The science of color measurement.

hue: The attribute of color perception by means of which a color is judged to be red, orange, yellow, green, blue, purple, or intermediate between adjacent pairs of these, considered in a close ring (red and purple being an adjacent pair.) White, black and grays possess no hue.

illuminant: A mathematical description of the relative power emitted by a real or imaginary light source at each wavelength in its emission spectrum.

lightness: (1) The attribute of color perception by which a nonself-luminous body is judged to reflect more or less light. (2) The attribute by which a perceived color is judged to be equivalent to one of a series of grays ranging from black to white.

metamerism: Property of two specimens that match under a specified illuminator and to a specified observer and whose spectral reflectances or transmittances differ in the visible wavelengths.

perfect reflecting diffuser: Ideal reflecting surface that neither absorbs nor transmits light, but reflects diffusely, with the radiance of the reflecting surface being the same for all reflecting angles, regardless of the angular distribution of the incident light.

reflectance: Ratio of the reflected radiant or luminous flux to the incident flux in the given conditions. The term reflectance is often used in a general sense or as an abbreviation for reflectance factor. Such usage may be assumed unless the above definition is specifically required by the context.

reflectance factor: Ratio of the flux reflected from the specimen to the flux reflected from the perfect reflecting diffuser under the same geometric and spectral conditions of measurement.

59.1 Basic Concepts

Different properties of optics are used in many instrumentation and measurement devices. Applications vary from photographic imaging to high-speed data transmission via fibers. Once the light is generated and propagated from a source, it can be expanded, condensed, collimated, reflected, polarized, filtered, diffused, absorbed, refracted, scattered, etc. for manipulation and processing. Some of these manipulations are done to serve a particular purpose, and some results from physical characteristics of the light and optical properties of the media. In many applications, the intensity of light at the beginning will not be the same at the end due propagation characteristics and losses. It is important to point out that the word “light” is usually taken as radiation in the range of from about 380 nm to about 800 nm. This understanding limits important applications to those in the near-infrared and ultraviolet regions of the spectrum. In here, when the term “light” is used, the IR and UV portions of the spectrum are not left out.

The interpretation and treatment of “optical loss” is different for each individual instrumentation and measurement activity. It entirely depends on the purpose and method of measurements. For example, scattering of the light (radiation) from clouds is a useful property for determining atmospheric characteristics, whereas scattering of light in optical fibers may not be desirable due to resulting losses in power and decrease in efficiency. While many instrumentation systems (e.g., imaging) make use of scattering, absorption, refraction, and reflection as useful properties, in others these are considered to be mere losses that cause undesirable attenuations. In recent years, fiber optics has attracted considerable attention, and most of the following discussion on optical loss is centered on this subject. Likewise, this chapter concentrates on optical losses in fiber optics to clearly demonstrate the fundamental principles. Nevertheless, it is important to recognize that the same as losses in fiber optics may not be regarded as losses in other applications. It will be shown here that losses in fiber optics have useful properties in determining the optical fiber characteristics.

Theoretically, light propagation in fibers can be treated in a number of ways. For example, in treating propagation by modes, the fibers are viewed as optical waveguides, whereas treatment by rays is an approximate description of fibers with diameters much greater than the wavelength. In this chapter, both approaches will be used as appropriate.

An optical fiber is a circular dielectric glass (some polymers are also used) waveguide that can efficiently transport optical energy, and the information in the energy, usually by using the principle of total internal reflection. In some cases, it consists of a central glass core surrounded by a concentric cladding material with a slightly lower ($\approx 1\%$) refractive index. Since the core has higher index of refraction than the cladding, light is confined to the core if the angular condition of total internal reflection is met. Attenuation of the light begins the moment light enters the fiber. The acceptance and transmission of light depends greatly on the angle at which the light enters the fiber. The angle must be less than the *critical acceptance angle* of the particular fiber being used, as shown in Figure 59.1.

There are three basic types of fibers: single-mode step-index, multimode graded index, and multimode step index, as shown in Figures 2a, 2b, and 2c, respectively. The characteristics of optical losses in these three types of fibers vary slightly due to differences in construction and the nature of propagation of light. For example, in the case of multimode step-index fibers, light striking the core–cladding junction at an angle greater than the angle of internal reflection passes through and becomes absorbed by the opaque jacket. This represents a significant source of attenuation, limiting the injection efficiency at the transmitting end.

Single-mode fibers, Figure 59.2a, are used in transmitting broadband signals over large distances. Their attenuation is generally very small, and their transmission band is large. Owing to material properties, low attenuations can be expected for wavelengths around 1.3 to 1.6 μm . Additional attenuation arises from splices and fiber bending.

Multimode graded-index fibers have medium size cores (50 to 100 μm) and refractive indices that decrease radially outward. The two optical materials with different refractive indices are mixed together in such a way that the index of refraction decreases smoothly with distance from the fiber axis. The graded index causes the light to gradually bend back and forth across the axis in sinusoidal manner when very small injection angles are used. This greatly reduces the light losses from the fiber and results in relatively better bandwidth and efficiency. The graded-index fibers also allow the use of simpler splicing techniques.

Good-quality fibers are typically made of pure silica with index modifying dopants such as GeO_2 . While bandwidth is the primary consideration in the use of fiber optics in communication applications, light attenuation characteristics are equally important. The overall quality of a fiber optic light guide is determined by its light transmissivity, defined as the ratio of the output light to that put into the fiber.

FIGURE 59.1 An optical fiber is a circular dielectric glass waveguide that can efficiently transport optical energy. It consist of a central glass core surrounded by a concentric cladding material. An important requirement for the connection of a light source is that a sufficient amount of useful light must be coupled into the fiber. The core has a higher index of refraction than the cladding; therefore, light is confined to the core only if the angular condition of total internal reflection is met. The acceptance and transmission of light depend greatly on the angle at which the light rays enter the fiber, and it must be less than the *critical acceptance angle* of a particular fiber.

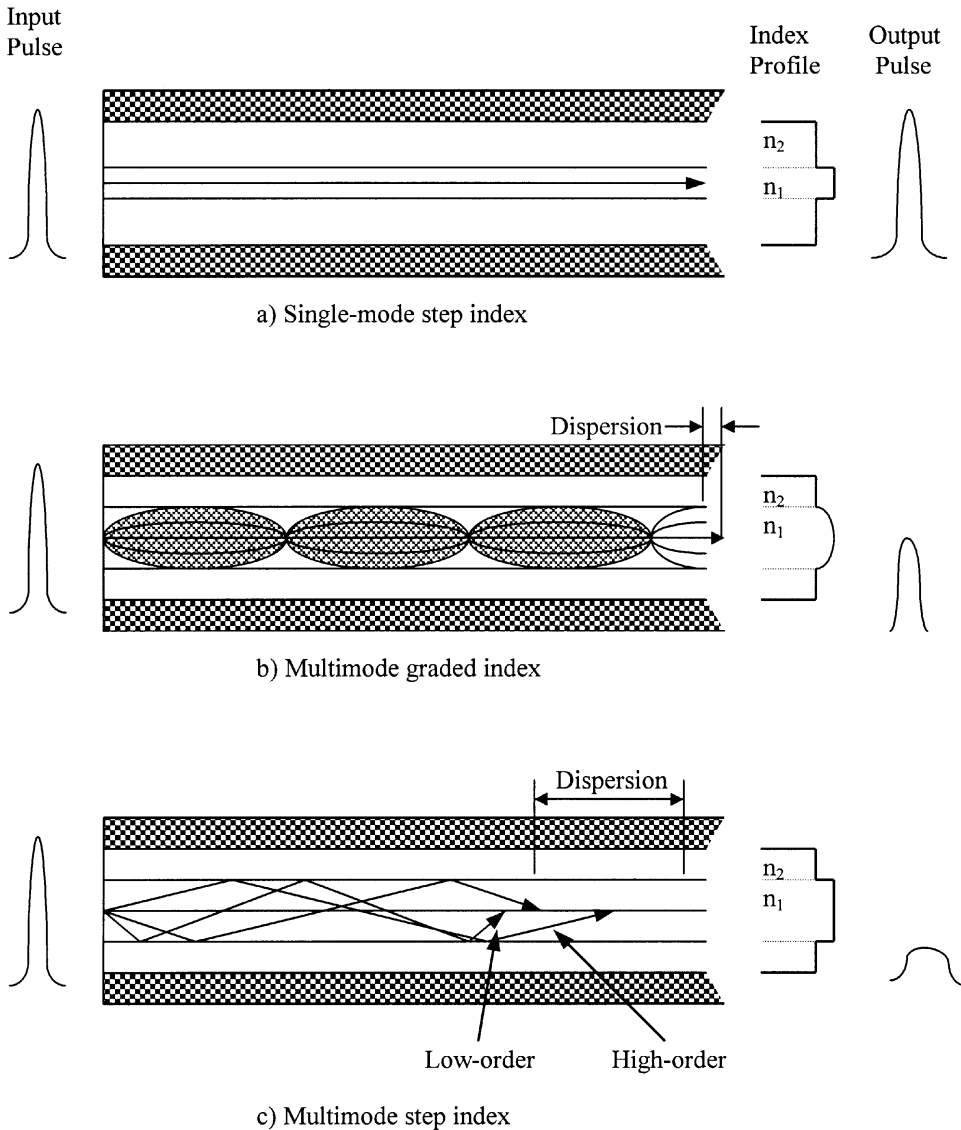

FIGURE 59.2 Three basic types of fibers. (a) Single-mode step-index fibers, used in transmitting broadband signals over large distances, (b) multimode graded index, obtained by mixing two optical materials with different refractive indices together in such a way that the index of refraction decreases smoothly with distance from the fiber axis, and (c) multimode step index fibers, in which the refractive index changes between fiber and cladding, and rays striking the core-cladding junction reflect back in the glass.

LEDs are the primary light source used in fiber-optic links for bit rates up to 200 Mb/s and distances up to 2 km. For higher bit rates and longer distances, diode lasers are preferred. LEDs used in fiber-optic applications operate at three narrowly defined wavelength bands 650, 820 to 870, and 1300 nm. The choice of wavelength is also determined by the transmission characteristics of optical fibers.

59.2 Optical Loss Mechanisms in Optical Fibers

There are two basic categories of sources of light loss in the fiber optic systems: extrinsic and intrinsic losses.

Extrinsic Fiber Losses

These losses are specific to geometry and handling of the fibers and are not functions of the fiber material itself. There are three basic types:

- bending losses
- launching losses
- connector losses

Bending Losses

Bending losses are the result of distortion of the fiber from the ideal straight-line configuration. While the light is traveling inside the fiber, part of the wavefront on the outside of the bend must travel faster than the part of the smaller inner radius of the bend. Since this is not possible, a portion of the wave must be radiated away. Losses are greater for bends with smaller radii, particularly for kinks or microbends in a fiber.

An important cause of attenuation is due to microbending of the fiber. Microbending is due to irregularly distributed undulations in the fiber with radii of curvature of a few millimeters and deviations from the mean line of a few micrometers, as exemplified in Figure 59.3. Microbends arise from mechanical tensile forces by which the fiber is pressed against a rough surface. Although the effect of variations in diameter can be discussed at length by waveguide theory, here it will be sufficient to say that those components of the light that are traveling in the fiber near its acceptance limit cross outside this boundary and are lost from the fiber. These losses may be avoided by careful cable constructions, avoiding excessive mechanical forces, and controlling the temperature variations of the cable. This is achieved by a loose encasing of the fiber in a plastic sheath or by covering the fiber with soft flexible material, as shown in Figure 59.4.

Launching Losses

The term *launching loss* refers to an optical fiber not being able to propagate all the incoming light rays from an optical source. These occur during the process of coupling light into the fiber (e.g., losses at the interface stages). Rays launched outside the angle of acceptance excite only dissipative radiation modes in the fiber. In general, elaborate techniques have been developed to realize efficient coupling between the light source and the fiber, mainly achieved by means of condensers and focusing lenses. The focused input beam of light needs to be carefully matched by fiber parameters for good coupling.

FIGURE 59.3 An important cause of attenuation is due to microbending of the fiber. This is due to irregularly distributed undulations in the fiber and from mechanical tensile forces when the fiber is pressed against a rough surface. Absorption losses are caused by the presence of impurities such as traces of metal ions (e.g., Cu^{2+} , Fe^{3+}) and hydroxyl (OH^-) ions. Despite careful manufacturing techniques, fibers can be inhomogeneous, having disordered, amorphous structures. Power losses due to scattering are caused by such imperfections in the core material and irregularities between the junction and cladding.

FIGURE 59.4 Some fiber losses can be avoided by careful cable construction, eliminating excessive mechanical forces, and controlling the temperature variations of the cable assembly. This is achieved by a loose encasing of the fiber in a plastic sheath or by covering the fiber with soft flexible materials. Most optical fibers constructed for communication purposes have inner and outer jackets for protection and strength.

Equally, once the light is transmitted through the fiber, output fiber characteristics must also match the output target characteristics to be able to couple the largest proportion of the transmitted light. This can be done by a suitable focusing lens arrangements in the output end.

There are also initial face (Fresnel) losses due to reflections at the entrance aperture. The Fresnel losses are greater if the fiber/source is air coupled. Hence, most optical couplings to a fiber utilize index matching materials, thus reducing coupling loss substantially.

Connector Losses

Connector losses are associated with the coupling of the output of one fiber with the input of another fiber, or couplings with detectors or other components. The significant losses may arise in fiber connectors and splices of the cores of the joined fibers having unequal diameters or misaligned centers, or if their axes are tilted. Mismatching of fiber diameters causes losses that can be approximated by $-10 \log(d/D)$. There are other connection losses such as offsets or tilts or air gaps between fibers, and poor surface finishes. Some of these are illustrated in [Figure 59.5](#).

To take full advantage of fiber characteristics in transmission systems of very low intrinsic attenuation, the contribution of losses from other sources must also remain very small. The attenuation $a_s(d)$ due to coupling efficiency may be expressed as:

$$a_s(d) = -10 \text{ dB } \log \eta(d) \tag{59.1}$$

where $\eta(d)$ is the coupling coefficient.

In general, the positions and shapes of the fiber cores are controlled to tight manufacturing tolerances. Fibers having attenuations greater than 1 dB/km are rarely used in communication networks. Nevertheless, the attenuation of badly matched fibers may exceed 1 dB/km per connector or splice if they are badly handled during installation stages. A good coupling efficiency requires precise positioning of the fibers to center the cores. The simplest way to avoid connector losses is by splicing the two ends of the fibers permanently, either by gluing or by fusing at high temperatures.

Losses in gaps can be viewed as a type of Fresnel loss because existing air space introduces two media interfaces and their associated Fresnel reflection losses. In this case, there are two major losses to be considered. The first loss takes place in the inner surface of the transmitting fiber, and the second loss occurs due to reflections from the surface of the second fiber. One way of eliminating these losses is by introducing a coupler that matches the optical impedances of the two materials. This arrangement results in matched reflection coefficients, which is analogous to matching of impedances.

FIGURE 59.5 Connector losses are associated with the coupling of the output of one fiber with the input of another fiber or other components. Significant losses may arise in fiber connectors and splices of the cores of the joined fibers having unequal diameters, misaligned centers, tilted axes, and air gaps between fibers. In practical applications, fibers are permanently spliced by gluing or fusing at high temperatures.

Intrinsic Fiber Losses

Intrinsic fiber losses are those associated with the fiber optic material itself, and the total loss is proportional to length L . Once inside the fiber, light is attenuated primarily because of absorption and scattering; therefore, these are the primary causes of the losses.

Absorption Losses

As in the case of most transmissive systems, light loss through absorption in an optical fiber tends to be an exponential function of length. Absorption loss is caused by the presence of impurities such as traces of metal ions (e.g., Cu^{2+} , Fe^{3+}) and hydroxyl (OH^-) ions. Optical power is absorbed in the excitation of molecular vibrations of such impurities in the glass, as illustrated in Figure 59.3. One characteristic of absorption is that it occurs only in the vicinity of definite wavelengths corresponding to the natural oscillation frequencies or their harmonics of the particular material. In modern fibers, absorption losses are almost entirely due to OH^- ions. The fundamental vibration mode of these ions corresponds to $\lambda = 2.73 \mu\text{m}$ and the harmonics at 1.37 and 0.95 μm . It is possible to employ dehydration techniques during manufacturing to reduce presence of OH^- ions.

Unlike scattering losses, which are relatively wideband effects, absorption losses due to each type of impurity act like a band-suppression filter, showing peak absorption at well defined wavelengths.

Scattering Losses

Despite the careful manufacturing techniques, most fibers are inhomogeneous that have disordered, amorphous structures. Power losses due to scattering are caused by such imperfections in the core material and irregularities between the junction and cladding as shown in Figure 59.3.

Inhomogeneities can be either structural or compositional in nature. In structural inhomogeneities, the basic molecular structure has random components, whereas, in compositional inhomogeneity, the chemical composition of the material varies. The net effect from either inhomogeneity is a fluctuation in the refractive index. As a rule of thumb, if the scale of these fluctuations is on the order of $\lambda/10$ or less, each irregularity acts as a scattering center. This is a form of Rayleigh scattering and is characterized by an effective absorption coefficient that is proportional to λ^{-4} . Rayleigh scattering can be caused by the existence of tiny dielectric inconsistencies in the glass. Because these perturbations are small with respect to the waves being propagated, light striking a Rayleigh imperfection scatters in all directions. Scattering losses are less at longer wavelengths, where the majority of the transmission losses are due to absorption from impurities such as ions. Rayleigh scattering losses are not localized, and they follow a distribution law throughout the fiber. However, they can be minimized by having low thermodynamic density fluctuations.

A small part of the scattered light may scatter backward, propagating in the opposite direction. This backscattering has important characteristics and may be used for measuring fiber properties. Usually, the inhomogeneities in the glass are smaller than the wavelength λ of the light. The scattering losses in glass fibers approximately follow the Rayleigh scattering law; that is, they are very high for small wavelengths and decrease with increasing wavelength.

In general, optical losses in the glass cause the optical power in a fiber to fall off exponentially with the length L of the fiber,

$$P(L) = P(0) 10^{(-\alpha L/10\text{dB})} \quad (59.2)$$

where $P(0)$ = optical power that couples to the fiber, $P(L)$ = power remaining after length L , and α is the attenuation coefficient indicating the rate of loss of optical power in dB/km.

The product αL is called the *attenuation of the fiber*. An attenuation of 10 dB means that the optical power $P(L)$ at the end of the fiber is only 10% of the initial power $P(0)$. A 3-dB attenuation gives 50%, and 1 dB is about 80%.

A typical attenuation coefficient α against wavelength λ is shown in Figure 59.6 for common low-loss fused silica fiber. The optical losses for wavelengths below 1 μm are mainly due to Rayleigh scattering. At larger wavelengths absorption losses are important, notably at 1.4 μm through absorption by OH^{-1} ions. Above 1.6 μm , absorption due to impurities becomes dominant. Because of attenuations, only limited wavelength ranges are appropriate for optical data transmission.

Although intrinsic fiber losses can be associated with the core index n_p , the core index has an important role in determining the propagation time delay of optical signals. The propagation time delay t_p may be expressed by

$$t_p = n_f L/c \quad (59.3)$$

where c = velocity of light in the fiber, and L = fiber length.

Another type of loss in optical fibers occurs due to the propagation of light at different angles. Light propagating at shallow angles is called *low-order mode*, and light propagating at larger angles is called *high-order mode*. For a given length of fiber, the high-order modes reflect more often and cover longer distances than the low-order modes. Therefore, high-order modes suffer more losses, thus causing modal dispersions. The modal dispersion is one of the primary cause of rise time degradation for increasing fiber wavelengths. In addition, propagation time varies with index of refraction, so different wavelength components of the source spectrum have different travel times, thus causing *chromatic dispersion*.

FIGURE 59.6 Attenuation characteristics of a typical optical fiber. The attenuation coefficient α varies with wavelength for all low-loss fused silica fibers due to Rayleigh scattering and impurity absorptions. The optical losses for wavelengths below 1 μm are mainly due to scattering. At greater wavelengths, absorption losses are important, notably at 1.4 μm through absorption by OH^- ions. Above 1.6 μm absorption due to impurities becomes dominant.

59.3 Optical Time Domain Reflectometry Method

Optical time domain reflectometers (OTDRs) are used mainly for link testing. In this instrument, optical power is launched into the fiber, and the reflected power associated with Rayleigh scattering and other backscattering mechanisms are measured in the sending end, as shown in Figure 59.7. Manufacturers usually provide the instrument with customized analysis software and optical modules to be integrated into a computer. OTDR complements attenuation measurements by measuring the backscattering. This permits not only the attenuation of the complete fiber to be measured, but also different attenuation coefficients of fiber segments, as well as optical losses in connectors and splices. Furthermore, it indicates the location of such optical losses as well as the length of the fiber.

FIGURE 59.7 Optical time domain reflectometers (OTDRs) are used in link tests. The optical power is launched into the fiber, and the reflected power associated with Rayleigh scattering is measured from the same sending end. OTDRs usually are offered with customized analysis software and optical modules to be integrated into a computer. OTDR complements attenuation measurements by measuring the backscattering. This permits not only the attenuation of the complete fiber to be measured but also different attenuation coefficients of fiber segments, as well as optical losses in connectors and splices.

In OTDRs, as [Figure 59.8](#) illustrates in block diagram form, short, intense laser pulses with duration $\Delta t = 10$ to 100 ns at peak power $M_{ax}(0)$ are coupled to the fiber. Backscattering echoes are detected from different regions of the fiber. In traversing the fiber, the power of these impulses decreases exponentially with the length of the fiber, predominantly due to scattering. A small portion of the scattered light reverses its direction and returns to the transmitter. The returned signal is uncoupled from the fiber by means of a beam splitter, to be processed further. The time history of the returned signals can be expressed as:

$$P_R(t) = K_R M_{ax}(0) \Delta t 10^{(-2\alpha L/10 \text{ dB})} \quad (59.4)$$

where K_R = the backscattering factor of the fiber.

The backscattering factor depends on scattering and numerical aperture. It is small, such that $P_R(t)$ is reduced as compared to $M_{ax}(0)$, typically by a factor of 50 to 60 dB. Despite this reduction, it is possible to measure the characteristics of fibers that are several kilometers long. In many cases, light pulses with high energy contents are used, along with sensitive receivers based on avalanche photodiodes.

The evolution with time of the backscattering signal $P_R(t)$ is given in [Figure 59.9](#). If the attenuation coefficient and backscattering factors were constant throughout the length of the fiber, a curve that decreases exponentially from left to right would result. However, some power is reflected back from the end of the fiber because of some discontinuity. This appears as a sharp pulse at the right-hand side of the curve. In practical fibers, local optical losses as well as continuous losses occur due to imperfect connectors and splices. From the location and height of the steps, the position and magnitude of the local losses can easily be identified. The length of the fiber can also be obtained from timing of this pulse.

Other disturbances in the propagation of the light are also revealed in the backscattering signal. For example, variations in the attenuation coefficient of spliced fiber segments can be seen as slope changes in the $P_R(t)$ curve. In such cases, all information of importance can be drawn from the backscattering signal to enable the calculation of the attenuation and the local attenuation coefficients. A practical advantage of this method is that in measurements only one end of the fiber needs to be accessible; therefore, measurements can be done on optical cables that have already been laid.

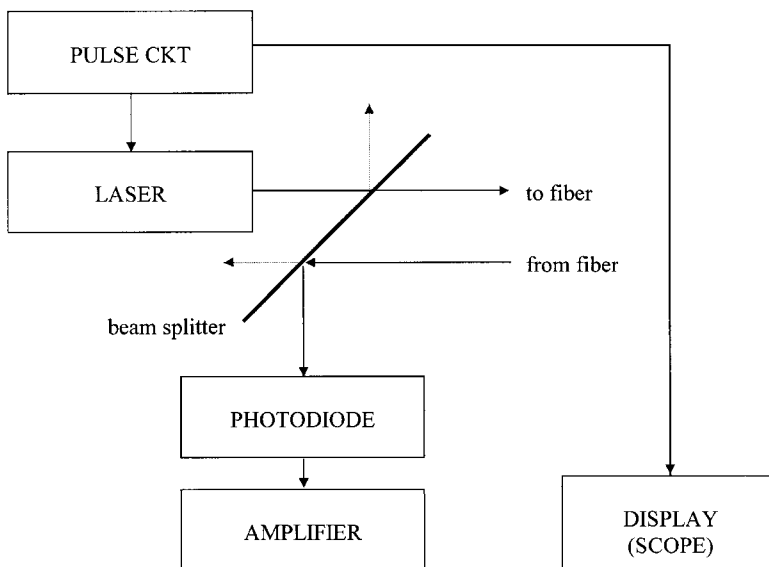

FIGURE 59.8 OTDRs usually come with a laser source, with modules that allow wavelength selection. The short, intense laser pulses with high peak power are coupled to the fiber. Backscattering echoes are detected from different regions of the fiber. The returned signal is uncoupled from the fiber by means of a beam splitter, to be processed further for analysis.

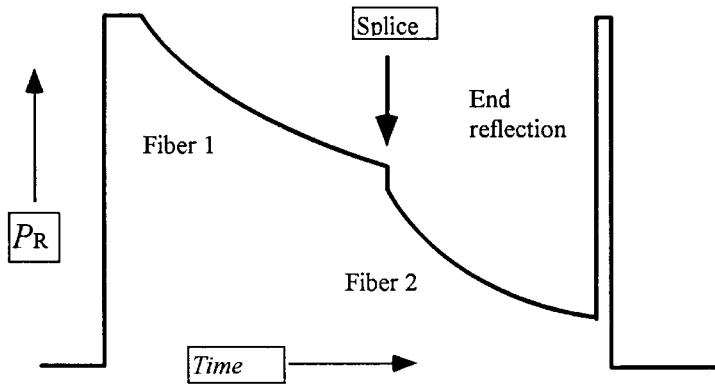

FIGURE 59.9 A typical example of the evolution of a backscattering signal in time. An exponential curve that decreases from left to right is obtained due to attenuation coefficients and backscattering factors. Some power reflects back from the end of the fiber and other discontinuities such as glass-air boundaries, appearing as sharp pulses. From the location and height of these returned sharp pulses, the positions and magnitudes of the local losses can easily be identified. The change of slope of curve also indicates the change in attenuation coefficient if different fibers are used.

59.4 Standard Field Fiber Optic Attenuation Test

In practical applications of optical fibers, it is necessary to have quantitative knowledge on the whole range of properties. Most important properties are length, attenuation, and bandwidth of the fibers, along with external diameter, core diameter, numerical aperture, and refractive index profile. The actual performance of installed links may be different from the desired performance. Therefore, it is important that both individual components and the entire assembled system undergo testing to verify compliance with the required operations. Additional testing may be conducted over the life of the system to ensure continued functional operation over long periods of time.

There are two basic standard fiber optic attenuation tests: the component acceptance test and the link test. The component acceptance test is performed prior to installation to verify the power and performance acceptance levels of each fiber. The acceptance testing of a functional module begins with power testing of the transmitter. The testing is done by attaching the module set into a reference link and verifying the data rates and bit error rates taken at the other end of the fiber, as shown in Figure 59.10.

Fiber acceptance testing also requires power testing, which can be done by launching a known power from a reference source, as explained in the OTDR section. The functional testing verifies power budget of coupling attenuation effects as well as bandwidth for the fiber. The attenuation and power transmission depend on the mode distribution within the fiber. In short fibers, higher modes dominate, whereas in

FIGURE 59.10 The measurements of transmission properties of laid optical fibers are obtained by end-to-end tests. The testing is done by attaching the module set into a reference link and verifying the data rates and bit error rates taken at the other end of the fiber.

long fibers, power is more concentrated in lower order modes. Mode stripping is often used by introducing small bends into the fiber to correlate the performance of tested fiber to actual in-service performance.

In addition to acceptance tests, fibers undergo other tests such as pull strength, breaking, humidity resistance, prolonged tension, and bend tests. Connectors, splitters, combiners, and fiber amplifiers need to be tested frequently to minimize power transmission losses.

In almost all fiber optics, low noise and very sensitive photodetectors are used in measurements. Semiconductor photodiodes made from silicon are suitable for measurements with wavelengths below 1 μm . For larger wavelengths, other detectors are used, such as those made of germanium.

Semiconductor photodiodes work via the internal photoelectric effect; that is, they absorb photons of energy $h\nu$ containing the incoming light beam power P and emit a number of electrons proportional to the number of photons, creating a current:

$$i_p = P\eta e/h\nu \quad (59.5)$$

where h = Planck's constant, ν = frequency of the absorbed light ($\nu = c/\lambda$), η = a constant of proportionality or quantum efficiency ($\eta < 1$), and e = the charge of an electron.

Photodetectors are used to measure the attenuation in fibers by measuring the optical power in the input $P(0)$ and power $P(L)$ at the end of the of the fiber. From Equation 59.1, the attenuation of the fiber can be calculated as:

$$a_0 = \alpha L = -10 \log P(L)/P(0) \quad (59.6)$$

When photodetectors are used Equation 59.4 can be written as

$$a_0 = -10 \log i_p(L)/i_p(0) \quad (59.7)$$

It is worth noting that optical power is proportional to current i_p , not to i_p^2 .

Light-emitting diodes (LEDs) or incandescent halogen lamps are suitable for use as light sources for attenuation measurements. If LEDs are used, several interchangeable ones are needed, suitable to different wavelengths to make measurements. On the other hand, halogen lamps yield a wide spectrum of radiation, from which light of various wavelengths can be filtered with a monochromator that uses optical filters, prisms, or diffraction gratings. With an arrangement of this kind, the attenuation of the fiber can be measured as a function of the wavelength of the light.

To measure small optical powers precisely for the purpose of determining attenuation, the photodetector is usually connected to a selective amplifier, and the light source is modulated at low frequency (e.g., 400 Hz) using a rotating disk called a *chopper*. The selective amplifier amplifies only the similarly modulated components of the photocurrent, so that detector noise and the influence of background light are suppressed. For this purpose, frequency-selective level meters or lock-in amplifiers are often used. In both cases, the frequency and phase of the modulation are fed back in the form of reference voltage.

59.5 Out-of-Plane Scattering and Polarization Methods

The art of scatter measurements has long been evolved to established forms within the optics industry. Scatter methods provide extremely sensitive measurements in many diverse applications. There are two basic instruments developed for this purpose; the scatterometer and the polarimeter.

The basic setup for a scatterometer is given in [Figure 59.11](#). Measured scatter is a good indicator of surface quality as well as discrete defects. However, the scattered signals are generally small compared to the specular beams, and they can vary by several orders of magnitude in just a few degrees. Therefore, scatter measurements need sophisticated instrumentation and the signal processing is more complex than many other optical techniques. Usually, for successful applications, the system specifications and measurements must be given in terms of accepted, well defined quantities. Scatter methods are used

FIGURE 59.11 A typical scatterometer. In this particular type, the source is fixed in position, and the sample is rotated to the required incident angle. The receiver is rotated about the sample in the plane of incidence. In other types, the source and receiver may be fixed, and the sample is rotated so that the scatter pattern moves past the receiver. Scatterometers are offered with full supporting software.

routinely as a quality check on optical components in fiber-optic applications. Conversion of surface scatter data to other required formats, such as surface roughness, is common practice. Out-of-plane measurements and polarization-sensitive measurements are areas currently experiencing rapid advancements.

Another instrument in common use is the polarimeter, which senses the polarization of scattered light. The scattering characteristics of a sample are generally described by its bidirectional reflectance distribution function. The reflectance distribution function is the ratio of scattered flux in a particular direction to the flux of an incident beam. The scattered light is often a sensitive indicator of surface conditions. A small amount of surface roughness may reduce the specular power by less than 1% while increasing the scattered power by orders of magnitude. The retardance, attenuation, and depolarization of scattered light similarly provide sensitive indicators of conditions, such as uniformity of refractive index, orientation of surface defects, texture, strain, subsurface damage, coating microstructure, and the degree of multiscattering. Among many other methods, the use of prisms helps polarization and depolarization of the scattered light.

Instrument manufacturers are listed in [Table 59.1](#), along with contact information.

60.1 Basic Concepts of Polarization

Polarization of light is a property of electromagnetic (EM) waves, which include heat, microwaves, radio waves, and x-rays. An EM wave has orthogonal electric and magnetic fields associated with it which vibrate in directions perpendicular to the direction of propagation. The *electric field* of a sinusoidal EM wave, in particular, can always be decomposed into two orthogonal components; each component has an *amplitude* and a *phase*. The amplitude is the maximum value of the field component, and the light *intensity* is proportional to the square of the amplitude. The phase, referred to a fixed position or time, tells what part of the cycle the electric field is vibrating in. G. G. Stokes pointed out in 1852 that these two orthogonal components do not interfere in amplitude but are additive according to vector algebra [1]. When the two orthogonal components are in phase, the EM wave is *linearly polarized*. When the two orthogonal components have the same amplitude and a relative phase of 90° , the EM wave is *circularly polarized*. In general, an EM wave has arbitrary amplitudes and phases for the two orthogonal fields and is elliptically polarized. The concept of polarization ellipse and the descriptions for the polarization of an EM wave in terms of Jones vectors and Stokes vectors are given in the subsection, “Polarization of an EM Wave,” and also in References 1 through 9.

Light is composed of an ensemble of EM waves. A group of EM waves traveling in the same direction can have some linearly polarized waves, some circularly polarized waves, and some elliptically polarized

waves. When they are combined, resulting light can be unpolarized, partially linearly polarized, or partially elliptically polarized. Unpolarized light occurs when there are no fixed directions of the electric field and also no fixed phase relations between the two orthogonal field components. In general, light is partially polarized and can be decomposed into unpolarized light and elliptically polarized light. These concepts are described in terms of Stokes vector in the subsection, “Polarization of Light,” and also in References 1 through 6.

Polarized light can be produced by passing light through a polarizer. An ideal polarizer transmits only light whose electric field is parallel to the transmission axis of the polarizer and rejects light with the orthogonal field. Polarization of light can be observed by stacking two polarizers together and turning one with respect to the other. The transmitted light intensity through these two polarizers will vary, and at some particular positions it will vanish. In this case, light is linearly polarized after passing through the first polarizer. When the second polarizer is turned until its axis is perpendicular to the axis of the first polarizer, light cannot pass through the second polarizer. The transmitted intensity varies according to the square of the cosine of the angle between the two polarizers [5, 9–12]. Real polarizers are not perfect and transmit light with minimum intensity I_{\min} when the polarizer axis is perpendicular to the polarization of purely linearly polarized incident light. This is caused by the small depolarization of a polarizer [12]. Depolarization is a mechanism that turns polarized light into unpolarized light and is the opposite effect of polarization. The maximum transmitted intensity I_{\max} occurs when the polarizer axis is parallel to the incident polarization direction. The extinction ratio of a polarizer is defined as I_{\min}/I_{\max} . Other relations for polarizers can be found in References 9 through 12.

Besides the polarizer, another basic element in polarization measurements is the phase retarder or wave plate. A phase retarder changes the relative phase between the two orthogonal fields of an EM wave [4–11]. The change of relative phase between the two orthogonal components is called the *phase retardation* or *retardance*. The retardance of a quarter-wave retarder is 90° , and that of a half-wave retarder is 180° . Circularly polarized light can be generated by passing linearly polarized light through a quarter-wave plate whose axis is at 45° with respect to the incident linear polarization direction. A half-wave plate may change the polarization direction of linearly polarized light. In general, a phase retarder changes linearly polarized light into elliptically polarized light. Representations of the optical response of polarizers, retarders, and other materials in terms of the Müller matrix and Jones matrix are given in the subsection “Polarization by the Response of a Medium” and also in References 4 through 8 and 12 through 24.

Polarization is generated by the anisotropic response of materials and/or anisotropic geometry of systems. The mechanisms for producing polarization include preferential absorption in a dichroic material, reflection and transmission at oblique incidence, double refraction in a birefringent material, diffraction by grating or wires, and scattering by particles [2–11, 13]. These properties can be utilized to make polarizers and phase retarders. For example, a wire-grid polarizer is made of parallel fine conducting wires. When light is incident on a wire-grid polarizer with the grid period smaller than the wavelength, the electric field parallel to the wires is shorted and absorbed so that only the electric field perpendicular to the wires passes through the polarizer. In a dichroic polarizer, anisotropic molecules are aligned in a preferential direction so that absorption is very different for the two orthogonal directions referred to the alignment direction. The nonpreferential field is absorbed by the molecules in the medium, while the preferential field passes through the medium [5, 8]. In a prism polarizer, the two orthogonal fields are separated by double refraction in a birefringent crystal, and the unwanted polarization is deflected away by the special geometry of a prism. A material is birefringent when it has different refractive indices for different field directions. When a light beam passes through a birefringent slab, a phase retardation is generated. Birefringent slabs can be used to make phase retarders or wave plates. Different kinds of polarizers and retarders are described in detail in References 5 and 9 through 11.

When special arrangements of polarizers and phase retarders are combined with a light source and a detector, polarized light can be generated and analyzed. Such an optical system is called a *polarimeter* or an *ellipsometer*. The subsection “Principles of Polarimetry” discusses the generation and analysis of polarized light and the operational principles for Polarizer-Sample-Analyzer (PSA) ellipsometry and

Polarizer-Compensator-Sample-Analyzer (PCSA) ellipsometry using the intensity approach associated with Stokes vectors and Müller matrices [4, 17–23, 25, 26]. A phase retarder is also called a *compensator* because it was introduced into a polarimeter to compensate the phase change by a sample. The intensity approach was chosen because intensity, but not electric field, is measured in most experiments, and also because the electric field approach cannot treat depolarization. However, the electric field approach is convenient to use for highly polarized light when depolarization does not cause appreciable errors in the measurement. Discussion of ellipsometry using the electric field approach can be found in References 4, 15, 16, and 27 through 33].

Polarization effects are widely applied in modern optical technologies. The electro-optic modulator and shutter are based on tunable birefringence by applying a high voltage across a birefringent crystal to modulate the phase of transmitted light and hence to achieve intensity modulation [4, 7, 9, 34, 35]. Liquid crystal displays use similar principles [36]. Birefringence can also be modulated by the photo-elastic effect [37, 38]. The magneto-optical readout for laser disks utilizes the magneto-optical Kerr effect that generates phase retardation upon reflection from magnetic materials [34, 39]. Other applications of polarization are fiber optics, nonlinear optics, material characterization, medical optics, and many other fields. All of these applications utilize the anisotropic nature of materials or the anisotropic geometry of systems. This chapter is concerned with the application of polarization on material characterization. In this application, a polarimeter or ellipsometer is used to measure optical properties and surface properties of materials and thin films [40–48, see also Chapter 61, “Refractive Index”]. In the subsection “Polarization Instrumentation and Experiments,” different components of polarimeters are discussed using an example of an automated reflection null ellipsometer, and two sample experiments are described to measure birefringence of a birefringent slab and the optical constants of a material.

60.2 Polarization of an Electromagnetic Wave

The electric field $E(z, t)$ of a monochromatic EM wave propagating along the z -direction with a frequency ω and an angular wave-number k can be decomposed into two orthogonal components E_x and E_y , and represented by

$$\begin{cases} \mathbf{E}(z, t) = \hat{x}E_x(z, t) + \hat{y}E_y(z, t) \\ E_x(z, t) = a_x e^{i(\omega t - kz + \delta_x)} \\ E_y(z, t) = a_y e^{i(\omega t - kz + \delta_y)} \end{cases} \quad (60.1)$$

where a_x and δ_x are the amplitude and phase, respectively, for E_x , and a_y and δ_y are for E_y [1–4]. k is related to wavelength λ by $k = 2\pi/\lambda$. In vacuum, $k = \omega/c$. Let $\delta = \delta_y - \delta_x$ be the relative phase between E_y and E_x . Then Equation 60.1 can be simplified to

$$\mathbf{E}(z, t) = (\hat{x} a_x + \hat{y} a_y e^{i\delta}) e^{i(\omega t - kz + \delta_x)} \quad (60.2)$$

Polarization Ellipse

It is often convenient to express \mathbf{E} in terms of a complex variable. The observed field is actually the real part of \mathbf{E} . The projection of $\text{Re}[\mathbf{E}(z, t)]$ with $\delta_x = 0$ onto the xy -plane at $z = 0$ is given by

$$\mathbf{E}(0, t) = \hat{x} a_x \cos \omega t + \hat{y} a_y \cos(\omega t + \delta) \quad (60.3)$$

The loci of $\mathbf{E}(0, t)$ with $a_x = 3$, $a_y = 2$ and different values of δ are shown in [Figure 60.1](#). For $\delta = 0$, the locus of \mathbf{E} is a line with a slope of a_y/a_x . The EM wave is linearly polarized when E_x and E_y are in phase

with each other. In other cases, the loci are ellipses, which are called *polarization ellipses*, and the EM wave is elliptically polarized. The instantaneous electric field can be visualized by drawing an arrow from the origin to a point on an ellipse. The electric field direction rotates in the clockwise direction for $0 < \delta < 180^\circ$, while in the counter clockwise direction for $-180 < \delta < 0^\circ$. When $\delta = \pm 90^\circ$, the axes of the ellipse correspond to the x and y coordinate axes. If $a_x = a_y$, this ellipse then becomes a circle, and the EM wave is circularly polarized. The convention in ellipsometry defines the right-handed circularly polarized wave as the one whose field rotates in the clockwise direction with $\delta = 90^\circ$ [4, 5]. A left-handed circularly polarized wave thus corresponds to $\delta = -90^\circ$ for a counterclockwise rotating electric field.

In Figure 60.1, a polarization ellipse is specified by a set of three parameters: a_x , a_y , and δ . The ellipse can also be specified by the other set of three parameters: the major axis a , the minor axis b , and the orientation angle ϕ of the major axis measured from the x -axis. Figure 60.2 shows the geometry of an ellipse with these parameters. Parameters a and b can also be expressed in terms of the ellipticity e and ellipticity angle ϵ , defined by $e = b/a = \tan \epsilon$. For linear polarization, $\delta = 0$, $b = 0 = e = \epsilon$, and $\tan \phi = a_y/a_x$. For $\phi = 0$, the major and minor axes of the ellipse always correspond to the coordinate axes. For circular polarization, $a = b = a_x = a_y$ and $\delta = \pm 90^\circ$. Right-handed circularly polarized light has a positive ellipticity with $e = 1$ and $\epsilon = 45^\circ$, and left-handed circularly polarized light has a negative ellipticity with $e = -1$ and $\epsilon = -45^\circ$. In general, ϕ represents the orientation of the ellipse, and ϵ indicates the shape of the ellipse and the direction of field rotation. References 2 through 7 give more details about this subject.

Jones Vector and Stokes Vector

The electric field expressed in vector form in Equation 60.1 can also be expressed as a column matrix. A polarization ellipse depends on a_x , a_y , δ_x , and δ_y , but not on k and ω . By neglecting the common factor of $e^{i(\omega t - kz)}$ in both E_x and E_y , the Jones vector is defined as [4, 7, 8]

FIGURE 60.1 Projection of the electric field of an EM wave with amplitudes $a_x = 3$, $a_y = 2$ and different values of phase retardation δ onto the $z = 0$ plane. Most of these loci are ellipses and reduce to lines or circles in special cases. The electric field changes in the clockwise direction for δ between 0 and 180° .

Polarization Ellipse

FIGURE 60.2 Characteristic parameters for a polarization ellipse. a_x and a_y are the field amplitudes in the x - and y -directions, and δ is the phase retardance; a and b are the major and minor axes of the ellipse, ϕ is the orientation of the major axis with respect to the x -axis, and ϵ is the ellipticity angle which is equal to $\tan^{-1}(b/a)$. A polarization ellipse can be characterized by (a_x, a_y, δ) , (a, b, ϕ) or (I, ϕ, ϵ) , where I is the intensity of the EM wave.

$$\mathbf{E} = \begin{pmatrix} E_x \\ E_y \end{pmatrix} = \begin{pmatrix} a_x e^{i\delta_x} \\ a_y e^{i\delta_y} \end{pmatrix} \quad (60.4)$$

Both elements of a Jones vector are complex numbers. Jones algebra is convenient for describing perfectly polarized light. Since a light sensor measures only intensity but not electric field in most cases, the Stokes vector is more convenient to use in metrology. The Stokes parameters are four intensity-based parameters used to describe the polarization state of light, represented by S_0, S_1, S_2, S_3 , or by I, Q, U, V [1–6, 14]. The Stokes vector is the set of these Stokes parameters, defined as [4, 14]

$$\mathbf{S} = \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} \equiv \begin{pmatrix} \langle E_x E_x^* \rangle + \langle E_y E_y^* \rangle \\ \langle E_x E_x^* \rangle - \langle E_y E_y^* \rangle \\ \langle E_x E_y^* \rangle + \langle E_y E_x^* \rangle \\ i \langle E_x E_y^* \rangle - i \langle E_y E_x^* \rangle \end{pmatrix} \quad (60.5)$$

For an EM wave, the average bracket in Equation 60.5 represents the time average. $\langle E_x E_x^* \rangle = I_x$ is the intensity of the component of light linearly polarized in the x -direction. Similarly, $\langle E_y E_y^* \rangle = I_y$. All of the Stokes parameters are real numbers and are measurable. For an ensemble of EM waves, the average brackets represent both time and ensemble averages.

Perfectly Polarized Light

Stokes vectors for different polarization states of light can be evaluated using Equation 60.5. Table 60.1 lists the Jones vectors and Stokes vectors for different states of perfectly polarized light. The Jones vector \mathbf{E} and Stokes vector \mathbf{S} expressed in terms of ellipticity angle ϵ and orientation angle ϕ are

$$\mathbf{E} = a \begin{pmatrix} \cos \epsilon \cos \phi - i \sin \epsilon \sin \phi \\ \cos \epsilon \sin \phi + i \sin \epsilon \cos \phi \end{pmatrix} \quad (60.6)$$

$$\mathbf{S} = I \begin{pmatrix} 1 \\ \cos 2\epsilon \cos 2\phi \\ \cos 2\epsilon \sin 2\phi \\ \sin 2\epsilon \end{pmatrix} \quad (60.7)$$

In Equations 60.6 and 60.7, the amplitude a and intensity I are totally separated from the angles ϕ and ϵ which determine the polarization state. The degrees of linear and circular polarization are $\cos 2\epsilon$ and $\sin 2\epsilon$, correspondingly. Stokes parameters for perfectly polarized light given in Equation 60.7 satisfy the identity

$$S_0^2 = S_1^2 + S_2^2 + S_3^2 \quad (60.8)$$

60.3 Polarization of Light

Light is composed of an ensemble of EM waves. A single EM wave has a certain electric field direction and phase. Unpolarized light can be visualized as an ensemble of EM waves with random field directions and phases. The field direction and phase for unpolarized light can not be defined then. The description of light in terms of Jones vector is therefore inadequate to describe the polarization of unpolarized light. For an ensemble of many EM waves, the electric field components in the Stokes vector given by Equation 60.5 is the sum of the corresponding components for all waves. In particular, for an ensemble of incoherent EM waves, the Stokes vectors for individual waves are additive:

$$\mathbf{S} = \sum_{i=1}^N \mathbf{S}_i \quad (60.9)$$

TABLE 60.1 Jones Vectors and Stokes Vectors for Different Polarization States for Perfectly Polarized Light

Polarization	Linear	Linear	Linear	Circular	Elliptical
Direction	0°	90°	±45°	right/left	
Phase	0°	0°	0°	±90°	δ
Jones vector	$\begin{pmatrix} 1 \\ 0 \end{pmatrix}$	$\begin{pmatrix} 0 \\ 1 \end{pmatrix}$	$\frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ \pm 1 \end{pmatrix}$	$\frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ \pm i \end{pmatrix}$	$\begin{pmatrix} a_x \\ a_y e^{i\delta} \end{pmatrix}$
Stokes vector	$\begin{pmatrix} 1 \\ 1 \\ 0 \\ 0 \end{pmatrix}$	$\begin{pmatrix} 1 \\ -1 \\ 0 \\ 0 \end{pmatrix}$	$\begin{pmatrix} 1 \\ 0 \\ \pm 1 \\ 0 \end{pmatrix}$	$\begin{pmatrix} 1 \\ 0 \\ 0 \\ \pm 1 \end{pmatrix}$	$\begin{pmatrix} a_x^2 + a_y^2 \\ a_x^2 - a_y^2 \\ 2a_x a_y \cos \delta \\ 2a_x a_y \sin \delta \end{pmatrix}$

For an ensemble of EM waves with identical $\phi_i = \phi$ and $\epsilon_i = \epsilon$, the resultant polarization is still the same as the individual wave, as indicated by Equations 60.6 and 60.7, regardless of whether these waves are coherent.

Unpolarized and Partially Polarized Light

If an ensemble consists of randomly oriented linearly polarized waves, all $\epsilon_i = 0$ and ϕ_i are random, then $S_1 = S_2 = S_3 = 0$, according to Equations 60.7 and 60.9. Light is thus unpolarized, and $\mathbf{S} = I(1, 0, 0, 0)$. If an ensemble consists of elliptically polarized waves with the same orientation $\phi_i = \phi$ or $\phi + \pi$ and perfectly random ellipticity angle ϵ_i , then the Stokes vector is $I(1, 0, 0, 0)$, and light is also unpolarized. Thus, the Stokes vector \mathbf{S} in Equation 60.9 already implies the sense of the ensemble average of polarization. The average brackets in Eq. (5) can be considered as both the time average and ensemble average for incoherent waves.

For unpolarized light with $S_1 = S_2 = S_3 = 0$, Equation 60.8 does not hold. In general, light is partially polarized, i.e., part of it is perfectly polarized and the rest is unpolarized [1–6]. Stokes parameters for arbitrary polarizations satisfy

$$S_0^2 \geq S_1^2 + S_2^2 + S_3^2 \quad (60.10)$$

The degree of polarization is given by

$$\mathcal{P} = \frac{\sqrt{S_1^2 + S_2^2 + S_3^2}}{S_0} \quad (60.11)$$

Perfectly polarized light has $\mathcal{P} = 1$, and unpolarized light has $\mathcal{P} = 0$. Partially polarized light has $0 < \mathcal{P} < 1$. The intensity of the polarized part is $\mathcal{P}I$, and the intensity of the unpolarized part is $I(1 - \mathcal{P})$. By the superposition concept, the Stokes vector for partially polarized light can be obtained from Equation 60.7 as

$$\mathbf{S} = I \begin{pmatrix} 1 \\ \mathcal{P} \cos 2\epsilon \cos 2\phi \\ \mathcal{P} \cos 2\epsilon \sin 2\phi \\ \mathcal{P} \sin 2\epsilon \end{pmatrix} \quad (60.12)$$

The degree of linear polarization \mathcal{P}_L and circular polarization \mathcal{P}_C are

$$\begin{cases} \mathcal{P}_L = \mathcal{P} \cos 2\epsilon = \frac{\sqrt{S_1^2 + S_2^2}}{S_0} \\ \mathcal{P}_C = \mathcal{P} \sin 2\epsilon = \frac{S_3}{S_0} \end{cases} \quad (60.13)$$

Polarization by the Response of a Medium

Jones Matrix

To measure polarization, light must interact with a medium to give a response. The response of a polarizer is to pass one polarization and reject the orthogonal one. The response of a phase retarder is to change

the relative phase between the two polarizations. A medium can be any optical component, a test sample or any object under investigation. The response of a medium relates the state of output light to the state of incident light. The polarization state of light can be described by a complex vector EM field, a Jones vector, or a Stokes vector [4, 5, 7, 8]. Let an incident EM wave be specified by a complex field or Jones vector (E_x, E_y) , and the output field be (E'_x, E'_y) , the general relations between these two fields are

$$\mathbf{E}' = \begin{pmatrix} E'_x \\ E'_y \end{pmatrix} = \begin{pmatrix} r_{xx} & r_{xy} \\ r_{yx} & r_{yy} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} = \mathbf{J} \mathbf{E} \quad (60.14)$$

\mathbf{J} in Equation 60.14 is a 2×2 matrix that relates the input Jones vector \mathbf{E} to the output Jones vector \mathbf{E}' and is called the Jones matrix. The response of a medium is characterized by the elements of the Jones matrix, r_{xx} , r_{xy} , r_{yx} , and r_{yy} , which are all complex numbers.

Principal Coordinate System

Since the directions of an electric field are different in different rotated coordinate systems, $\{r_{ij}\}$ are not unique. For many symmetric media, there exists a coordinate system in which r_{xy} and r_{yx} are zero, and r_{xx} and r_{yy} are called the eigenvalues for $\{r_{ij}\}$. This is the principal coordinate system or principal frame whose x - and y -axes are the two principal axes. Finding the principal frame is an eigenvalue problem. If the incident polarization is along one of the principal-axis \hat{x} , then the output polarization is still along \hat{x} . In the principal frame, $\{r_{ij}\}$ are called the coefficients of response. For example, $\{r_{ij}\}$ may represent the reflection coefficients for a reflection response, or the scattering coefficients for a scattering response, etc. In the principal coordinate system, Equation 60.14 is simplified to

$$\mathbf{E}' = \begin{pmatrix} E'_x \\ E'_y \end{pmatrix} = \begin{pmatrix} r_{xx} & 0 \\ 0 & r_{yy} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} = \mathbf{J}(0) \mathbf{E} \quad (60.15)$$

$\mathbf{J}(0)$ is the diagonalized Jones matrix in the principal frame. For a polarizer, the principal axes are the transmission and extinction axes. The former is assigned to the x -axis. For a phase retarder, the principal axes are the fast- and slow-axes. The phase change for the EM wave with its field along the fast-axis is larger than the slow-axis. The fast-axis is usually assigned to the x -axis. The principal Jones matrices \mathbf{p} for a perfect polarizer, and \mathbf{c} for a perfect wave plate with a retardance τ are [4, 5, 7, 8]

$$\mathbf{p} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \quad \mathbf{c} = \begin{pmatrix} e^{i\tau/2} & 0 \\ 0 & e^{-i\tau/2} \end{pmatrix} \quad (60.16)$$

Ellipsometric Parameters

For reflection from a surface, the two principal axes are the s - and p -polarizations. The s -polarization field is along the y -axis which is chosen to be perpendicular to the plane of incidence. The p -polarization field is along the x -axis which is in the plane of incidence. The complex reflection coefficients for these two polarizations are designated as $r_p = r_{xx}$ and $r_s = r_{yy}$. The ellipsometric parameters ψ and Δ are defined by [4, 15, 16]

$$\frac{r_p}{r_s} = \frac{r_{xx}}{r_{yy}} = \tan \psi \exp(i\Delta) \quad (60.17)$$

Δ is the phase change between reflected and incident light. If the electric field direction of incident light is given by ϕ_0 , then the field direction ϕ of reflected light can be obtained from $\tan\phi = \tan\phi_0/\tan\psi$. At the Brewster angle, where $r_p = 0$ and $\psi = 0$, then $\phi = 90^\circ$, and reflected light is vertically polarized. Equation 60.17 can also be applied to transmissive systems. Since a vacuum does not change the polarization of light, the ellipsometric parameters are $\psi = 45^\circ$ and $\Delta = 0^\circ$. A perfect polarizer with the polarization along the x -axis has $\psi = 90^\circ$ and $\Delta = 0^\circ$, a perfect quarter-wave plate has $\psi = 45^\circ$ and $\Delta = 90^\circ$, and a perfect half-wave plate has $\psi = 45^\circ$ and $\Delta = 180^\circ$.

Müeller Matrix

The Jones calculus is convenient for perfectly polarized light and a nondepolarizing response [8]. If unpolarized light is incident on a sample, the Jones vector can not describe the field direction and phase for unpolarized light. The Stokes vector and Müeller matrix are more convenient to use in treating polarization for general cases. A relation between the output Stokes vector \mathbf{S}' and the input Stokes vector \mathbf{S} is

$$\mathbf{S}' = \mathbf{M} \mathbf{S} \quad (60.18)$$

The matrix \mathbf{M} that relates the input and output Stokes vectors is called a Müeller matrix. \mathbf{M} is a 4×4 matrix of real numbers.

For the general transformation of electric field given by Equation 60.14, the components M_{ij} of \mathbf{M} can be derived from Equations 60.5, 60.14, and 60.18. The expressions for M_{ij} have been obtained by van de Hulst [13] and are also given as Equation (2.243) of Reference 4. In a measurement, the EM waves of output light may come from many different area or volume elements of a medium, so that statistical averages must be considered in the evaluation of M_{ij} . The ensemble average of \mathbf{M} can still be expressed by the same expressions, with the ensemble average bracket applying to all M_{ij} . To make the Müeller matrix meaningful, the new subscripts of Equation 60.14 are reassigned as 1: xx , 2: yy , 3: xy , 4: yx . Subscripts 1 and 2 correspond to the copolarized response, and subscripts 3 and 4 correspond to the cross-polarized response. The ensemble average of any two of the response coefficients is called a *correlation function* for these coefficients. Let us define the self-correlation functions to be $2F_j$ and the cross-correlation functions to be $G_{jm} + i g_{jm}$ as follows:

$$\left\{ \begin{array}{l} 2F_j \equiv \langle r_j r_j^* \rangle \\ G_{jm} + i g_{jm} \equiv \langle r_j r_m^* \rangle \end{array} \right. \quad j, m = 1, 2, 3, 4; j \neq m \quad (60.19)$$

The cross-correlation functions have the properties of $G_{jm} = G_{mj} = \text{Re} \langle r_j r_m^* \rangle$, and $g_{jm} = -g_{mj} = \text{Im} \langle r_j r_m^* \rangle$. All F_j , G_{jm} , and g_{jm} are real numbers. \mathbf{M} is then

$$\mathbf{M} = \begin{pmatrix} F_1 + F_2 + F_3 + F_4 & F_1 - F_2 - F_3 + F_4 & G_{13} + G_{24} & g_{13} - g_{24} \\ F_1 - F_2 + F_3 - F_4 & F_1 + F_2 - F_3 - F_4 & G_{13} - G_{24} & g_{13} + g_{24} \\ G_{14} + G_{23} & G_{14} - G_{23} & G_{12} + G_{34} & g_{12} - g_{34} \\ -g_{14} + g_{23} & -g_{14} - g_{23} & -g_{12} - g_{34} & G_{12} - G_{34} \end{pmatrix} \quad (60.20)$$

The upper left quadrant of \mathbf{M} corresponds to the self-correlation terms. The lower right quadrant corresponds to the cross-correlations between the two co-polarized responses and between the two cross-polarized responses. The upper right and lower left quadrants correspond to the cross-correlations between the co-polarized and cross-polarized responses.

Principal Müller Matrix

For the Jones matrix in the principal frame given by Equation 60.15, the cross-polarized responses are zero, so that the M_{jm} in the upper right and lower left quadrants of Equation 60.20 are zero. \mathbf{M} can be expressed in terms of ψ and Δ using Equations 60.17 and 60.20 as [4, 17–19]

$$\mathbf{M} = R \begin{pmatrix} 1 & -\cos 2\psi & 0 & 0 \\ -\cos 2\psi & 1 & 0 & 0 \\ 0 & 0 & \sin 2\psi \cos \Delta & \sin 2\psi \sin \Delta \\ 0 & 0 & -\sin 2\psi \sin \Delta & \sin 2\psi \cos \Delta \end{pmatrix} \quad (60.21)$$

where $R = (r_{xx} r_{xx}^* + r_{yy} r_{yy}^*)/2$. For reflection, R is the average reflectance, and for transmission, R is the average transmittance. For a vacuum, $\psi = 45^\circ$ and $\Delta = 0^\circ$, \mathbf{M} is a unit matrix. Using Equation 60.21 or Equations 60.16, 60.19, and 60.20 directly, matrix \mathbf{P} for a perfect polarizer ($\psi = 90^\circ$, $\Delta = 0^\circ$) and matrix \mathbf{C} for a perfect wave plate ($\psi = 45^\circ$, $\Delta = \tau$) in the principal frame are obtained as [4, 5, 20]

$$\mathbf{P} = \frac{1}{2} \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \quad \mathbf{C} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \cos \tau & \sin \tau \\ 0 & 0 & -\sin \tau & \cos \tau \end{pmatrix} \quad (60.22)$$

Depolarization

A very interesting example is the perfectly random response. Analogous to the conditions used for incoherent scattering [17–19], the random response coefficients δr_j have the properties that

$$\begin{cases} \langle \delta r_j \rangle = 0 \\ \langle \delta r_j \delta r_m^* \rangle = \langle |\delta r_j|^2 \rangle \delta_{j,m} & j, m = 1, 2, 3, 4 \\ \langle |\delta r_j|^2 \rangle = \text{constant} \end{cases} \quad (60.23)$$

The first line states that all δr_j are each averaged to zero, so that they would not appear in the average of Equation 60.14. By substitution of r_j of Equation 60.19 by δr_j and using the conditions for δr_j given by Equation set 60.23, the correlation functions F_j and $G_{jm} + i g_{jm}$ can be evaluated. The second line of Equation set 60.23 states that all δr_j are uncorrelated with one another, so that all G_{ij} and g_{ij} are zero. The third line states that δr_j are isotropic, so that all F_j are the same. Eventually, all $M_{jm} = 0$ except $M_{00} = 4 F_1$. The depolarization matrix \mathbf{D} for a perfectly random response is then

$$\mathbf{D} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \quad (60.24)$$

\mathbf{D} is an ideal depolarizer as defined in Reference 20. The general Müller matrix of Equation 60.20 satisfies the physical condition [14, 24]

$$\sum_{i,j=0}^3 M_{ij}^2 \leq 4M_{00}^2 \quad (60.25)$$

The sum of all the squares of the elements of \mathbf{D} is M_{00}^2 . \mathbf{D} satisfies the inequality of criterion in Equation 60.25. The matrix of Equation 60.21 is nondepolarizing such that output light is still perfectly polarized if incident light is perfectly polarized. The equality in Equation 60.25 holds for \mathbf{M} of Equation 60.21. This section discusses optical components and samples that are nondepolarizing. References 12 and 17 through 19 give more details about the Müller matrices for samples that exhibit both polarization and depolarization properties.

Coordinate Transformation

In polarimetric measurements, polarizers and retarders are frequently rotated to desired positions. When a component is rotated, the incident field is not changed, but the representations of this field in the principal and laboratory coordinate systems are different. Transformations of the electric fields, Stokes vectors, Jones and Müller matrices between these two coordinate systems or frames are basic exercises in polarimetry. Let the laboratory frame axes be x - and y -axes, and the principal frame axes be x' - and y' -axes, and the principal frame is rotated to an angle α with respect to the laboratory frame, as shown in Figure 60.3. The Jones vector (E_x', E_y') in the principal frame is related to (E_x, E_y) in the laboratory frame by

$$\mathbf{E}' = \begin{pmatrix} E_x' \\ E_y' \end{pmatrix} = \begin{pmatrix} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} = \mathbf{r}(\alpha)\mathbf{E} \quad (60.26)$$

The rotation matrix $\mathbf{r}(\alpha)$ is the 2×2 matrix in Equation 60.26 for transformation of Jones vectors. The inverse transform is given by $\mathbf{E} = \mathbf{r}^T(\alpha)\mathbf{E}'$, where the superscript \mathbf{T} denotes the transpose of a matrix. In Figure 60.3, \mathbf{E}' appears to be turned by an angle of $-\alpha$, since the coordinate system is rotated by an angle α . The Faraday rotation matrix that rotates \mathbf{E} by an angle of α is equivalent to $\mathbf{r}(\alpha)$.

One can substitute $r_1 = r_2 = \cos\alpha$ and $r_3 = -r_4 = \sin\alpha$ into Equations 60.19 and 60.20 to construct the rotation matrix $\mathbf{R}(\alpha)$ for transformation of a Stokes vector \mathbf{S} to a coordinate system oriented at an angle α .

$$\mathbf{R}(\alpha) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos 2\alpha & \sin 2\alpha & 0 \\ 0 & -\sin 2\alpha & \cos 2\alpha & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \quad (60.27)$$

FIGURE 60.3 Coordinate transformation for the electric field components (E_x, E_y) in the laboratory system (x, y) and the components (E_x', E_y') in the principal coordinate system (x', y') . The principal frame is oriented at an angle α with respect to the laboratory frame.

The transformations between Stokes vector \mathbf{S}' in the principal frame and \mathbf{S} in the laboratory frame are

$$\begin{cases} \mathbf{S}' = \mathbf{R} \mathbf{S} \\ \mathbf{S} = \mathbf{R}^T \mathbf{S}' \end{cases} \quad (60.28)$$

The transformation of a Müller matrix $\mathbf{M}(0)$ in the principal frame to $\mathbf{M}(\alpha)$ in the laboratory frame can be obtained by a similarity transformation:

$$\mathbf{M}(\alpha) = \mathbf{R}^T(\alpha) \mathbf{M}(0) \mathbf{R}(\alpha) \quad (60.29)$$

Equation 60.29 can also be used for the transformation of Jones matrix $\mathbf{J}(0)$ in the principal coordinate frame to $\mathbf{J}(\alpha)$ in the laboratory frame, provided that \mathbf{M} is replaced by \mathbf{J} and $\mathbf{R}(\alpha)$ by $\mathbf{r}(\alpha)$ in Equation 60.29.

The Jones matrix for a polarimetric component orientated at an angle α is

$$\mathbf{J}(\alpha) = \begin{pmatrix} r_{xx} \cos^2 \alpha + r_{yy} \sin^2 \alpha & \sin \alpha \cos \alpha (r_{xx} - r_{yy}) \\ \sin \alpha \cos \alpha (r_{xx} - r_{yy}) & r_{xx} \sin^2 \alpha + r_{yy} \cos^2 \alpha \end{pmatrix} \quad (60.30)$$

The Müller matrix $\mathbf{P}(P)$ for a perfect polarizer oriented at an angle P and $\mathbf{C}(C)$ for a perfect compensator with a retardance τ at an angle C are [4, 6, 21]

$$\mathbf{P}(P) = \frac{1}{2} \begin{pmatrix} 1 & \cos 2P & \sin 2P & 0 \\ \cos 2P & \cos^2 2P & \sin 2P \cos 2P & 0 \\ \sin 2P & \sin 2P \cos 2P & \sin^2 2P & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \quad (60.31)$$

$$\mathbf{C}(C) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos^2 2C + \sin^2 2C \cos \tau & \sin 2C \cos 2C (1 - \cos \tau) & -\sin 2C \sin \tau \\ 0 & \sin 2C \cos 2C (1 - \cos \tau) & \sin^2 2C + \cos^2 2C \cos \tau & \cos 2C \sin \tau \\ 0 & \sin 2C \sin \tau & -\cos 2C \sin \tau & \cos \tau \end{pmatrix} \quad (60.32)$$

Equations 60.16, 60.22, and 60.30 through 60.32 can be used to calculate the Jones matrices and Müller matrices for polarizers and wave plates at arbitrary orientations. Table 60.2 lists some of these matrices for the most frequently used devices.

For a light beam passing through successive components oriented at different angles, Müller matrices or Jones matrices in the laboratory frame must be used for successive multiplications. According to Equation 60.18, the matrix $\mathbf{M}_1(\alpha_1)$ for the component that light first passes through should be placed at the extreme right, and the matrix $\mathbf{M}_n(\alpha_n)$ for the last component at the extreme left. The combined matrix \mathbf{M} is

$$\mathbf{M} = \mathbf{M}_n(\alpha_n) \dots \mathbf{M}_1(\alpha_1) \quad (60.33)$$

TABLE 60.2 The Jones Matrices and Müller Matrices for Perfect Polarizer and Wave Plates at Different Orientation Angles

Device	Angle	Jones matrix	Müller matrix
Polarizer	0°	$\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$	$\frac{1}{2} \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$
Polarizer	90°	$\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$	$\frac{1}{2} \begin{pmatrix} 1 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$

60.4 Principles of Polarimetry

Polarimetry is a method for measuring the polarization of light and the polarization response of materials. An optical system used for such purposes is called a polarimeter or an ellipsometer. To measure the polarization response of a sample, polarized light is generated and incident on the sample. By examining the polarization states of both incident and reflected or transmitted light, the characteristics of a sample can be determined. A schematic diagram of a polarimeter used to measure the polarization response of a sample is shown in [Figure 60.4](#). The light source and polarizer are used to generate polarized light, and the analyzer and detector are used to analyze the polarization of light [4, 20]. An analyzer is a polarizer used to analyze polarized light.

FIGURE 60.4 Schematic diagram of a polarimeter to measure polarization response. The light source and polarizer are used to generate polarized light, and the analyzer and detector are used to analyze the state of polarization of the light.

Analysis of Polarized Light

Measurement of polarization of light is essential in polarimetry, since polarized light to be examined is not limited to that generated in a laboratory. The instrument to measure the four Stokes parameters is called a photo-polarimeter or a Stokesmeter. To measure linear polarization, pass the light beam through a linear analyzer oriented at angle $A = 0^\circ, 90^\circ,$ and $\pm 45^\circ,$ and measure the corresponding intensities $I_x, I_y, I_+,$ and $I_-.$ To measure circular polarization, first pass the light beam through a quarter-wave retarder with $C = 0^\circ,$ then through an analyzer oriented at $A = \pm 45^\circ,$ and measure the intensities I_R and $I_L.$ The pair of quarter-wave retarder and analyzer constitutes a circular analyzer. A detector measuring intensity corresponds to an operation given by a row vector $\mathbf{I} = (1, 0, 0, 0).$ The combined operation of a detector following an analyzer is $\mathbf{I}\mathbf{A} = 0.5(1, \cos 2A, \sin 2A, 0).$ The operations for the linear and circular analyzers on a Stokes vector \mathbf{S} and the intensities obtained are given in [Table 60.3](#). The Stokes parameters can be obtained from the difference and sum of the intensities for these pair operations, and are given by

$$\mathbf{S} = \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} = \begin{pmatrix} I_x + I_y \\ I_x - I_y \\ I_+ - I_- \\ I_R - I_L \end{pmatrix} \quad (60.34)$$

Equation 60.34 is a general expression that is good for any polarization states and is also the operational principle for most Stokesmeters. The four-detector Stokesmeter designed by Azzam is an exception that contains no moving components and can measure the four Stokes parameters in real time [26].

Generation of Polarized Light

Characterization of polarization response of a sample requires incident polarized light whose polarization state is controllable. A convenient source is a laser, which may be constructed to emit polarized light directly without the help of extra devices. A half-wave plate may be used to rotate the laser polarization

TABLE 60.3 Intensities I for a Light Beam with Stokes Parameters $S_0, S_1, S_2,$ and S_3 Analyzed by Linear and Circular Analyzers. A circular analyzer consists of a quarter-wave plate oriented at $C = 0^\circ,$ followed by an analyzer oriented at $A = \pm 45^\circ.$

Analyzer	Linear	Linear	Circular

to a desired direction by placing the fast-axis bisecting the new and old directions, as shown in Figure 60.5a. Light generated from a lamp and a monochromator is usually partially polarized [12]. To generate linearly polarized light at an angle P , a linear polarizer oriented at an angle P is placed behind the monochromator as shown in Figure 60.5b. To generate circularly polarized light, first generate linearly polarized light, and then put a quarter-wave plate behind with the fast-axis oriented at an angle of 45° or -45° with respect to the linear polarization as shown in Figure 60.5c. Such a combination of polarizer and quarter-wave plate is called a circular polarizer. When a phase retarder has an arbitrary retardance or is placed at an arbitrary angle relative to the polarizer, elliptically polarized light is then generated. Given an incident Stokes vector of (S_0, S_1, S_2, S_3) , the Stokes vector S' for polarized light generated by the polarizers mentioned above can be obtained from Equations 60.18 and 60.31 through 60.33. The obtained S' are listed in Table 60.4. Note that S' is not directly proportional to S_0 unless incident light is unpolarized. Care must be taken in generating polarized light in an ellipsometer because incident light is rarely completely unpolarized.

Polarizer–Sample–Analyzer Ellipsometry

An ellipsometer is an instrument to measure the ellipsometric parameters ψ and Δ of a sample. It can be used for both reflection and transmission. An ellipsometer is usually referred to as the reflection system, and a polarimeter as the transmissive system [4]. Different ellipsometers are designed to measure different responses for different kinds of samples. It is important to know about the sample when designing an experiment. The simplest ellipsometer is a polarizer–sample–analyzer (PSA) ellipsometer. A more general one is a polarizer–compensator–sample–analyzer (PCSA) ellipsometer. Figure 60.6 shows

FIGURE 60.5 Generation of light linearly polarized at a desired direction using (a) a laser source and a half-wave plate and (b) a lamp, monochromator, and a polarizer, plus (c) generation of circularly polarized light using a polarizer and a quarter-wave plate.

FIGURE 60.6 Schematic diagram of a PCSA ellipsometer.

S'	$\frac{S_0 \pm S_1}{2} \begin{pmatrix} 1 \\ \pm 1 \\ 0 \\ 0 \end{pmatrix}$	$\frac{S_0 \pm S_2}{2} \begin{pmatrix} 1 \\ 0 \\ \pm 1 \\ 0 \end{pmatrix}$	$\frac{S_0 \pm S_3}{2} \begin{pmatrix} 1 \\ 0 \\ 0 \\ \pm 1 \end{pmatrix}$

a schematic diagram of a PCSA reflection ellipsometer. A PSA system can be visualized by removing the compensator C in Figure 60.6.

Let the oriented angles of the polarizer and analyzer be P and A , respectively, as measured from the plane of incidence. For unpolarized incident light and a sample matrix M given by Equation 60.21, the measured intensity I for a PSA ellipsometer is [22]

$$\begin{aligned}
 I(P, A) &= \mathbf{I} \mathbf{A}(A) \mathbf{M}(R, \psi, \Delta) \mathbf{P}(P) \mathbf{S} \\
 &= T_p T_a R I_0 [1 - \cos 2\psi (\cos 2P + \cos 2A)] + \cos 2P \cos 2A + \sin 2\psi \cos \Delta \sin 2P \sin 2A \quad (60.35)
 \end{aligned}$$

I_0 is the intensity of incident light, T_p and T_a are the transmittance of the polarizer and analyzer, respectively. If incident light is partially polarized with a Stokes vector (S_0, S_1, S_2, S_3) , then the right-hand side of Equation 60.35 should be multiplied by the factor $(S_0 + S_1 \cos 2P + S_2 \sin 2P)/S_0$. In such a case, the dependence on P is more complicated. A good practice is to keep P fixed and vary only A . Many different ways can be devised to extract ψ and Δ from Equation 60.35, such as the Stokes polarimeter, null polarimeter, and rotating-analyzer ellipsometer.

For a Stokes polarimeter, P is set at 45° or -45° , and A at 0° , 90° , and $\pm 45^{\circ}$. The ellipsometric parameters ψ and Δ can be solved from the four equations evaluated at these P and A positions via the relations

$$\begin{cases} \cos 2\psi = \frac{I_y - I_x}{I_y + I_x} \\ \sin 2\psi \cos \Delta = \frac{I_+ - I_-}{I_+ + I_-} \end{cases} \quad (60.36)$$

For a null polarimeter, set $P = \pm 45^\circ$, and vary A to find the null positions. This method is excellent for reflection from transparent materials with Δ equal to 0 or π . The value of ψ is related to the null position A_\pm as [22]

$$\tan 2A_\pm = \mp \tan 2\psi \cos \Delta \quad \text{for } P = \pm 45^\circ \quad (60.37)$$

Average of A_\pm at $P = \pm 45^\circ$ can eliminate errors from the misalignment of analyzer and polarizer.

In a rotating-analyzer ellipsometer (RAE), the analyzer is rotated at an angular frequency ω_r . Set $P = 45^\circ$ or -45° , and $A = \omega_r t$. The measured intensity is

$$I = T_p R T_a I_0 [1 - \cos 2\psi \cos 2\omega_r t + \sin 2\psi \cos \Delta \sin 2\omega_r t] \quad (60.38)$$

The Fourier coefficients, being equal to $-\cos 2\psi$ and $\sin 2\psi \cos \Delta$, can be recovered from the demodulated signals or from a fast Fourier transform (FFT) technique [28, 29]. However, the measured Δ cannot be distinguished from $-\Delta$. This system can be fully automated for realtime operation. With a white light source and monochromator, an RAE can serve as a spectroscopic ellipsometer [15, 16, 28, 29].

Polarizer–Compensator–Sample–Analyzer Ellipsometry

In a PCSA or a PSCA ellipsometer, a compensator of retardance τ is inserted in front of or following the sample. Figure 60.6 shows a schematic diagram of a PCSA ellipsometer. For unpolarized incident light in a PCSA system, the measured intensity for general conditions of B , C , and A is given by [21]

$$\begin{aligned} I(P, C, A) &= \mathbf{I} \mathbf{A}(A) \mathbf{M}(R, \psi, \Delta) \mathbf{C}(C) \mathbf{P}(P) \mathbf{S} \\ &= T_p T_c R T_a I_0 [Y_0 + Y_1 \cos 2A + Y_2 \sin 2A] \end{aligned} \quad (60.39)$$

where

$$\begin{cases} Y_0 = \{1 - \cos 2\psi [\cos 2C \cos 2(P - C) - \cos \tau \sin 2C \sin 2(P - C)]\} \\ Y_1 = \{-\cos 2\psi + [\cos 2C \cos 2(P - C) - \cos \tau \sin 2C \sin 2(P - C)]\} \\ Y_2 = \sin 2\psi \{ \cos \Delta [\sin 2C \cos 2(P - C) + \cos \tau \cos 2C \sin 2(P - C)] - \sin \tau \sin \Delta \sin 2(P - C) \} \end{cases} \quad (60.40)$$

If incident light is partially polarized, then I_0 in Equation 60.39 should be replaced by $(S_0 + S_1 \cos 2P + S_2 \sin 2P)$. For a PSCA system, interchange P and A in Equations 60.39 and 60.40. These formulas can be used to design different kinds of PCSA ellipsometers by choosing different conditions and different types of modulation. For certain special conditions, Equations 60.40 can be greatly simplified.

Null Ellipsometry

Consider a PCSA null ellipsometer (NE) in which the compensator is a perfect quarter-wave retarder ($\tau = 90^\circ$) which is set at $C_\pm = \pm 45^\circ$. The measured intensity is

$$I(P, C_{\pm}, A) = T_p T_c R T_a I_0 [1 - \cos 2\psi \cos 2A \pm \sin 2\psi \sin 2A \cos \Delta \pm (2P - 90^\circ)] \quad (60.41)$$

An NE is an instrument to find the null positions in order to determine ψ and Δ . The four zones that will null the intensity in Equation 60.41 and the null positions are listed in Table 60.5. The null positions of A give ψ directly, and the null positions of P give Δ directly. Although ψ and Δ can be determined from measurements in only one zone, systematic errors caused by imperfect components, misalignment, and partially polarized incident light can be nonnegligible. By taking the average of four zones, many of these linear systematic errors can be cancelled [4, 21, 30, 31]. To look for the null positions manually is a slow process; automation of the nulling process can speed up the measurements. Different methods can be used to automate the NE: (1) both polarizer and analyzer are controlled by servo-motors with the feedback from the detector to find the null intensity, (2) the intensity is digitized and fed into a computer which is used to find the null positions, (3) Faraday rotators are used to rotate and modulate the polarization directions of light incident on and reflected from the sample to get the slopes of intensity versus angle until the slopes are zero at the null positions [4, 27]. The advantage of NE is its simplicity in obtaining ψ and Δ . Also, its accuracy is unbeatable by other kinds of ellipsometry.

TABLE 60.5 The Null Positions of Polarizer Angle P and Analyzer Angle A for the Four Different Zones at $C = \pm 45^\circ$ in a Null Ellipsometer.

Zone	$C(^\circ)$	P	A
1	-45	$-45^\circ + \Delta/2$	ψ
2	45	$-45^\circ - \Delta/2$	ψ
3	-45	$45^\circ + \Delta/2$	$-\psi$
4	45	$45^\circ - \Delta/2$	$-\psi$
Average	$\psi = (A_1 + A_2 - A_3 - A_4)/4, \quad \Delta = (P_1 - P_2 + P_3 - P_4)/2$		

Phase-Modulated Ellipsometry

A phase-modulated ellipsometer (PME) uses a phase retarder whose retardance is modulative. For a PME, a good choice of P , C , and A in Equations 60.39 and 60.40 is $P = 0^\circ$, $C = 45^\circ$, and $A = 45^\circ$. The intensity is then

$$I(\tau) = T_p T_c R T_a I_0 [1 - \cos 2\psi \cos \tau + \sin 2\psi \sin \Delta \sin \tau] \quad (60.42)$$

The retardance τ is modulated, and the modulated intensity is detected. If τ is modulated according to $\tau = \tau_0 \cos \Omega t$, then $I(\tau)$ can be expanded in a Fourier series with the Fourier coefficients, depending on $\cos 2\psi$, $\sin 2\psi \cos \Delta$ and the Bessel functions of τ_0 . These coefficients can be recovered from the demodulated signals, and the values of ψ and Δ can then be solved. τ can be modulated by electro-optic modulation using the Pockels effect, or piezoelectric modulation using the photoelastic effect [32, 33]. These modulations are fast, and demodulation using a lock-in amplifier is convenient. The advantage of a PME is that it contains no moving components and offers real-time measurement.

60.5 Polarization Instrumentation and Experiments

Figure 60.7 shows a schematic diagram of a PCSA reflection null ellipsometer. The instrument is composed of five systems: the source system, polarimetric system, sample system, detection system, and computer system for automatic control, data acquisition, and processing.

The simplest source is a polarized laser. The monochromatic source system in Figure 60.7 is usually used in visible, ultraviolet and infrared spectrometers. Light from a lamp source L is focused by a lens system or a spherical mirror system onto the entrance slit of a grating monochromator M . Light leaving

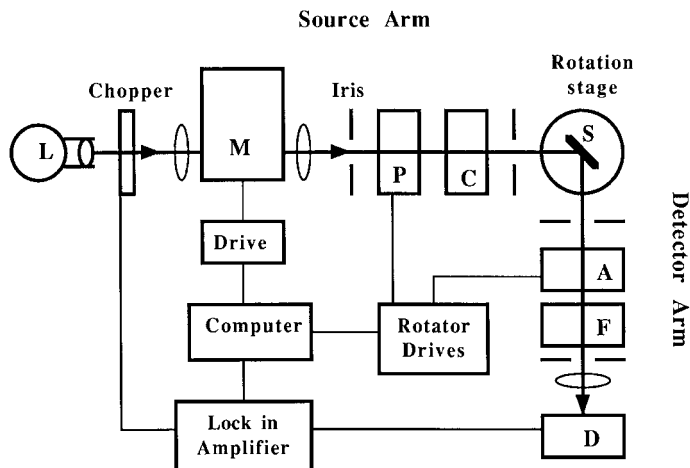

FIGURE 60.7 Schematic diagram of a PCSA reflection null ellipsometer, which is composed of five systems: the source system, polarimetric system, sample system, detection system, and computer system. The symbols are L = light source, M = monochromator, F = wavelength filter, and D detector. The symbols P, C, S, and A have their customary meanings.

the exit slit of M is collimated by another lens system and a set of iris apertures. The long-pass filter F in the detector arm is used with a grating monochromator to remove undesired short-wavelength radiation. Choices of monochromators include a grating monochromator, prism monochromator or Fourier transform spectrometer. A spectrometer is a necessary component for a spectroscopic ellipsometer. Synchrotron radiation is also a continuum source and is used to replace the lamp in the vacuum ultraviolet region [25]. The synchrotron radiation beam is intense and polarized. Grazing incidence reflection optics are usually used to avoid absorption in the components.

The polarimetric system shown in Figure 60.7 is a PCSA ellipsometer. For a PSA ellipsometer, remove the compensator C. For a PCSA system, add another compensator in the detector arm [20]. It is better to mount the polarizers and phase retarders on automatic rotators so that their orientations can be easily aligned and read. For simple experiments, manual rotators can also do the job. References 10 and 11 give detailed descriptions and references for different kinds of polarizers and phase retarders. Many of the well known optical companies sell polarizers and wave plates (retarders) for use in the visible, ultraviolet, and near infrared spectral regions. The Buyers Guide of Laser Focus World [49] and the Photonics Buyers' Guide [50] list companies that manufacture and sell polarizers, phase retarders and polarimeters. Tables 60.6 and 60.7 list some companies that make these products. Commonly used polarizers in the visible are Glan prisms and dichroic sheets or plates. The best polarizer in the visible is the calcite Glan-Thompson prism, which has a very small extinction ratio and a large acceptance angle. It is more difficult to find a good broadband polarizer in the mid-infrared spectral region (λ : 3 to 5 μm). Wire-grid polarizers are good in the long-wave infrared region ($\lambda > 8 \mu\text{m}$). For a broadband phase retarder, a Babinet-Soleil compensator is convenient, since it can be set to any retardance value using a micrometer adjustment. Inexpensive wave plates are good for laser sources. Phase modulation can be achieved by modulation of the birefringence of electro-optic or photo-elastic retarders.

The sample system depends on the type of experiment to be performed. Components on the detector side of Figure 60.7 are normally mounted on a rail that is rotatable about the axis of the rotation stage. The sample holder S on the rotation stage should have enough degrees of freedom for easy alignment. In a reflection ellipsometer, the x-axes for P, C, and A should be well aligned to lie in the plane of incidence. A transmission polarimeter is much simpler to align.

The detection system consists of a detector and a noise suppression system. Diode detectors for use in the visible and near-infrared spectral regions are inexpensive. Photomultipliers for the visible and

near-infrared regions have high sensitivity, and cooled semiconductor detectors give good performance in the mid-infrared to far-infrared regions. In Figure 60.7, the noise suppression system includes a chopper and a lock-in amplifier. The chopper modulates incident light intensity, and the intensity detected by detector D is demodulated by a lock-in amplifier. This combination eliminates most broadband noise and greatly improves the signal-to-noise ratio. RAE and PME have their own modulations, and do not need a chopper.

A computer system provides the automatic functions to control the polarizers, retarder, and monochromator, and to acquire and process data. A computer system is essential for making accurate and rapid measurements. In Figure 60.7, the computer records the polarizer angle P , the analyzer angle A , the intensity I from the detector, and the wavelength λ of the monochromator. The data of $I(P)$ and $I(A)$ can be used to find the null positions of P and A . Then the computer controls the drivers to move P or A to the null positions. In a spectroscopic RAE, data of $I(t)$ are recorded as the analyzer is rotating. The computer uses the FFT program to find the Fourier coefficients, solves for ψ and Δ , records the results, and then drives the monochromator to a new wavelength and repeats the process. A spectroscopic PME uses similar computer process as RAE, besides the different modulation and demodulation.

Measurement of Birefringence

Retardance can be measured using a transmission PSA ellipsometer. A wave plate is a good sample for this experiment. The retardance δ for a birefringent slab of thickness d and principal refractive indices n_e and n_o is

$$\delta = \frac{2\pi d(n_e - n_o)}{\lambda} \quad (60.43)$$

in the absence of multiple reflections. For a wave plate, the value of ψ is close to 45° , and the Δ value is equal to δ . Use a lamp source with a monochromator to scan the wavelength. Put a polarizer at 45° and an analyzer at -45° with respect to the fast-axis of the wave plate [40]. When λ is scanned, the transmitted intensity I through the PSA ellipsometer will vary, in proportion to $(1 + \cos\delta)$ according to Equation 60.35. I is a maximum when δ is 0° , and is a minimum when $\delta = 180^\circ$. From the wavelengths at which a maximum or a minimum intensity occurs, the birefringence $n_e - n_o$ can be determined.

Measurement of Optical Constants

A reflection ellipsometer can be used to measure optical constants n and k of materials. Light is incident obliquely on a sample at an angle of θ . The refractive index n and the extinction coefficient k can be calculated from the measured ψ and Δ values using the following formula [2, 4, 16, 22]

$$(n + ik)^2 = \sin^2\theta \left\{ 1 + \tan^2\theta \left[\frac{1 - \tan\psi \exp(i\Delta)}{1 + \tan\psi \exp(i\Delta)} \right]^2 \right\} \quad (60.44)$$

If an automated system is not available, try an NE to obtain ψ and Δ manually. Automated systems such as an RAE or a PME can take data much faster. For transparent materials, Δ is either 0 or π , the simple null polarimeter with a PSA system offers satisfactory results [22]. The method is effective near the Brewster angle region. At the Brewster angle θ_b , $\psi = 0$, then $n = \tan \theta_b$ according to Equation 60.44. For metals whose ψ is large when $\Delta = -90^\circ$, the principal angle ellipsometry (PAE) can be used [2]. At the principal angle θ_p , $\cos \Delta = 0$, Equation 60.44 can be simplified to

$$(n + ik)^2 = \sin^2\theta_p [1 + \tan^2\theta_p (\cos 4\psi + i \sin 4\psi)] \quad (60.45)$$

In PAE, the principal angle θ_p is searched and then ψ is measured. The Stokes polarimeter with a PSA system is suitable to search θ_p and measure ψ for PAE.

Determination of optical constants using reflection ellipsometry is subject to errors caused by surface roughness, natural oxides and surface contamination [15, 16, 41–48]. These effects can be corrected by assuming that there is an effective layer on the surface and then using a least-square regression method to fit the ellipsometric data to the appropriate model [16, 43–48]. Ellipsometry is also used to measure refractive index and thickness of a thin film on a bulk substrate whose optical constants are known [4,

15, 16, 27]. Other applications of polarimetry and ellipsometry can be found in recent proceedings about polarization [51–53].

Acknowledgment

The author would like to thank Dr. J. M. Bennett for her review of the original manuscript and her suggestions especially for the introduction. This work was supported partially by the “Polarizer Standard and Metrology Program” funded by the U.S. Naval Warfare Assessment Division.

61.1 Introduction

Light is electromagnetic radiation of wavelength about 450 to 700 nm, in which region the human eye is sensitive and refractive index measurements are commonly made. The refractive index or indices of a substance describe an important part of its interaction with electromagnetic radiation. Refractive index is a dimensionless quantity, real for transparent materials and complex if there is absorption. It generally depends on the direction of light relative to axes of the material; such substances, e.g. many crystals, are anisotropic and possess more than one refractive index. In general, the index is a tensor (3×3 matrix) with up to 9 components. Many substances are isotropic, e.g., liquids, glasses, and other noncrystalline materials, and one refractive index is sufficient. Some substances are optically inhomogeneous and possess refractive index fluctuations over distances comparable in size with a wavelength. They scatter light and appear milky or turbid. Many foodstuffs and drinks are optically heterogeneous. Refractometry is, fortunately, a robust technique in the face of material complexities. It has widespread application to many industries and materials. This chapter treats the refractive index as the principal measurand; the complications of real materials may require extra attention. Excluded are strongly absorbing materials such as metals in which absorption may be more important than refraction. The appropriate measurement technique is then ellipsometry, in which the amplitude and phase of the reflected light are measured, as the polarization and the angle of incidence are varied. Some refractometric methods are essentially ellipsometric, but for transparent samples transmission methods are also important. Refractive index measurements of high precision, e.g. 10^{-4} to 10^{-5} , are possible with relatively simple techniques. Although ocular instruments remain popular, semiconductor technology has been applied to refractive index measurement in recent years, improving the measurement speed and precision. One of the limits to improvement in precision is the sample's absorption or heterogeneity, a factor considered herein. Several online instruments exist, and the application of refractive index measurements to complex industrial fluids has been recently described [1]. Fiber-optical methods do not yet possess the precision of conventional methods but offer the possibility of remote sensing.

Refractive index is measured for many reasons. It is clearly important to know the refractive index of materials used for their clarity, such as glasses and solid plastics. In complex fluids such as drinks or foods, the refractive index is a measure of dissolved or submicronic material. The Brix scale relates refractive index to sugar concentration. Common industrial applications are to microemulsions to measure their oil/water ratio, to antifreeze to check the glycol/water ratio, and to inaccessible liquids such as the electrolyte of rechargeable cells [2]. The clinical applications of light have stimulated interest in biotissue refractometry [3], and refractometry is useful for the analysis of small samples of biofluids.

61.2 Physical Principles

The electromagnetic nature of light and the atomic origin of refraction are described herein only in enough detail to be useful to refractometry; detailed descriptions of them are readily found in optics textbooks [4].

Monochromatic light can be described as an electromagnetic radiation of frequency ν (Hz) and free-space wavelength λ_0 . In free space (vacuum), the phase velocity c_0 is given by $c_0 = \nu\lambda_0$. In a medium or material substance, the phase velocity changes to $c = \nu\lambda$, the refractive index n of that substance then being defined as $n = c_0/c$. As the frequency is unchanged by entering the medium, $n = \lambda_0/\lambda$. In an electromagnetic wave, the vibration directions of the electric and the magnetic fields are 90° apart, and both fields vibrate at 90° to the wave's direction of propagation. In transparent and nonmagnetic materials, refractive index is determined primarily by the interaction of the electric field of the wave with the permittivity ϵ of the medium. This quantity is written as $\epsilon = \epsilon_r\epsilon_0$, where ϵ_r is the relative permittivity of the medium, and ϵ_0 is the permittivity of free space being $10^7/(4\pi c_0^2)\text{F m}^{-1}$, or about 8.854 pF m^{-1} . In the wave theory of light, ϵ_r is determined by the strength of elastic interaction between the wave's electric field and the bound charges (electrons and protons) in the atoms and molecules of the medium. For nonmagnetic transparent materials, $n = \sqrt{\epsilon_r}$ can be shown if both quantities are measured at the same frequency, and this relation is also closely true if the absorption is weak. Absorption can be ascribed to the inelasticity of the interaction of the wave's electric field with the bound charges, some of the wave's energy being turned to heat during propagation.

The time (t) and distance dependence of the electric field E of a wave propagating in the z direction can be written

$$E = E_0 \exp i(\omega t - k_0 z) \quad (61.1)$$

where $\omega = 2\pi\nu$ = the pulsance or angular frequency, $k_0 = 2\pi/\lambda_0$ = the free-space wave number, and $i = \sqrt{-1}$. The field E in Equation 61.1 is complex, and the physical field is understood to be the real part of the complex one, i.e. $E = E_0 \cos(\omega t - k_0 z)$. The wave amplitude E_0 is the maximum excursion of E , both quantities being coparallel and normal to the direction of propagation z . The optical power per unit area (radiance) conveyed by the wave is proportional to $|E|^2$, or also $|E_0|^2$. The phase velocity c is given by ω/k , which the above relations show to be c_0/n . Waves in absorbing media are attenuated as z increases. This is described by a complex refractive index in Equation 61.1, i.e., writing $n = n' - n''$ so that the field oscillates in space and time as before, but decays exponentially with propagation distance z as $(-k_0 n'' z)$. The cause of the index n'' may be absorption, scattering, or both. It will be clear from context whether n refers to the real part of the complex quantity, or to the complex quantity itself. For the most part, this chapter deals with transparent or only slightly absorbing materials, where n'' is very small.

Equation 61.1 shows that n determines the phase of a wave, and this is the basis of the interferometric methods of refractometry, most used for either highly precise measurements on liquids or solids, or for gases where the refractive index is close to 1. Other common refractometric methods rely on the reflection or transmission of light at the interface between the sample and a material of known refractive index. Reflection and refraction of light at optically smooth interfaces are treated (Fresnel relations) in optics textbooks. A description follows that should suffice for the experimental refractometrist.

FIGURE 61.1 Light beams reflected (R) and transmitted or refracted (T) at the interface between two refractive indices, n_1 and n_2 , the second being greater than the first.

Simple laws apply to the incident, reflected, and transmitted beams at a planar interface between two transparent media. For brevity, we consider only isotropic media. A parallel-collimated incident light beam produces a parallel-collimated reflected and transmitted beam. All beams are coplanar and define a plane of incidence, which is orthogonal to the planar interface. The interface normal also lies in the plane of incidence. Figure 61.1 shows the incident, reflected, and transmitted beams in the plane of incidence. In the first medium, the angle of incidence and reflection made to the interface normal are equal; both θ_1 . The angle of transmission θ_2 into the second medium is given by Snell's law

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \quad (61.2)$$

where the subscripts refer to the first and second medium. If n_1 is known and the angles are measured, n_2 can be obtained.

Equation 61.2 is the basis of deviation refractometry, q, v .

If $n_1 > n_2$, Equation 61.2 shows that real angles of transmission do not exist for $\theta_1 > \arcsin(n_2/n_1)$; i.e., θ_2 is imaginary. The incident and reflected beams are then of equal power, transmitted light is absent, and the reflection is said to be total. However, although in the second medium no wave propagates, there is an evanescent wave close to the interface, which is nonpropagating and therefore transmits no power. The critical angle is given by

$$\theta_c = \arcsin\left(\frac{n_1}{n_2}\right) \quad (61.3)$$

(See Figure 61.2.) Reversing the light direction, Figure 61.3 shows that a beam traveling parallel to the interface in the least refractive index medium enters the second medium at a transmission angle also given by θ_c . A full analysis (Fresnel's equations) shows that, in the region of the critical angle, the reflected or transmitted optical power changes very rapidly with angle of incidence. If there is no absorption, there is actually a discontinuity of reflected or transmitted radiance at θ_c . This makes θ_c easy to measure accurately and gives the critical angle or Abbe method of refractometry used by most commercial refractometers.

FIGURE 61.2 Total reflection at the critical angle of the incident beam (I) in the first medium of greater refractive index than the second. No light is transmitted into the second medium for angles exceeding the critical angle.

FIGURE 61.3 Total refraction of incident beam (I) transmitted as beam T into the medium of lesser refractive index at the critical angle. No light exists for angles in the second medium bigger than the critical angle.

The Fresnel laws of reflection at a plane interface between two media show that if the incident light is linearly polarized with its electric field in the plane of incidence, then there is no reflected light at the Brewster angle θ_B given by

$$\theta_B = \arctan\left(\frac{n_2}{n_1}\right) \quad (61.4)$$

FIGURE 61.4 Light incident in the first medium at the Brewster angle, and polarized with its electric vector parallel to the plane of incidence, is transmitted (T) wholly into the second medium with zero reflection R.

(See [Figure 61.4](#).) Measurements of θ_B , usually in air (n_1 close to 1), will give n_2 . The reflected optical power is zero at θ_B and it increases approximately quadratically for angles below and above θ_B . Consequently, the Brewster angle method is regarded to be of lower precision than the critical angle method, and so is relatively less used. However, unlike the critical angle method, it does not require a reference medium of higher refractive index than the sample.

If the sample is a finely divided particulate solid or has an irregular interface, none of the preceding methods is useful. Fresnel's equations show the reflectance of any shape of interface to be zero if the refractive index difference across the interface is also zero. In the method of refractive index match, the turbidity or scattering from a cloud of particles suspended in a liquid is measured, and the refractive index of the liquid is found, which gives minimum turbidity or scattering. The liquid should not swell or interact with the interior of the solid.

61.3 Techniques

Interferometry

The sample, with parallel input and output faces, is put in the sample beam of a two-beam interferometer (e.g. Rayleigh, Michelson, or Jamin). From Equation 61.1, a sample of length z and refractive index n causes a phase lag of $2\pi n z / \lambda_0$, compared with $2\pi n_{\text{air}} z / \lambda_0$ for the reference beam in air. The phase difference between the two beams is thus

$$\delta = \frac{2\pi z(n - n_{\text{air}})}{\lambda_0} \quad (61.5)$$

The refractive index of air is 1 for approximate purposes, or is known more precisely [5]. Sample insertion causes a step increment of δ in the phase difference, which is measured by adjusting a calibrated phase compensator in the reference beam to regain the zero-order fringe of white-light fringes. Equation 61.5 enables n to be calculated. For gaseous samples, use of the compensator may be avoided by allowing the gas to enter an initially evacuated tube with rigid and parallel window faces placed in the sample beam. As the gas enters slowly, the interference fringes passing a fiducial mark may be counted. Each whole fringe corresponds to a change in δ of π radian. The refractive index of a gas depends, through its density, on pressure and temperature. The number of fringes between a vacuum ($n = 1$) and the gas at a given pressure and temperature will then give the gas refractive index.

In interferometry, the effect of optical attenuation (via absorption or scattering) by a sample of complex refractive index decreases the fringe brightness but does not affect the phase. Thus, only the real part the complex refractive index is measured.

About 0.1 of a fringe can be judged by eye; electro-optic methods can measure 10^{-6} of a fringe. The method's potential precision is very high. However, an interferometer is delicate and expensive, and good sample quality (homogeneity, face parallelism) is necessary. A difference in dispersion (wavelength dependence) of the sample and compensator refractive index can be a problem. For a sufficiently large number of fringes, the dispersion difference between the sample and compensator can make the white-light fringe pattern and zero-order fringe invisible [6]. One solution is to use a compensator more closely matched to the sample dispersion. A cheaper option is to reduce the sample length, with some loss of precision. A major use of the interference method is for gases, where $n - 1$ is about 1000 times less than $n - 1$ of solids and liquids. It is also used in solution differential refractometry, e.g. to measure the concentration in the eluted solvent relative to the pure solvent. A stable folded Jamin interferometer for refractive index measurements is described by Moosmüller and Arnot [7]. Liquid refractive index measurements using a Michelson interferometer are described by Richerzhagen [8].

Deviation Methods

Lateral and angular deviation methods make use of Snell's law (Equation 61.2). The incident beam is usually in air, of refractive index n_{air} .

FIGURE 61.5 Lateral deviation l of a light beam on passage through a parallel-sided refractive sample slab of thickness L .

Lateral deviation l occurs for a beam of light transmitted through a parallel-sided sample of thickness L (see Figure 61.5). If the incident angle is θ_{air} , Snell's law (Equation 61.2) gives

$$\frac{n}{n_{\text{air}}} = \left[1 + \left(\frac{\cos \theta_{\text{air}}}{\sin \theta_{\text{air}} - \frac{l}{L}} \right)^2 \right]^{\frac{1}{2}} \sin \theta_{\text{air}} \quad (61.6)$$

If θ_{air} and L can be measured the most accurately, the precision of the method depends on the accuracy of measuring l . Modern electro-optic beam-displacement detection devices permit a precision of a few micrometers in l , giving a typical precision in n of about 0.001. The lateral deviation method is suitable for samples in sufficiently thick sheet form.

In the angular deviation method, parallel-collimated light is incident on one face of the sample of refractive index n in triangular prism form with vertex angle A , the vertex line of the prism being normal to the plane of incidence (see Figure 61.6). The exit beam deviates angularly from the direction of the incident beam. At the angle of minimum deviation D , the analysis is simplest Equation 61.1, showing that

$$\frac{n}{n_{\text{air}}} = \frac{\sin\left(\frac{A+D}{2}\right)}{\sin\left(\frac{A}{2}\right)} \quad (61.7)$$

For $A = 60^\circ$, a 1 minute ($1'$) uncertainty in D gives 0.0003 for the corresponding precision in n . Angular deviation requires the sample to be a less convenient shape than the parallel-sided sheet of the lateral deviation method. However, measurements of D and A can be made simply using an ocular goniometer. Lateral or angular deviation methods can be applied to liquid samples in a suitable cell with walls having parallel sides. Such cell walls will, however, give some lateral deviation but not cause angular deviation if used to make a hollow prism to contain a liquid sample. In the Hilger-Chance angular deviation

FIGURE 61.6 Angular deviation D of a light beam on passage through a prism of vertex angle A . If the interior beam forms an isosceles triangle with A at the vertex, then D is the angle of minimum deviation.

refractometer [9], the liquid sample is contained in a glass 90° V-block of refractive index n_{glass} , with parallel outer faces. A parallel-collimated light beam incident normally on one outer face of the block suffers angular deviation D (not minimum), Equation 61.2, giving

$$n^2 = n_{\text{glass}}^2 + (n_{\text{glass}}^2 - \sin^2 D)^{\frac{1}{2}} \sin D \quad (61.8)$$

For a $1'$ uncertainty in D , the precision in n is about 10^{-5} . Solid samples can be measured by coupling a prism of the sample into the V-block using a thin film of liquid of refractive index intermediate between that of the sample and the prism.

Critical Angle Method

In the region of the critical angle, Fresnel's equations show that the transmitted or reflected optical power varies discontinuously with angle. Thus, θ_c is accurately measurable and a refractive index precision of about 10^{-4} to 10^{-5} is obtained. Liquid samples are placed directly onto one face of the refractometer prism of known refractive index. Solid samples need only one face to be flat and optically polished, which is coupled to face of the refractometer prism using a liquid film of intermediate refractive index. For a transparent sample, either the transmission or the reflection mode can be used, as θ_c is the same for both (see Figures 61.2 and 61.3). In the transmission mode, the sample–prism interface is illuminated diffusely through the sample, the critical angle then being the largest angle of transmission in the prism. In the reflection mode, useful for highly scattering or absorbing samples, the prism–sample interface is illuminated diffusely from within the prism. The critical angle is then where the reflectance changes discontinuously with angle of reflection within the prism, being total for $\theta \geq \theta_c$. In the transmission mode, the transmittance from the sample into the prism is zero for $\theta \geq \theta_c$ and finite for $\theta \leq \theta_c$ whereas, in the reflection mode, typically a few percent of the light is reflected for $\theta \leq \theta_c$, and 100% is reflected for $\theta \geq \theta_c$. If the interface is illuminated with diffuse light, the transmission mode gives a dark–bright contrast at the critical angle, with a dim–bright contrast for the reflection mode. For ocular observation, this difference can make the transmission method preferable. Automatic instruments invariably use the reflection mode, this being necessary for samples that attenuate by absorption or scattering. For such samples, however, the discontinuity of reflectance is replaced by a continuous function with a maximum gradient at an angle θ_{max} that differs increasingly from θ_c as the sample becomes more absorbing [10–12]. A separate measurement of the absorption index is required before θ_c can be obtained from θ_{max} . Attempts to improve the precision of critical angle refractometry of nontransparent samples are expected to become increasingly limited by this effect.

The critical angle method, however, is robust and simple to use. Despite the problems associated with optically attenuating samples, it is likely to persist as the preferred method in commercial refractometers.

Brewster Angle Method

Here, the angle of reflection θ_B is measured for which there is no linearly polarized light reflected from the sample surface. Equation 61.4 then gives the sample refractive index, where n_1 is the refractive index of the medium containing the incident and reflected light, usually air. The light is polarized such that its electric field vector vibrates parallel to the plane of incidence (see Figure 61.4). A linearly polarized laser is a suitable source of monochromatic light. Nonpolarized sources require polarizing with a Glan-Thomson prism or a quality dichroic polarizer. With a 1 mW HeNe laser and ocular judgement of the minimum reflectance, a precision in θ_B of about 0.1° can be obtained, giving a precision in the sample refractive index of about 0.005. Precision improvement by factors of 10 to 100 can be expected if photometric analysis replaces the eye. The Brewster angle method is then comparable in precision to the critical angle method. Unlike the critical angle method, however, it does not require a reference material of higher refractive index than the sample. If the sample is absorbing, the reflectance zero at θ_B is replaced by a reflectance minimum at an angle θ_{\min} . It can be shown that a given absorption produces less error in the Brewster angle method than in the critical angle method [6, 12]. Despite these good features of the Brewster angle method, a commercial Brewster angle refractometer is not known to this author.

Index Match Method

The refractive index match method does not require the sample to be in any special shape or form. Thus, it might be finely divided, i.e., a powder. Assuming the particles to be isotropic and homogeneous, then the reflected radiance, the angular or lateral deviation, and the relative phase shift of transmitted light all become zero at refractive index match. If the sample is absorbing, the refractive index of the surrounding liquid which gives the minimum visibility still gives closely the real part of the sample's refractive index. Similarly, if the sample is heterogeneous or anisotropic, the method gives the average refractive index of the sample. The liquid should not dissolve, permeate, or react in any way with the solid sample.

For macroscopic samples a precision of about 0.005 in n has been estimated [6] from the index-match method, where a simple ocular estimation of match is employed. For a matching liquid of refractive index n_{liq} , the reflectance from an interface varies approximately as $(n - n_{\text{liq}})^2$. This quadratic dependence makes the sensitivity of the method decrease as the match is approached, and makes it difficult in practice to judge whether n_{liq} should be increased or decreased to improve the match.

Microscopy and Scattering Methods

The refractive index of individual particles large enough to image in a microscope can also be measured by the index-match method. Central or oblique illumination modes can be used corresponding to the Becke, and Schroeder-Van der Kolk methods, respectively, which utilize null deviation at refractive index match. A precision of 0.0002 in n is quoted [13] for the Becke line method. Whether n_{liq} is lesser or greater than the sample's refractive index n is shown by the appearance of the image.

The phase difference between light transmitted through and around the particle is proportional to $n - n_{\text{liq}}$, so that the phase changes sign each side of match. This is used in measurement of refractive index of particles by phase-contrast or interference microscopy, in which the image is brighter or darker than the background according to whether $n > n_{\text{liq}}$ or $n < n_{\text{liq}}$. These methods can measure the refractive index of particles below the conventional resolving limit, as the details of an object need not be fully resolved in order to discern match or otherwise. Users of microscopy in refractometry should refer to texts on phase-contrast and interference microscopy. Newer forms of optical microscopy (e.g., scanning confocal) have greater resolving power and can be used for refractive index matching of finer particles.

For a suspension of particles smaller than about $1 \mu\text{m}$, the optical turbidity and light scattering are zero at refractive index match, leading to turbidimetric or nephelometric methods of measuring the

particle refractive index. For particles of colloidal size, it is important to avoid aggregation or flocculation, and suspension destabilization. Thus, chemical restrictions can preclude the attainment of match, particularly if the particle's refractive index is large compared with n_{liq} . In such cases, the turbidity E is measured for changes in n_{liq} which do not destabilize the suspension, and the value of n_{liq} is found by extrapolation to $E = 0$. Extrapolation to obtain this value of n_{liq} is difficult unless the experimental parameters can be arranged to have a linear relation. Theory and experiments described by Griffin and Griffin [14] showed that linearity is obtained if $n_{\text{liq}}\sqrt{E}$ is plotted versus n_{liq} .

Anisotropic and Heterogeneous Materials

If a plane face is made from a general optically anisotropic sample, and this face is then offered to the prism of a critical angle refractometer, two critical angles can be simultaneously observed. One can be enhanced over the other through the use of a linear polarizer rotated in the incident or refracted light path. The interpretation of these critical angles, in the general case, is not simple, and the reader is referred to analyses [15–17]. Similar complexity is visited upon the Brewster angle method if the sample is anisotropic, and again the reader is referred to Reference 6 for works on ellipsometry.

Highly turbid samples, such as polymer latexes and other concentrated colloidal fluids, have been investigated using the critical angle method [1, 18–20]. It appears that if the particle size is less than about half a wavelength, the critical angle method remains successful for volume fractions up to at least 0.5. For high concentrations of larger particles, there is a rapid degradation of the reflectance or transmittance discontinuity at the critical angle. This angle is replaced by a region where the reflectance or transmittance may vary in an unexpected way as the particle size and concentration increase.

The effect of heterogeneity on the reflection of polarized light, and on the Brewster angle, is also affected by sample heterogeneity [21, 22]. Whereas for a homogeneous sample the parallel-polarized reflectance at the Brewster angle is zero, the effect of sample heterogeneity on the wavelength scale is to cause finite reflectance. Comparison of the Brewster angle and the critical angle methods for heterogeneous materials awaits investigation.

Gate and coworkers have measured the refractive index of emulsion paint films [23] and coated paper [24] by a non-Brewster angle reflection method. Both materials were strongly heterogeneous on the wavelength scale and so (in air) had a strong nonspecular or diffuse reflectance. Some specular reflection remained, however, and the method derives the refractive index of the surface of the film from the ratio of the specular reflectances at a non-Brewster angle for polarizations parallel and normal to the plane of incidence.

The application of refractometry to heterogeneous and absorbing samples is clearly a developing art and, although it is clear that refractometry offers valuable information, the refractometrist should use existing instruments critically.

61.4 Review of Refractometers

The author's initial review of refractometer manufacturers revealed about 30 companies, and the true number may be more than 50. A very large number of general- and special-purpose instruments are offered by each company, e.g., 31 different models by the Atago Co., Ltd. It is clearly not possible to review, compare, and advise on individual models. The aspiring refractometrist should do this according to needs and budget. The generalities that follow should assist.

Most instruments use the critical angle (or Abbe) method. They thus have a prism of known refractive index with a face to which the sample is offered. The larger manufacturers offer three types of critical angle instrument:

1. The portable hand-held models, which require no power or battery and are customized and calibrated for Brix (sugar), urine, antifreeze, cutting oil, etc. Their refractive index precision is typically between 10^{-3} and 10^{-4} , but their range is small owing to their particular application. The user looks into an eyepiece and reads a scale on which is superposed the dark–light boundary

caused by transmission or reflection in the region of angle each side of the critical angle; often termed the critical edge. The price varies greatly between models and manufacturers, typically U.S. \$200 to \$400.

Some manufacturers offer a digital readout portable models, of similar weight (less than 1 kg) and precision, and battery powered. These cost roughly U.S. \$1000 to \$2000.

2. The laboratory (Abbe) refractometer, which has a refractive index precision of typically 10^{-4} to 10^{-5} and covers a wide range of refractive index, typically 1.3 to 1.75 in a low refractive index instrument, and 1.4 to 1.85 in a high refractive index model. Such instruments are calibrated so that the temperature can be varied using an external liquid bath, and the wavelength can be varied using external light sources. Very roughly, their weight, cost, and precision are about 10 times that of the portable instruments in (1) above. They require the user to estimate the position of the critical edge on a graduated scale viewed through an eyepiece.
3. The digital refractometer. Compared with those in (2) above, these have similar precision and general facilities, a cost typically a few times greater, but with the advantage of a digital or electronic readout of the data. The upper refractive index offered by several manufacturers appears to be restricted to about 1.55.
4. The process refractometer is a version of those described in (3) above, but where the prism is mounted to contact a fluid in a reactor or a pipe, and viewed via a fiber-optic cable. Thus, high pressures and temperatures can be accommodated. The prism is usually of sapphire to avoid wear of the optical face, and the precision generally tend to be somewhat lower than those described in (2) and (3) above.

62.1 Introduction

For nearly 50 years, turbidity measurements have been used to perform a wide variety of physical measurements. These include the determination of particle concentration per unit volume when the scattering cross-section per particle is known, the determination of particle size (scattering cross section) when the concentration of particles is known [1–3], and the determination of some of the critical exponents associated with second-order and nearly second order phase transitions [4–7].

The basic ideas necessary to understand turbidity measurements are fairly simple. In the absence of reflection losses, when a weak beam of light passes through a dielectric sample, the two processes most responsible for reducing the intensity of the transmitted beam are absorption and scattering. The reduction in transmitted light intensity due to scattering is called the sample's turbidity. Extinction includes the effects of both absorption and scattering. The Beer-Lambert or Lambert law describes the effects of both absorption and turbidity on the transmitted intensity. This law is written as

$$I_T = I_0 \exp-(\alpha + \tau)l \quad (62.1)$$

where I_T = intensity of the light transmitted through the sample, I_0 = intensity of the light incident on the sample, α = absorption coefficient per unit length, τ = turbidity per unit length, and l = length of the light path in the sample. As discussed below, it is more correct to use powers rather than intensities, thus this equation should be written as:

$$P_T = P_0 \exp-(\alpha + \tau)l \quad (62.2)$$

The most general situation is to have an absorbing medium with absorbing and scattering particles embedded within it; however, the focus here is on the simpler case of nonabsorbing medium and consider the two most common cases: nonabsorbing particles in medium and scattering caused by fluctuations in the medium itself.

Instruments generally fall into two categories: commercial and laboratory constructed. The commercial units are of two general types: (a) attachments to spectrophotometers, and (b) white-light turbidity meters, which operate under ambient conditions. Anyone interested in the former should consult the catalog of accessories for the instrument in question. Those interested in the latter should check under “nephelometers” in scientific supply catalogs. Units of this type perform their designed function admirably and probably are sufficient for routine work. However, they may need modification for the more specialized measurements performed in many research laboratories. For this reason, it is common to construct special laboratory instruments. These come in at least two types, most commonly either single-beam or dual-beam instruments. The single-beam instrument usually has an intensity-stabilized light source, whereas the dual-beam instrument corrects for drift in the light source and reflection losses by either electronically or mathematically taking the ratio of the transmitted light power and a reference beam power.

The balance of this chapter is divided into three parts. The first part briefly discusses the physical basis of turbidity measurements and demonstrates how such measurements may be used to infer the scattering cross section of the particles in the solution or the concentration of the scatters in the solution. The second section discusses turbidity of pure fluids and shows how certain critical exponents may be determined from such measurements. The last section discusses laboratory instruments and the relative trade-offs involved in such instruments.

62.2 Extinction and Turbidity: Particles in a Nonabsorbing Medium

Suppose that electromagnetic radiation is incident upon a slab of medium consisting of randomly positioned particles and that the transmitted radiation is detected as shown in Figure 62.1. For the present discussion, assume that the source and detector are in the medium. The radiation that is received by the detector will be less than that incident on the slab because of the presence of the particles in the medium—the particles have caused extinction (or attenuation) of the beam. The extinction of the radiation depends on two physical processes, scattering and absorption, whereas the turbidity depends only on scattering. In scattering, there is no change in the total energy of the radiation; rather, some of

FIGURE 62.1 Idealized experiment indicating the physical basis of turbidity.

the incident radiation is redistributed away from the incident direction. In absorption, some of the energy of the incident beam is transformed into other energy forms. This extinction of the beam is rather complicated; it will, in general, depend on the chemical composition, size, shape, number, and orientation of the particles; the chemical composition of the medium; and the frequency and polarization of the incident radiation [2,3].

In discussions of scattering one often focuses on the *cross sections*, C_i , of the particles. On the basis of conservation of energy one must write:

$$C_{\text{ext}} = C_{\text{scatt}} + C_{\text{abs}} \quad (62.3)$$

where C_{ext} , C_{scatt} , and C_{abs} = cross sections for extinction, scattering, and absorption, respectively. These cross sections all have the dimension of area, and in all cases a larger cross section (area) indicates a larger effect, and a smaller cross section a smaller effect. In general the cross section will depend on all the intensive quantities that describe the extinction. Finally, note that for nonabsorbing media, $C_{\text{abs}} = 0$.

To see how this relates to the measured turbidity, assume now that the medium is nonabsorbing, that all the particles are nonabsorbing and have the same scattering cross section (C), and that there are n of these particles per unit volume. Then, one obtains the following expression for the transmitted light power:

$$P_T = P_0 \exp(-nCl) \quad (62.4)$$

where P_T = transmitted power, and P_0 = incident power. We have switched from intensity to power because power is the quantity detected, and power is independent of the details of the spatial distribution of electromagnetic radiation. Upon noting this change and comparing this to Eq. 62.2, when $\alpha = 0$, it is clear that the turbidity can be expressed as

$$\tau = nC \quad (62.5)$$

Thus, a measured turbidity can be related to C_{scatt} if n is known, or n may be determined if C_{scatt} is known. The difficulty is then in determining C_{scatt} . There are a number of approaches that can be used. For well characterized particles, theoretical expressions may be determined [2]. In the absence of such theory, measurements may be made as a function of concentration and then, since $\tau = nC$, C may be determined. The generalizations to account for nonmonochromatic beams and extinction by a collection of noninteracting particles of the same type but different sizes are straightforward. The simplest generalization to include different sizes assumes that there is one parameter, ζ , that describes the distribution of particle size and the corresponding C_{scatt} [1]. That is, let $C_{\text{scatt}}(\zeta)$ be the scattering cross section for a particle characterized by the parameter (for instance, radius) ζ , and let the number per unit volume with parameter between ζ and $\zeta + d\zeta$ be $N(\zeta)d\zeta$, such that

$$n = \int_0^{\infty} N(\zeta) d\zeta$$

Then

$$\tau = \int_0^{\infty} C_{\text{scatt}}(\zeta) N(\zeta) d\zeta \quad (62.6)$$

A similar integral exists when the incident radiation is not monochromatic, but, in this case, the average is over the wavelength variation of the incident radiation.

62.3 Turbidity Due to Density Fluctuations in Pure Fluids

It is well known that even in very pure and well filtered liquids, in which there are essentially no particles, there is still some reduction in the detected power due to scattering [3]. The explanation is that there are always thermal fluctuations in the dielectric constant of the media, ϵ , and it is these fluctuations from the mean dielectric constant that lead to the scattering of light. Through application of thermodynamic and statistical mechanical principles [3], the following expression for the turbidity results:

$$\tau = \frac{8\pi^3}{2\lambda^4} \left[\rho \left(\frac{\partial \epsilon}{\partial \rho} \right)_T \right]^2 kT \beta_T \quad (62.7)$$

where ρ = density, ϵ = dielectric constant, k = Boltzmann's constant, T = absolute temperature, λ = wavelength of the incident light, and β_T = isothermal compressibility. Near a second order phase transition the fluctuations become correlated over larger distances, and this expression must be generalized to include the effects of this increase in the *correlation length*, ξ . In this case the turbidity is given by [5]

$$\tau = A\pi\beta_T \left[\frac{2\alpha^2 + 2\alpha + 1}{\alpha^3} \ln(1 + 2\alpha) - \frac{2(1 + \alpha)}{\alpha^2} \right] \quad (62.8)$$

where

$$A = \frac{\pi^2}{\lambda^4} \left[\rho \left(\frac{\partial \epsilon}{\partial \rho} \right)_T \right]^2 kT \quad \text{and} \quad \alpha \equiv 2 \left(\frac{2\pi n \xi}{\lambda} \right)^2$$

where n is the (mean) index of refraction of the fluid. Both the isothermal compressibility and the correlation length exhibit approximate power-law behavior of the form

$$\beta_T, \xi \sim \left(\frac{T_c - T}{T_c} \right)^{-x_i} \quad (62.9)$$

near these phase transitions. Thus, a measurement of $\tau(T)$ allows the determination of the critical exponents, x_i , and the values of β_T and ξ far from the phase transition. This technique has been generalized to binary liquid mixtures, liquid crystals, and other systems. In these cases, the isothermal compressibility is replaced by the appropriate generalized susceptibility. There are also, in some cases, small corrections to the above expressions. These can also be found in References 8–10.

62.4 Design of Laboratory Instruments

When more exact measurements are required than can be obtained using commercial instruments, and other enhancements such as mK temperature and/or pressure controlled sample chamber are required, it is common to construct a turbidity instrument. There are basically two types of instruments (single-beam and dual-beam). With both types of instruments, both ac and dc detection schemes are possible. Generally, the long-term time stability of synchronous ac detection techniques is superior to dc techniques. This section discusses all of these techniques.

Single-Beam Instruments: Optics

The basic optical design of a single-beam instrument is shown in [Figure 62.2](#). The light source is a low power (1 to 5 mW) vertically polarized He-Ne laser. It is important to use a polarized laser. The

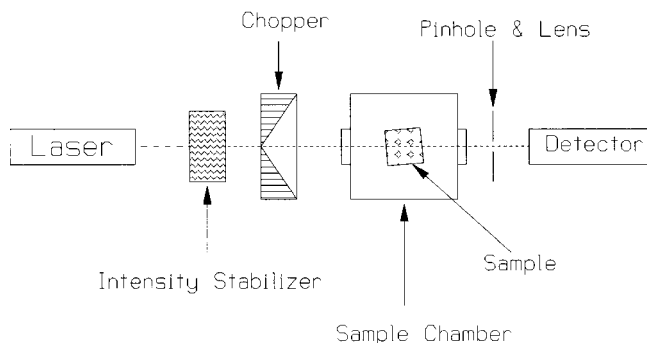

FIGURE 62.2 Block diagram of the optics for a single-beam turbidity apparatus.

polarization direction of an unpolarized laser wanders, and this can lead to time-dependent reflection coefficients from the various surfaces in this instrument, and hence reduced performance. The beam passes through a laser intensity stabilizer. This device reduces long-term drift in the laser power to ≤ 0.1 percent, thus allowing single-beam operation. Table 62.1 shows several commercial intensity stabilizers. To reduce any possible heating of the sample due to absorption, the beam is then passed through a neutral density filter, which attenuates the beam further to a level of 50 to 100 μW . The next item in the beam line depends on the detection scheme. For ac operation a light chopper is inserted into the beam line, while for dc detection nothing else is required before the sample. An output from the chopper is used for synchronous detection. The sample chamber then follows. This chamber requires an input and an output port and a design that precludes interference of any beam with other reflected beams. Other design details are determined by the materials to be studied and any required external factors that are to be controlled. After the beam has been transmitted through the sample, it passes through either a pinhole or a lens-pinhole combination [11, 12]. This results in a small angle of acceptance for the detector which, in turn, reduces the scattered light at small angles from the transmitted beam that reaches the detector. A detector then completes the optical train. For most applications, a *pin* photodiode is an excellent, inexpensive detector; however, in some applications, other types of detectors may be superior.

Single-Beam Systems: Electronics

For both synchronous and dc detection, the output of the photodiode, which is a current device, must be transformed into a voltage using a current-to-voltage converter (CVC). It is important not to use just a resistor for this function. The simplest workable current-to-voltage converter uses an FET-input operation amplifier such as an LM-11 and one resistor. The circuit, also known as a transimpedance amplifier, is standard and can be found in many sources [13].

When dc detection is used, the output voltage from the CVC is read on a voltmeter. The relationship between this voltage and the turbidity will be discussed below. The stability of dc operation is greatly improved by maintaining the photodiode and the electronics at a stable temperature. The drifts in detector

efficiency and in component values associated with temperature changes can limit the accuracy of the instrument. Furthermore, the detector must be shielded from stray light, which means the instrument must be operated in a darkened room or under a light tight cover. Such covers may cause excessive heating of the laser and the system. A “spike” filter that passes the wavelength of the laser may also assist in solving this problem.

When synchronous ac detection is used, the output from the CVC is the input to a lock-in amplifier which is synchronized to the chopper. Commercial units are available and can be used. One can also construct a simple lock-in using an Analog Devices AD-630 balanced modulator/demodulator, a phase shifter to ensure that the reference signal and the transmitted signal are in phase, and an RC filter. The output voltage from the RC filter is then read with a dc voltmeter. The necessary wiring diagrams are available from Analog Devices [14]. Synchronous detection has the advantage of having lower $1/f$ noise than dc circuits. Also, synchronous detection can discriminate against signals not synchronized with the reference, and hence offers much greater immunity to room lights and other stray light sources. The advantages of such detection are discussed elsewhere [13, 15].

Single-beam techniques are most useful for measuring changes in turbidity. To see this, note that the voltage output from the current-to-voltage converter or the lock-in, V_t , is given by $V_t = AP_T$, where A is an instrument constant that includes factors such as current-to-voltage gain, light power level to current conversion in the photodiode, reflection losses from the various interfaces, incident light power, gain of the lock-in, and so on. Now, P_T is given by Equation 62.2, hence V_{dc} , the measured dc voltage may be written as:

$$V_{dc} = B \exp(-(\alpha + \tau)) \quad (62.10)$$

where $B = AP_0$ is another constant, and we have included absorption. B may be determined by putting a solution of known extinction in the instrument and solving Equation 62.10 for B . Then, knowing l , α , B , and V_{dc} , the turbidity may be found by solving Equation 62.10 for τ , that is

$$\tau = \frac{1}{l} \ln\left(\frac{V_{dc}}{B}\right) - \alpha \quad (62.11)$$

This technique is rather limited if a large number of different samples must be compared. For a given sample, the change in turbidity is easily measured as a function of externally controlled parameters. However, putting samples into and taking them out of the instrument usually produces small random errors that slightly change the instrumental constant A and degrade performance. In some cases, the difference in turbidity between two samples may be small and result in a situation in which one must deal with a small difference of large numbers. This situation may be rectified using dual-beam instruments.

Dual-Beam Instruments: Optics

The optical design of a dual-beam, two-detector instrument is shown in [Figure 62.3](#). The first several parts of the optical train are the same as for the single-beam instrument, and the same comments apply in this case. The first real difference is that there need not be an intensity stabilizer in the dual-beam system. However, inclusion of the intensity stabilizer may improve system performance. The second difference is the inclusion of a beam splitter which splits the laser beam into two parts. We have found that a microscope slide works well as a beam splitter [16]. One of these beams (usually the reflected beam) becomes a reference beam that passes through a reference sample. The other passes through the sample as in the single-beam instrument. The beams from these two paths go through lens-pinhole combinations and fall on detectors. All of the comments that apply to the single-beam instrument also apply here. The associated electronics are also identical. Once more, both dc and ac detection may be used. Experience in our laboratory shows that the best results are obtained when the sample signal is

FIGURE 62.3 Block diagram of the optics for a dual-beam, two-detector turbidity apparatus.

simultaneously divided by the reference signal using an integrated circuit divider. A modification that uses two beams and one detector is shown in Figure 62.4. This modified design eliminates the need for absolute stability of two separate detectors but requires somewhat more complex optics.

The following analysis assumes that the measured output is the ratio of the sample signal voltage to the reference signal voltage. Let the voltage output from the detector's CVC be V_{sig} , and the voltage output of the reference signal detector's CVC be V_{ref} . Then

$$V_{sig} = AP_T \quad (62.12)$$

and

$$V_{ref} = CP_R \quad (62.13)$$

where A and C = instrumental constants totally analogous to the instrumental constant A above, and P_R = the power of the reference beam at the detector. It is important to realize that A and C are constant, but they need not be identical. The output voltage ratio, V_{out} is given by:

$$V_{out} = \frac{V_{sig}}{V_{ref}} = \frac{AP_T}{CP_R} = D \frac{P_T}{P_R} \quad (62.14)$$

where $D = A/C$ is a constant. Note that, in this arrangement, common multiplicative noise on the two voltages will tend to cancel out. Now P_T can be replaced by Equation 62.1, and P_R is given as

FIGURE 62.4 Block diagram of the optics for a dual-beam, one-detector turbidity apparatus.

$$P_R = f * P_0 \exp -(\alpha_R + \tau_R) l_R \quad (62.15)$$

where α_R = absorption, τ_R = turbidity of the sample in the reference beam, l_R = thickness of the sample in the reference beam, and f is a constant determined by the beam splitter. Then, assuming that l_R is the same as l the following expression results:

$$V_{out} = D \frac{P_0 \exp -(\alpha + \tau) l}{f * P_0 \exp -(\alpha_R + \tau_R) l} \quad (62.16)$$

and thus:

$$\tau = - \frac{1}{l} \ln \left(\frac{V_{out}}{D'} \right) + \tau_R - \alpha + \alpha_R \quad (62.17)$$

where $D' = D/f$. Often, this can be considerably simplified when the reference sample is a pure liquid because then τ_R is of order 10^{-5} , and α_R is totally negligible. Normally, the reference sample is chosen so that its optical properties approach those of the sample in the case where the concentration of particles is low or the system is far from a phase transition. The constant D' may be determined by using the same sample in both the reference and the signal arms of the instrument—in this case $V_{out} = D'$.

Dual-Beam Instruments: Electronics

The electronics for dc detection consists of two CVC converters, one for each detector. The voltage outputs from these may be read directly. However, experiments indicate that greater stability is achieved by simultaneously dividing these two signal outputs as discussed above. In our laboratory, this is accomplished using an Analog Devices AD-532 internally trimmed integrated circuit divider. These can be purchased with different accuracies. In the present application, they typically perform slightly better than the factory specifications indicate. The circuit details are available from Analog Devices [17].

The electronics for ac detection generally consist of two synchronous detectors followed by division of the sample signal by the reference signal. Once more, this may be accomplished using two Analog Devices AD-630 balanced modulator/demodulators or two commercial lock-in amplifiers. Division can be accomplished in the same way as in the dc technique section.

62.5 Limitations

Highly turbid samples, which transmit very little light, may be difficult to measure using a photodiode. In such cases, the photodiode in the sample arm may be replaced with a photomultiplier (PM). In this case, a chopper can be used to reduce the effects of the dark signal from the PM. The outputs, when the signal is present and when it is blocked, are both measured and averaged (preferably digitally), and the difference is computed. By counting for a fixed number of reference counts (requiring another PM), drift in the source may be eliminated. A Stanford Research Instruments photon counter [18] may be configured in this mode. Furthermore, unless extreme precautions are taken in this situation, erroneous results may occur because the scattered power is as large or larger the transmitted beam power.

63.1 Introduction

A laser is a device that emits an optical beam. A laser beam carries a certain amount of optical power. Lasers emit beams in two different ways: **continuous wave (CW)** or pulsed. A CW laser emits a steady power as shown in [Figure 63.1](#). CW laser power is measured in terms of watts. The power of commonly used CW lasers ranges from a fraction of milliwatts for a small helium neon (He-Ne) laser to tens of kilowatts for a carbon dioxide (CO₂) laser. A pulsed laser emits a pulsed power as shown in [Figure 63.2](#). The pulse can be repeated. The pulse duration and repetition rate vary for lasers of different types and are adjustable for some types of lasers. **Pulsed laser power** is more easily measured in terms of energy per pulse such as joules per pulse. The term “per pulse” is usually omitted. The energy of commonly used pulsed lasers ranges from a few picojoules for a semiconductor laser to tens of megajoules for a semiconductor laser array. The pulse repetition rate ranges from a single pulse for an excimer laser or

FIGURE 63.1 A CW laser emits a steady power.

FIGURE 63.2 A pulsed laser emits a pulsed power.

an X-ray laser to hundreds of megahertz for a neodymium:YLF laser. The pulse duration ranges from tens of femtoseconds for a Ti:Sapphire laser up to continuous wave for a CO₂ or He-Ne laser.

A laser beam may contain more than one wavelength (monochromatic) component. One wavelength component may have an optical intensity different from that of another wavelength component. Optical spectral intensity is defined as power per unit wavelength. The optical intensity-wavelength profile of a laser beam is known as the “spectrum.” Spectrum measurement usually means measuring the spectral profile. The absolute value of the optical spectral intensity is in fact not important. Figure 63.3 shows a typical spectrum of a multimode semiconductor laser. The wavelength components are inside several bands. Each band may be a “longitudinal mode,” and the width of a band is known as the “mode linewidth.” Figure 63.4 shows a typical spectrum of a single mode He-Ne laser. There is only one longitudinal mode with a very narrow linewidth. The power of a laser beam can be calculated by integrating over the [laser spectrum](#).

The wavelength of a laser is referred to as the *central wavelength* of the spectrum. But the term “central” is usually omitted. For example, the wavelength is 780 nm for the semiconductor laser shown in Figure 63.3 and is about 632.8 nm for the He-Ne laser shown in Figure 63.4. The wavelength of commonly used lasers ranges from 270 nm in ultraviolet for a neodymium:YAG laser, or even lower for an X-ray laser, to 10.6 μm in infrared for a CO₂ laser. Many lasers have a beam with single longitudinal mode and very narrow linewidth like that shown in Figure 63.4. The spectrum measurement for these lasers then virtually reduces to wavelength measurement.

Power, spectrum, and wavelength are the three most important parameters describing a laser. Laser manufacturers should provide information about these three parameters of their lasers. Some lasers have adjustable power, spectrum, or wavelength. Users often need to measure these parameters to ensure

FIGURE 63.3 Spectrum of a multimode semiconductor laser.

FIGURE 63.4 Spectrum of a single-mode helium neon laser.

appropriate use of these lasers. This chapter discusses the principles and techniques involved in the measurement of laser power, spectrum, and wavelength.

Readers interested in knowing more about laser working principles and characteristics can read laser textbooks such as Reference 1, available in many libraries.

63.2 Measurement of Laser Power

A laser power meter can measure laser power or energy. Figure 63.5 shows the scheme of a laser power meter. The three basic components of a laser power meter are a photodetector, an electronic conditioner, and a display device. The photodetector detects the laser beam under measurement and outputs an electrical response proportional to the laser power. The electronic conditioner processes the response and provides a digital or analog signal for displaying. The display device displays the measurement result in terms of watts or joules. To a large extent, the characteristics of the photodetector used determines the performance of a laser power meter. When selecting or using a laser power meter, the following issues are of primary concern:

1. *Spectral response range.* A photodetector has a certain spectral response range that limits the spectral range of a laser power meter. Some photodetectors have a wavelength-dependent spectral response. Calibration is necessary when using a laser power meter with such a photodetector to measure the power at different wavelengths.
2. *Power range.* The detection threshold and damage threshold of a photodetector usually determine the power range of a laser power meter. Incident laser power lower than the detection threshold can cause measurement error, while incident power higher than the damage threshold can cause permanent damage to the photodetector. Specifically, power range includes CW power range, peak

FIGURE 63.5 Scheme of a laser power meter.

power range, spatial power density range, single-pulse energy range, and spatial energy density range. An optical attenuator put in front of the photodetector can raise the damage threshold to as high as megawatt. However, an attenuator will also raise the detection threshold.

3. *Response time.* A photodetector needs a certain time to respond to an incident laser beam. In order to determine the shape of a laser pulse, the detector response time must be shorter than the width of the pulse.
4. *Detector window size.* The input window size of commonly used photodetectors are from a few to tens of millimeters. When the size of a laser beam under measurement is larger than the detector window size, focusing optics must be used to reduce the beam size. Power loss caused by the focusing optics must be excluded to avoid measurement error.

Photodetectors

Three photodetectors are commonly used in laser power meters. They are thermopiles, photodiodes, and pyroelectric probes.

Thermopiles

A thermopile is usually a light absorber disk onto which a ring of thermocouples has been deposited. The absorber converts the laser power incident on it into heat and generates between the absorber and a heat sink a temperature difference proportional to the incident laser power. The thermocouples generate and output an electrical response proportional to the temperature difference. Thermopiles usually have a long response time of a few seconds, a broad and flat spectral response range from 200 nm to 20.0 μm , and a power range of 1 mW to 5 kW for CW lasers or 0.01 J to 300 J for pulsed lasers. Because of the flat spectral response, calibration is independent of wavelength. Thermopiles are primarily used to measure moderate to high power output of CW lasers, moderate to high energy output of single-shot pulsed lasers, and the energy output of pulsed lasers with a repetition rate higher than 10 Hz.

Photodiodes

Silicon and germanium photodiodes are widely used as photodetectors. A photodiode absorbs the photons (laser beam) incident on it and utilizes the photon energy to create free carrier pairs (electrons and holes). These free carriers form a response current in an external circuit. The responsivity of a photodiode in amps/watt is given by

$$R\left(\frac{\text{A}}{\text{W}}\right) = \eta_D \frac{e}{h\nu} \quad (63.1)$$

where R = current produced by the photodiode for per watt of incident power, η_D = detection efficiency, e = electron charge (1.6×10^{-19} C), and $h\nu$ = photon energy. Since a typical photon energy is $2 \text{ eV} \approx 3 \times 10^{-19}$ J, $e/h\nu$ is of the order of 0.5 A/W. Normal detection efficiencies η_D exceed 0.5 at optical wavelengths (500 to 800 nm), leading to typical responsivities of 0.25 A/W. Silicon photodiodes have a narrow spectral response range (400 nm to 1.1 μm). The response peak is at about 800 nm. Germanium photodiodes also have a narrow spectral response range (800 nm to 1.8 μm). The response peak is at about 1.5 μm . Photodiodes usually have a power range of 1 nW to 50 mW for CW lasers or 1 pJ to 1 μJ for pulsed lasers, and a short response time of about 100 ms. Photodiodes are best for measuring low power output of CW lasers or low energy output of pulsed lasers. Because their spectral response is wavelength dependent, calibration is always required when measuring the power of lasers with different wavelengths. Manufacturers should attach a calibration data sheet to their laser power meters that use a photodiode as the detector. Several other semiconductor photodetectors with different spectral response ranges are available commercially. For example, the spectral response ranges are from 1.0 to 3.6 μm , 1.0 to 5.5 μm , and 2 to 22 μm for indium arsenide photodetectors, indium antimonide photodetectors, and mercury cadmium telluride photodetectors, respectively.

Pyroelectric Probes

A pyroelectric probe uses a ferroelectric material that is electrically polarized at a certain temperature. The material is placed between two electrodes. Any change in temperature of the material caused by the absorption of laser power produces a response electric current in the external circuit. Pyroelectric probes are primarily used to measure the energy of pulsed lasers because they only respond to the rate of temperature change. Pyroelectric probes usually have a spectral response range from 100 nm to 100 μm , a response time as short as a few picoseconds, and a pulsed energy range from 10 nJ to 20 J.

Integration Spheres

Integration spheres are designed to collect the power of highly divergent laser beams, such as semiconductor laser beams, since these beams can overflow the input window of a photodetector and cause considerable measurement error. Figure 63.6 shows the scheme of an integration sphere. The hollow spherical cavity has a diffusive internal wall and at least two windows. The reflectivity of the internal wall is high and slightly wavelength dependent. The highly divergent laser beam under measurement is incident into the sphere from one window. The photodetector of a laser power meter is mounted on another window. A baffle is used to prevent the photodetector being directly hit by the incident beam. The sphere can collect all the incident laser power and convert the power into a diffusive radiation proportional to the power. The laser power meter measures the radiation and displays the laser power under measurement based on the calibration data of the integration sphere.

Readers interested in knowing more about laser power meters can read References 2 through 4 or contact manufacturers. Section 8.1 of this handbook provides more information about photodetectors.

63.3 Measurement of Laser Spectrum

An instrument that can measure a laser spectrum is known as an optical spectrum analyzer. An optical spectrum analyzer consists of two basic components: an optical device and a laser power meter. The optical device can select and output a certain wavelength band of a polychromatic laser beam incident on the device. The central wavelength of the output wavelength band can be scanned over a certain range by the scan of the optical device. The laser power meter measures the power of the optical device output. The width of the output wavelength band usually does not change. Therefore, the power measured by the power meter is proportional to the optical spectral intensity. Since the absolute value of the optical spectral intensity is not important in the measurement of spectrum, the laser power meter sometimes can be as simple as a photodiode combined with a voltmeter. As the optical device is scanned, the power meter outputs the power (optical spectral intensity) as a function of the wavelength, and thereby measures the spectrum. Diffraction gratings and scanning Fabry-Perot interferometers (SFPI) are two widely used optical devices for spectrum analysis.

FIGURE 63.6 Scheme of an integration sphere.

Light Interference

Most optical spectrum analyzers make measurements utilizing light interference. The wave theory of light can explain interference. A single mode narrow linewidth laser beam can be described by its electric field $E(z)$:

$$E(z) = A \exp[-i\phi(z) + i\alpha(t)] \quad (63.2)$$

where A = amplitude, $\phi(z) = 2\pi z/\lambda$ = phase, λ = laser wavelength, z = coordinate in the direction of beam propagation, and $\alpha(t)$ = a phase factor that varies fast with time t . The intensity of the laser beam is given by:

$$I = |E(z)|^2 = A^2 \quad (63.3)$$

Two-Beam Interference

A beam splitter such as a partially transparent plate can split a laser beam into two described by:

$$E_1(z) = A_1 \exp[-i\phi(z) + i\alpha(t)] \quad (63.4)$$

$$E_2(z) = A_2 \exp[-i\phi(z) + i\alpha(t)] \quad (63.5)$$

where A_1 and A_2 are the amplitudes. Let the two beams propagate through two different distances, z_1 and z_2 , respectively, and then be recombined into one. The intensity of the recombined beam is:

$$I = |E_1(z_1) + E_2(z_2)|^2 = A_1^2 + A_2^2 + 2A_1A_2 \cos \frac{2\pi(z_2 - z_1)}{\lambda} \quad (63.6)$$

Equation 63.6 shows that I varies sinusoidally as $|z_2 - z_1|$ is varied. Such a phenomenon is known as *two-beam interference*. When $|z_2 - z_1| = m\lambda$ (m is any integer), I takes the maximum value of $(A_1 + A_2)^2$ and the situation is called "constructive interference." When $|z_2 - z_1| = (m + 1/2)\lambda$, I takes the minimum value of $(A_1 - A_2)^2$, and the situation is called *destructive interference*. Combining two beams with the same wavelengths but from two different lasers results in:

$$I = A_1^2 + A_2^2 + 2A_1A_2 \cos \left[\frac{2\pi(z_2 - z_1)}{\lambda} + \alpha_2(t) - \alpha_1(t) \right] \quad (63.7)$$

where $\alpha_1(t)$ and $\alpha_2(t)$ = two different phase factors of the two lasers, respectively. For broadband lasers, $\alpha_1(t)$ and $\alpha_2(t)$ are uncorrelated, and they vary rapidly and randomly. The last term at the right-hand side of Equation 63.7 can contribute to I only in a time-averaged way, and the time average of this term is zero. For narrowband lasers, a beat is obtained at the differential frequency of the two lasers, and I varies sinusoidally in time for any fixed $z_2 - z_1$. The time average of the last term in Equation 63.7 is also zero. Thus, I always equals a constant of $A_1^2 + A_2^2$, no matter how $|z_2 - z_1|$ is varied.

Multibeam Interference

Interference can occur among any number of beams obtained by splitting one laser beam. Let a laser beam with unit amplitude be split into N ($N > 1$) beams, the amplitudes of these N beams fall off progressively, and the phase difference between two successive beams be a constant $\Delta\phi$. These beams can be described by $E_k(z) = \rho^k \exp[-i\phi(z) - ik\Delta\phi + i\alpha(t)]$, where $k = 0; 1; \dots; N - 1$, and $\rho < 1$. Then, these N beams are recombined. Multibeam interference occurs among these beams. The intensity of the recombination of these beams is given by:

$$I = \left| \exp[-i\phi(z) + i\alpha(t)] \sum_{k=0}^{N-1} \rho^k \exp(-ik\Delta\phi) \right|^2 = \frac{1 + \rho^{2N} - 2\rho^N \cos(N\Delta\phi)}{1 + \rho^2 - 2\rho \cos(\Delta\phi)} \quad (63.8)$$

Equation 63.8 shows that I is a function of ρ and N , and is a periodic function of $\Delta\phi$. More information about the wave theory of light and light interference can be found in many advanced optics textbooks such as Reference 5.

Diffraction Gratings

A diffraction grating can spatially disperse a polychromatic laser beam into its monochromatic components and is the most widely used optical device for analyzing optical spectrum covering a relatively wide range. Several different types of diffraction gratings are available. A planar reflective diffraction grating is a collection of many small, identical and slit-shaped grooves ruled on a planar high reflective surface. Figure 63.7 shows two grooves of such a grating, an incident laser beam with three wavelength components $\lambda_1 < \lambda_2 < \lambda_3$ and three diffraction beams marked by $m = 0, 1$, and 2 , respectively. The beams are in the plane defined by the grating normal and the groove normal. The grooves illuminated by the incident beam generate diffraction beams with the same amplitude since the grooves are identical. Multibeam interference occurs among the diffraction beams. The phase difference $\Delta\phi$ between two adjacent diffraction beams of a grating is given by:

$$\Delta\phi = \frac{2\pi}{\lambda}d[\sin(\theta_1) + \sin(\theta_2)] \quad (63.9)$$

where d = groove period, θ_1 = angle between the incident beam and the grating normal, θ_2 = angle between the diffraction beams and the grating normal (θ_2 is not marked in Figure 63.7.), and $d[\sin(\theta_1) + \sin(\theta_2)] =$ path difference between two adjacent diffraction beams. Constructive interference among the diffraction beams occurs at

$$\Delta\phi = 2m\pi \quad (63.10)$$

where m = an integer known as the *diffraction order*. Combining Equations 63.9 and 63.10 results in

$$d[\sin(\theta_1) + \sin(\theta_2)] = m\lambda \quad (63.11)$$

Equation 63.11 is known as the *grating equation* and shows that, for a given θ_1 and m , θ_2 is a function of λ . θ_2 gives the diffraction beams a propagation direction in which I has the maximum value. The

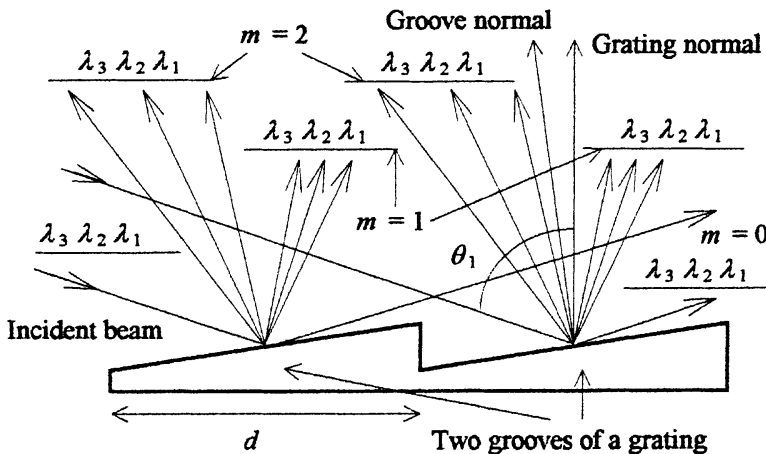

FIGURE 63.7 Two grooves of a planar reflective diffraction grating. The grating disperses an incident beam containing three wavelengths, $\lambda_1 < \lambda_2 < \lambda_3$. There are three diffraction beams with diffraction order $m = 0, 1, 2$.

angular dispersion resolution of a grating is defined by $d\theta_2/d\lambda$ and can be obtained by differentiating equation (63.11). The result is:

$$\frac{d\theta_2}{d\lambda} = \frac{m}{d \cos(\theta_2)} \quad (63.12)$$

where θ_1 is assumed to be a constant. Large $d\theta_2/d\lambda$ is often desired and can be obtained by the use of a small d , a large θ_2 close to 90° , and a large m . Usually, θ_2 must be smaller than 80° to maintain the proper functioning of the grating and $d \approx \lambda$; Equation 63.11 shows that the largest possible value of m is 2. Equations 63.11 and 63.12 also show that $m = 0$ leads to $\theta_2 = -\theta_1$ and $d\theta_2/d\lambda = 0$. That means that, in the zero diffraction order, the grating does not disperse the incident beam, and all the diffraction beams propagate in the same direction, $\theta_2 = -\theta_1$. Commonly used diffraction gratings have a groove density from 300/mm ($d \approx 3.33 \mu\text{m}$) to 2400/mm ($d \approx 420 \text{ nm}$). The corresponding dispersion resolution for $m = 1$ is from $d\theta_2/d\lambda = 4 \times 10^{-4} \text{ rad/nm}$ to $d\theta_2/d\lambda = 3.4 \times 10^{-3} \text{ rad/nm}$. The intensity of the diffraction beams of a grating can also be described by Equation 63.8 with $\rho = 1$. That is:

$$I = \frac{\sin^2\left(\frac{N\Delta\phi}{2}\right)}{\sin^2\left(\frac{\Delta\phi}{2}\right)} \quad (63.13)$$

Equation 63.13 is plotted in Figure 63.8 for $N = 5$ and 20, respectively. Equation 63.13 shows that I is a periodic function of $\Delta\phi$. I reaches maximum of N^2 at $\Delta\phi = 2m\pi$ and zero at $\Delta\phi = 2k\pi/N$ (k is any integer, but $k \neq mN$). The fringe width $\Delta\phi_w$ of I is given by

$$\Delta\phi_w = 2\left[2m\pi - \frac{2(mN - 1)\pi}{N}\right] = \frac{4\pi}{N} \quad (63.14)$$

Equation 63.14 shows that the resolution of a grating is proportional to N , since the resolution can be defined as $1/\Delta\phi_w$.

Most advanced optics textbooks (e.g., Reference 5) study gratings, and manufacturers' catalogs (e.g., Reference 6) give a product-oriented description of gratings.

FIGURE 63.8 Multibeam interference intensity I is a periodic function of the phase difference $\Delta\phi$ between two adjacent beams. I is plotted for beam number $N = 5$ and 20, respectively. The full fringe width at half maximum power $\Delta\phi_{\text{FWHM}}$ of I decreases as N is increased.

Monochromators

Monochromators are instruments widely used for optical spectrum analysis. Various types of monochromators have been developed. Figure 63.9 shows the scheme of a simple monochromator. The laser beam under measurement is incident through the entrance slit, two concave spherical mirrors collimate the beam, the grating disperses the beam, then one concave spherical mirror focuses the beam on the exit slit, and a laser power meter measures the power of the beam passing through the exit slit. The grating is mounted on a rotator. The position of the two slits are fixed. For any given grating orientation, θ_1 and θ_2 are known. The wavelength λ of the diffraction beams passing through the exit slit can be calculated using Equation 63.11. By rotating the grating and recording the power measured as a function of the corresponding λ , we can measure the spectrum. The widths of the two slits are Δs_1 and Δs_2 , respectively, and are adjustable. The three mirrors image the entrance slit on the exit plane. The image width $\Delta s_1'$ of the entrance slit is proportional to Δs_1 . Equation 63.15 gives the measurement resolution of a monochromator:

$$\Delta s \frac{d\lambda}{ds} = \frac{\Delta s d\lambda}{f d\theta_2} \quad (63.15)$$

where $d\lambda/ds$ is the linear dispersion resolution, Δs equals the larger of $\Delta s_1'$ and Δs_2 . $d\lambda/d\theta_2$ is the inverse of the angular resolution of the grating used, and f is the focal length of the focusing mirror. Equation 63.15 shows that reducing the widths of the two slits can increase the measurement resolution. However, the slits must be wide enough to allow enough laser power passing through for measurement. The grating rotation angular resolution also affects the measurement resolution of a monochromator. The resolution of commonly used monochromators is from 0.1 to 1 nm. Monochromators usually have a moderate price and measurement resolution. A product-oriented description of monochromators can be found in manufacturers' catalogs such as Reference 7.

Scanning Fabry-Perot Interferometer

Another widely used optical spectrum analyzer is a scanning Fabry-Perot interferometer (SFPI). An SFPI consists of two slightly wedged transparent plates with flat surfaces as shown in Figure 63.10. The two inner surfaces of the plates are set parallel to each other and are high-reflecting coated. The distance D between the two inner surfaces can be adjusted by a piezoelectric device. The two outer surfaces have a

FIGURE 63.9 Scheme of a simple monochromator.

small angle between them, so that reflections of the two outer surfaces can not interfere with the reflections of the two inner surfaces. The medium between the two plates is usually air with a unit refractive index. The laser beam under measurement is collimated by a lens and incident on the SFPI. The beam transmitted through the SFPI is focused by another lens onto the photodetector of a laser power meter. When a beam with unit amplitude is incident at angle θ on the inner surface of an SFPI, multiple reflections take place at the two inner surfaces and produce a series of transmitted beams whose amplitudes fall off progressively. In Figure 63.10, only three incident rays with a few reflections are plotted. The phase difference between two successive transmitted beams is:

$$\Delta\phi = \frac{4\pi D}{\lambda \cos(\theta)} \quad (63.16)$$

Interference occurs among the amplitude of the transmitted beams. The intensity of the combination of the transmitted beam is given by:

$$I = \left| T \sum_{k=0}^{\infty} R^k \exp(-ik\Delta\phi) \right|^2 \quad (63.17)$$

where R and $T = 1 - R$ = the power reflectivity and transmission coefficient of the inner surfaces of the SFPI, respectively, and the reflectivity of the outer surfaces of the SFPI is neglected. The laser power meter measures the power of the transmitted beams. Note that Equation 63.8 can be reduced to Equation 63.17 by letting the amplitude $\rightarrow T$, $\rho \rightarrow R < 1$, and $N \rightarrow \infty$. Therefore, the I obtained in Equation 63.17 can also be described by the curve shown in Figure 63.8. The full width at half the maximum (FWHM) power of I can be found by solving Equation 63.17. The result is:

$$\Delta\phi_{\text{FWHM}} = 4 \sin^{-1} \left(\frac{1-R}{2R^{1/2}} \right) \quad (63.18)$$

When R is close to 1, the right-hand side of Equation 63.18 is close to zero. We have:

$$\Delta\phi_{\text{FWHM}} = \frac{2(1-R)}{2R^{1/2}} \quad (63.19)$$

FIGURE 63.10 Scheme of a scanning Fabry-Perot interferometer. Only three incident rays and a few reflections are plotted.

Equation 63.19 shows that the fringe width of I reduces as R is increased, because larger R results in more reflections between the two inner surfaces of the SFPI. In an SFPI, the beam is usually arranged to incident at normal on the inner surface. θ becomes zero. Combining Equations 63.10 and 63.16 results in:

$$\lambda = \frac{2D}{m} \quad (63.20)$$

where λ is the wavelength at which the peak of I appears. Figure 63.8 shows that an SFPI functions like a multibandpass filter. The central wavelengths of the bands (fringes) are given by Equation 63.20 and can be adjusted by adjusting D . The FWHM of the bands is given by Equation 63.19. The spacing between two adjacent bands in terms of wavelength can be obtained by differentiating Equation 63.20 with respect to m , eliminating m and letting $\Delta m = 1$. The result is:

$$\Delta\lambda = \frac{\lambda^2}{2D} \quad (63.21)$$

$\Delta\lambda$ is known as the free spectral range (FSR) of an SFPI. The laser beam under measurement must have a wavelength bandwidth smaller than the FSR to ensure that the beam can transmit only through one band. When D is scanned, the transmitted wavelength is scanned, and the laser power meter measures and outputs the beam spectrum. The measurement resolution of an SFPI is limited by $\Delta\phi_{\text{FWHM}}$. Most SFPIs have an $R > 0.95$ to reduce the $\Delta\phi_{\text{FWHM}}$. The characteristics of an SFPI can be described by the fringe finesse F , defined as:

$$F = \frac{2\pi}{\Delta\phi_{\text{FWHM}}} = \frac{\pi R^{1/2}}{1-R} \quad (63.22)$$

where 2π is the period of the fringes given by Equation 63.10 in terms of phase. An SFPI usually has a resolution of FSR/100. For $\lambda = 500$ nm and $D = 5$ mm, the FSR is 0.025 nm, and the resolution is 0.00025 nm. Compared with monochromators, SFPIs are more expensive, and they have much higher resolution and a much smaller wavelength range.

More information about SFPIs can be found in many advanced optics textbooks such as Reference 5 and Chapter 6.5 of this handbook. A product orientated description of Fabry-Perot interferometers can be found in manufacturers' catalogs such as Reference 8.

63.4 Measurement of Laser Wavelength

For single-mode and narrow-linewidth lasers, the spectrum measurement reduces to wavelength measurement. Laser wavelength can be measured to a higher accuracy by the use of techniques that are not much different from those used to measure the spectrum. A laser wavemeter is an instrument designed to measure the wavelength without knowing the details of the spectrum.

Michelson CW Laser Wavemeter

Figure 63.11 shows the scheme of a widely used Michelson CW laser wavemeter that consists of a Michelson interferometer (MI), a laser power meter, and a computer system for data processing. The MI has two optical arms formed by a beam splitter and two mirrors, respectively. Mirror M_1 can be moved by a stepper motor driving system, and thereby the arm length z_1 can be changed. The position of mirror M_2 is fixed, and the arm length z_2 cannot be changed. Two lenses collimate the laser beam under measurement. The beam splitter splits the collimated beam into two. The two beams propagate in the

FIGURE 63.11 Scheme of a Michelson CW laser wavemeter.

two arms and are reflected by the two mirrors back to the beam splitter, respectively. Then the beam splitter recombines the two beams. Interference occurs between these two beams. Another lens focuses the combined beams onto the photodetector of a laser power meter. The computer system processes the output data of the laser power meter. The intensity I of the two combined beams can be described by Equation 63.6. As M_1 is moved, z_1 is changed, the path difference $|z_2 - z_1|$ between the two optical arms varies, and I varies periodically. The computer counts the number of the varying period of I , known as *counting the fringes*. Equation 63.23 relates the wavelength λ under measurement, M_1 moving distance L , and the counted fringe number $m + \Delta m$ by:

$$(m + \Delta m)\lambda = 2L \quad (63.23)$$

where $m =$ an integer, $\Delta m =$ a fraction, and the factor of 2 is introduced because the beam round trip distance is considered. A He-Ne laser with accurately known wavelength λ_H is used as a calibration source. For the He-Ne laser, there is the relation:

$$(m_H + \Delta m_H) = 2L \quad (63.24)$$

where m_H is another integer and Δm_H is another fraction. Combining Equations 63.23 and 63.24 results in:

$$\lambda = \frac{m_H + \Delta m_H}{m + \Delta m} \lambda_H \quad (63.25)$$

For $L = 500$ mm and $\lambda \approx 500$ nm, Equations 63.23 and 63.24 give $m \approx 2 \times 10^6$ and $m_H \approx 2 \times 10^6$. If Δm and Δm_H can be counted to an accuracy of 0.1, Equation 63.25 can provide six significant digits. Thus, λ can be calculated to a relative accuracy of about 10^{-6} . The commonly used commercial Michelson CW laser wavemeters have a relative measurement accuracy from 10^{-4} to 10^{-7} . The measurement range is usually from 400 nm to 1.1 μm , limited by the spectral range of the silicon photodetector used.

Steadily moving M_1 over a distance of 500 mm or so can take several seconds, and the computer is counting fringes during the entire moving period of M_1 . Several seconds is much longer than the pulse duration of most pulsed lasers. Thus, the computer will miss fringes in the period of time between two successive pulses when measuring the wavelength of a pulsed laser, and the measurement result will be erroneous. To measure the wavelength of pulsed lasers, the laser wavemeter must not have any moving parts and must be capable of taking data instantaneously.

More information about MIs can be found in many advanced optics textbooks such as Reference 5 and Chapter 6.5 of this handbook. Reference 9 presents a comprehensive study about the design and development of a MI CW laser wavemeter that achieves an accuracy of a few parts in 10^9 .

Pulsed Laser Wavemeter

Figure 63.12 shows the scheme of a Fizeau pulsed laser wavemeter, which consists of a Fizeau wedge, a charge coupled device (CCD) linear sensing array with 1024 pixels, a computer system for data processing, and an optical collimation system. The Fizeau wedge is made of a transparent material such as glass. The wedge has two flat surfaces. The angle α between the two surfaces is a few milliradians. The optical thickness $l(x)$ of the wedge is about 2 mm and varies linearly along the wedge. The optical system collimates the laser beam under measurement. The collimated beam is incident on the wedge. Both surfaces of the wedge reflect the incident beam. The two reflected beams form tens of spatial interference fringes on the CCD array. The CCD array detects the interference fringes and sends the data to the computer for processing. A Fizeau wavemeter does not have any moving parts and can measure the wavelength of pulsed lasers. It can be shown that the fringe period p is proportional to the wavelength λ under measurement by:

$$p = F_1(\alpha)\lambda \quad (63.26)$$

where $F_1(\alpha)$ is a function of α . A He-Ne laser with accurately known wavelength λ_H is used separately as a calibration source. The He-Ne laser also forms spatial interference fringes on the CCD array with a fringe period p_H proportional to λ_H by:

$$p_H = F_1(\alpha)\lambda_H \quad (63.27)$$

The data processing algorithm used in Fizeau wavemeters has two steps. λ is first calculated by combining Equations 63.26 and 63.27:

$$\lambda_1 = p \frac{\lambda_H}{p_H} \quad (63.28)$$

In Equation 63.28, the symbol λ_1 denotes the wavelength calculated in the first step because λ_1 is still not accurate enough. The data processing algorithm can calculate the fringe period p and p_H to an accuracy of higher than $10^{-4}p$ and $10^{-4}p_H$ utilizing the 1024 sensing data provided by the CCD array. Thus, Equation 63.28 can provide λ_1 to an accuracy higher than $10^{-4}\lambda_1$, and λ must fall somewhere inside the range:

$$\lambda_1 - 10^{-4}\lambda_1 < \lambda < \lambda_1 + 10^{-4}\lambda_1 \quad (63.29)$$

FIGURE 63.12 Scheme of a Fizeau pulsed laser wavemeter.

Any point on the CCD array corresponds to a point on the wedge with a certain optical thickness $l(x)$. It can be shown that at a given point on the CCD array, there is such a relation for λ and λ_H that:

$$(m + \Delta m)\lambda = F_2[l(x)] \quad (63.30)$$

$$(m_H + \Delta m_H)\lambda_H = F_2[l(x)] \quad (63.31)$$

where m and m_H are two integers and are unknown, Δm and Δm_H are two fraction orders at this point on the CCD array and can be measured, $F_2[l(x)]$ is a function of $l(x)$, and $l(x)$ is the thickness of the wedge at the point corresponding to the point on the CCD array. In the second step of the data processing, λ is calculated by combining Equations 63.30 and 63.31. The result is:

$$\lambda_2 = \frac{m_H + \Delta m_H}{m + \Delta m} \lambda_H \quad (63.32)$$

In Equation 63.32, we use the symbol λ_2 to denote the wavelength calculated, because λ_2 is still not necessarily equal to λ . A number of test m and m_H values are inserted into Equation 63.32 and result in a number of different λ_2 values. It can be shown that only one combination of m and m_H can result in a λ_2 that falls inside the range of Equation 63.29. This λ_2 is accepted as λ . m and m_H are of the order of 10^5 , and Δm and Δm_H can be measured to an accuracy of 0.01. Therefore, Equation 63.32 can provide λ to an accuracy of $10^{-5}\lambda$. The commercial Fizeau pulsed wavemeters have a measurement accuracy of $10^{-5}\lambda$. The measurement spectral range is from 400 nm to 1.1 μm , limited by the CCD array, which is made of silicon material. More information about Fizeau wedges can be found in many advanced optics textbooks such as Reference 5 and Chapter 6.5 of this handbook. Readers interested in learning more about the design and development of Fizeau pulsed wavemeters will find Reference 10 to be a good starting point.

63.5 Instrumentation and Components

Table 63.1 lists a few companies manufacturing photodetectors, laser power meters, diffraction gratings, monochromators, scanning Fabry-Perot interferometers, Michelson CW laser wavemeters, and Fizeau pulsed laser wavemeters. The price ranges of these instruments and components are also listed in Table 63.1. Table 63.2 lists the address of these companies. These two tables are far from exhaustive. Interested readers could consult two excellent books, *Laser Focus World Buyers Guide* [11] and *Photonics Buyers' Guide* [12]. These two books are published annually and contain up-to-date information about most optical and laser manufacturers in U.S.A and their products.

TABLE 63.1 Manufacturers, Components and Instruments, and Price Ranges

Product Description	Manufacturer	Approx. Unit Price
Thermopile for laser power meters	Coherent, Newport	\$500–\$2,000
Photodiode head for laser power meters	Coherent, Newport	\$500–\$1,000
Pyroelectric probe head for laser power meters	Coherent, Newport	\$900–\$1,200
Laser power meter (including one detector head)	Coherent, Newport	\$1,00–\$5,000
Integration sphere	Newport, Oriel	\$1,300–\$2,500
Diffraction grating	Milton Roy	\$100–\$4,000
Monochromator	Milton Roy, Oriel	\$1,000–\$7,000
Scanning Fabry-Perot interferometer	Burleigh Instruments	\$7,000–\$16,000
Michelson CW laser wavemeter	Burleigh Instruments	\$7,000–\$25,000
Fizeau pulsed laser wavemeter	New Focus	\$1,200

63.6 Defining Terms

Continuous wave (CW) laser power: Laser power that does not vary with time.

Pulsed laser power: Laser power that lasts only a short period of time.

Laser spectrum: Laser power-wavelength profile.

Laser wavelength: The spatial period of a laser electric field.

Vision is the act of seeing, a human capability derived from the combination of the image forming optical system of the eye, the array of light sensitive receptors in the retina of the eye, and the information processing capacity of the retina and human brain. Applications for instruments with a similar ability to sense a scene include broadcast television, monitoring industrial processes, quality control during manufacture, viewing inaccessible or hazardous places, aiding medical diagnosis, and remote sensing from satellites and space probes, to name but a few. Each application often has particular requirements more critical than others, and the problem is to find the most economical solution satisfying these most closely.

The human eye is a familiar imaging system, highly optimized to aid survival under the naturally occurring range of illumination conditions. It is useful to describe its basic characteristics [1] to provide a benchmark against which machine vision can be compared. Light intensity can be measured using radiometric quantities such as radiant power, which is the radiant energy transferred per second in watts; irradiance, which is the radiant power falling onto a surface of unit area in W/m^2 ; and radiance, which is the radiant power leaving unit area of a surface per unit solid angle in $W/st/m^2$. It can also be measured using photometric units that take into account the variation in response of a standard human eye with wavelength, the CIE (Commission Internationale de l'Éclairage) response curve. The photometric equivalent of radiant power is luminous flux, measured in lumens (lm); the photometric equivalent of irradiance is illuminance, measured in lm/m^2 or lux; and the photometric equivalent of radiance is luminance measured in $lm/st/m^2$ or cd/m^2 . At the wavelength of peak sensitivity (555 nm) in the CIE sensitivity curve, the conversion factor from radiometric to photometric units is 680 lm/W .

The eye has a response (observed brightness) to incident light intensity which is roughly logarithmic and is capable of adapting, given time, to an enormous range of different illuminance levels, from full sunlight (100,000 lux) to starlight (0.001 lux). The illumination generally recommended for surfaces in an office environment (about 100 lux) represents a comfortable working level. It takes about 30 min for

the eye to become fully dark adapted and a further 3 min to adapt again to increased lighting levels. Despite this adaption capability, when viewing any one point in a scene under bright light conditions, the eye is capable of discerning only about 25 different intensity levels. The eye achieves its enormous range of brightness adaptation partly through the action of a variable size iris (about 2 to 8 mm in diameter), but mainly through the presence of two types of light sensitive receptor in the retina of the eye.

At high illumination levels, corresponding to photopic vision, the eye perceives color due to the excitation of three different types of cone receptors. There is considerable overlap in the spectral sensitivity curves of these red, green, and blue receptors, which have peak responses near 600, 550, and 500 nm, respectively. The overall photopic response is greatest at a wavelength near 555 nm in the yellow green region of the spectrum and falls to zero toward the red and the blue ends of the spectrum at about 750 and 380 nm, respectively. At low levels of illumination, corresponding to scotopic vision, only the rod receptors are excited with a peak luminous efficiency of about 1700 lm/W near 510 nm in the green region of the spectrum. The sensitivity to contrast of the dark-adapted eye is much poorer than that of the light-adapted eye. The transition between photopic and scotopic vision is gradual, with both excited over a luminance range from about 0.001 to 0.1 cd/m². The photopic response extends higher to the glare limit, about five orders of magnitude brighter, while the scotopic response extends lower to the threshold of vision, about three orders of magnitude lower. The photopic (CIE) and scotopic spectral responses of the eye are shown in Figure 64.1 with the response of a typical silicon-based sensor for comparison. The latter has a spectral response that is quite different from that of the human eye, extending well beyond the red end of the visible spectrum toward 1100 nm, with maximum sensitivity around 800 nm. Assuming the average spectral response of silicon, an irradiation of 1 μW/cm² corresponds to an illumination of about 0.22 lux.

The distribution of the cones and rods over the inner surface of the eyeball is nonuniform, with the cones most densely packed in the region of the fovea, a circular region about 1.5 mm in diameter situated toward the rear of the eyeball. To achieve sharpest vision, the eye muscles automatically rotate the eyeball so that the object of interest in the scene is imaged onto the fovea. The separation of the approximately 400,000 cones in the fovea is such that a normal young eye is able to distinguish alternating black and white bands, each 1 mm wide at a distance of about 5 m, corresponding to an angular resolution of about 0.2 mrad. The resolution of the dark-adapted eye is very much poorer because, although the maximum number of rods per square millimeter is similar to that of cones, several rods are connected to a single nerve end, whereas only a single cone is connected to a nerve end.

The overall performance of the eye is difficult to equal. However, a machine vision system can surpass it in individual respects such as sensitivity to infrared and ultraviolet radiations invisible to the eye, speed of response (which can be as short as nanoseconds), and sensitivity to low light levels corresponding to the detection of individual photons of radiation over periods of several hours. Machine vision charac-

FIGURE 64.1 The linear responses, normalized to unity, of a typical bright-adapted human eye (photopic), a typical dark-adapted eye (scotopic) and a typical charge-coupled-device sensor to different wavelengths of light. The CIE response curve is an internationally agreed response curve for the photopic vision of a standard observer which is used to convert radiometric measurements to photometric. The individual responses of the red, green, and blue cones are also shown, drawn using thinner lines, beneath the photopic curve.

teristics depend on the type of image sensor employed and the modifying effects of additional components such as image intensifiers or optical fiber scopes. The machine vision equivalent of the eye includes a lens to project a 2-D image of the 3-D object of interest onto a sensor that transforms the light energy into an electrical signal. In this form, it may then be transmitted to a remote location, subjected to computer analysis, or displayed on a television screen. A rectangular 2-D image can be sensed using three different approaches. A single, small sensor can be moved in a zig-zag or raster fashion to sense the light intensity on a grid of points covering the whole image. A second approach is to use a line sensor composed of many individual sensors. If it is equal in length to one side of the image, it need only be moved in steps equal to the width of the individual sensors, a distance equal to the other side to cover the whole image. The third approach is to use an area sensor comprising a 2-D array of individual sensors. Whatever method is used, each individually sensed small region of the image is called a *picture element* or *pixel* and, in general, the resolution of the imaging system improves with increasing number of pixels. Although the first two methods require relative movement between sensor and scene, they are not limited by the sensor in the amount of resolution that can be achieved along the direction of motion. In addition, the inevitable variation in response between different sensors is easier to correct than with comparable area sensors, because there are fewer sensors. Two common applications of line sensors are monitoring objects on moving conveyer belts and scanning documents. In many cases, however, it is not practical to arrange relative movement of image and sensor, and the majority of image sensors in use are monochrome or color area sensors designed for use in television cameras. Monochrome and color cameras both use the same basic sensors, which have an inherently broad spectral response. Color sensitivity is achieved with the aid of color filters. A common approach is to deposit color filters directly on the sensor surface in a mosaic or stripe pattern. This is a cheap and compact solution but results in a lower spatial resolution in each color, compared with the resolution of the equivalent unfiltered sensor, and loses much of the incident light through absorption in the filters. Better sensitivity and resolution are obtained using three-sensor cameras that incorporate an optical arrangement (based on dichroic mirrors) that separates the incident light into three components—say red, green, and blue—which are each directed at a different sensor. However, this approach is both bulky and expensive, because it requires three sensors rather than one, and precision optics to align the images correctly on the individual sensors.

Most area sensors currently sold are designed to produce electrical signals compatible with either the 525-line American television standards (RS-170 for monochrome and NTSC for color) or the 625-line European television standards (CCIR for monochrome and PAL for color) [2]. These are interlaced television standards in which each complete image or frame is made up of two fields, each containing either odd or even numbered lines from the frame. Half the remaining lines, making up the odd total number in the frame, appear in each field, ensuring that the two fields interlace properly on the television display. Interlacing is used to avoid picture flicker without having to double the rate of information transmitted. According to the Ferry-Porter law, the critical frequency below which flicker is observed depends on the logarithm of the luminance of the picture highlights. At the brightness levels corresponding to normal viewing, flicker would be observable in pictures interrupted at 25 Hz or 30 Hz, but it is reduced to an acceptable level at the repetition rates of the fields (60 Hz for NTSC and 50 Hz for PAL). A consequence of the Ferry-Porter law is that an NTSC picture can be about six times brighter than a PAL picture and still be acceptable in terms of flicker. Many companies supply frame grabber computer boards that sample the TV-compatible voltage signals (about 1 V range) at a frequency of at least 10 MHz (for at least 512 samples per line), quantize the analog voltage to 256 or more discrete levels (8 bits), and store the resulting digital data for computer analysis. Interlaced operation is not ideal for some applications and, at higher cost, cameras are available that provide higher frames rates, higher resolutions, or progressive scan (no interlacing). These usually produce a standard digital output signal for easy input into a computer. A very wide range of sensors and cameras are currently commercially available, based on several different types of technology. Although each technology has particular advantages, the characteristics of different devices based on a specific technology can vary significantly. For example, the spectral responses of photodiode-based sensors generally extend to shorter wavelengths than those of CCD (charge-coupled device)-based sensors, but some CCD devices are available with extended blue-

end responses. Improved and/or cheaper sensors and cameras are appearing on the market all the time and, when considering a new imaging system, it is wise to review the characteristics of the devices currently available in comparison with the requirements of the application in order to select the most suitable. One of the first steps in the creation of a machine vision system for a new application is the design or selection of an appropriate optical system, and this is the subject of the next section. Later sections discuss the various sensor technologies that are available and other related devices that can be used to improve sensitivity or to allow image sensing in restricted spaces such as body or machine cavities.

64.1 Image Formation

The machine vision optical system has the tasks of matching the required field of view to the dimensions of the sensor and gathering sufficient light to achieve a sensor signal that has adequate signal-to-noise ratio (SNR) while maintaining the image sharpness required by the application. Resolutions of area sensors are sometimes specified by manufacturers as the maximum number of horizontal TV lines that can be distinguished. This value may be obtained from measurements of the visibility of a test chart (EIA test pattern), or it may simply be the number of horizontal pixels divided by 1.33, in the case of a monochrome sensor. In special circumstances, measurements to subpixel accuracy can be achieved by interpolation between pixel values, and Reference 3 describes the measurement of a knife edge to about 0.1 pixel accuracy. As a rule of thumb, however, for size measurement applications, the sensor should have a number of pixels at least equal to twice the ratio of the largest to smallest object sizes of interest [4], and a lens is then selected to provide the required magnification and working distance. A lens operating in a single medium such as air is characterized [5] by two focal points and two principal planes as indicated in Figure 64.2. The principal planes coincide with the lens center in the case of an ideal thin lens but may be separated by +20 to -10 mm (the negative sign indicating reversed order), depending on the design, in multielement lenses. They can be determined by first locating the two focal points and then measuring along the axis from these, distances equal to the focal length. A lens of focal length f produces an image in best focus at a distance l_i when the object is at distance l_o where

FIGURE 64.2 The trace of a ray from a distant object through a typical multielement lens system showing typical positions of focal points and principal planes. The distance from the back focal length to the lens flange mount is 17.3 mm for C-mount lenses, 12.5 mm for CS-mount lenses, and 46.5 mm for 35 mm photographic format Nikon F (bayonet) mount lenses. Adapters are available to accommodate the differences in distances and fittings of the different mounting systems.

$$\frac{1}{l_o} + \frac{1}{l_i} = \frac{1}{f} \quad (64.1)$$

and the distances are measured to the corresponding principal planes. The image magnification m , defined as the ratio of image to object size, is equal to the ratio of the image to object distances and is related to the total distance between object and image D_T by

$$D_T = \frac{F(m+1)^2}{m} + D_N \quad (64.2)$$

where D_N is the separation between the principal planes. Lenses generally have a focusing adjustment of 5 to 10% of the focal length, and extension rings between the lens and sensor are required for image magnifications greater than about 0.05. The lens extension required is simply the product of the magnification and the focal length. The depth of field F_o of an imaging system [6] is the displacement of the object along the optic axis that produces no significant degradation in the sharpness of the image. The corresponding movement of the image is the depth of focus. In the case of a lens with f /number $f_\#$ (equal to the ratio of focal length to lens iris diameter) and an image sensor with pixel size P , it is given by

$$F_o = 2f_\# \frac{P(m+1)}{m^2} \quad (64.3)$$

Television cameras sensors are manufactured to standard sizes such as 1, 2/3, 1/2, or 1/3 in. The size is defined to be twice the horizontal dimension of a rectangular image with 4:3 aspect ratio so that a 1-in. sensor has a width of 12.7 mm, a height of 9.5 mm, and a diagonal length of 15.9 mm. Lens sizes are similarly specified to allow easy matching of lenses to sensors. Because image distortion and sharpness worsen toward the edges of the field of view, it is permissible, for example, to use a 2/3-in. lens with a 1/2-in. sensor, but not the converse. A 35-mm camera lens, designed for a 24 by 36 mm image size, generally performs much better, at relatively low cost, than a corresponding C-mount lens supplied for a TV camera but a C-mount to Pentax, Cannon, or Nikon mount converter will then be required.

It is frequently necessary to relate lighting of a scene to camera sensitivity. Accurate calculations are difficult, and it is usually better to make a simple estimate and then make fine adjustments to the lighting or lens aperture. Manufacturers often specify camera sensitivities by quoting an illumination level in lux at the sensor faceplate. This may be the illumination required to achieve maximum signal output, some proportion of this maximum, or simply a “usable” signal level from the camera. The illumination of the sensor L_S in lux is related to the luminance of the object B in cd/m^2 by

$$L_S = \frac{TB\pi}{[2f_\#(m+1)]^2} \quad (64.4)$$

where losses in the lens are characterized by a transmission coefficient T . If the object is a uniform diffuse reflector (Lambertian surface) illuminated by L_o lux, then the luminance of the object is given by

$$B = L_o \frac{R}{\pi} \quad (64.5)$$

where R is the reflection coefficient of the surface. Some practical examples of radiometric calculations are given in a Dalsa application note [7].

64.2 Image Sensing

The primary functions occurring within a standard image sensor are the conversion of light photons falling onto the image plane into a corresponding spatial distribution of electric charge, the accumulation and storage of this charge at the point of generation, the transfer or readout of this charge, and the conversion of charge to a usable voltage signal. Each of these functions can be accomplished by a variety of approaches, but only the principal sensor types will be considered here. Sensors can be divided into two groups: (1) vacuum tube devices in which the charge readout is accomplished by an electron beam sweeping across the charge in a raster fashion similar to that in a television picture tube, and (2) solid-state devices based on charge-coupled devices or photodiodes. These three types of sensor will be described in the next three sections.

Television Camera Tubes

For many years, vacuum tubes [8] provided the only technology available for television applications, and they are still widely used because of the high-quality image signals they provide. Companies supplying tubes include Burle and Philips. Most modern tube cameras are based on the vidicon design whose basic components are indicated in [Figure 64.3](#). Light from the scene is imaged by a lens onto a photoconductive target formed on the inner surface of an end window in a vacuum tube. An electron gun is placed at the opposite end of the tube to the window, and it provides a source of electrons that are focused into a beam, accelerated toward the target by a positive potential on a fine mesh placed just in front of the target, and scanned across the target by an electrostatic or magnetic deflector system. The target consists of a glass faceplate on the inner surface, upon which is placed a transparent electrically conducting coating of indium tin oxide. On top of this is deposited a thin layer of photoconductive material in a pattern of tiny squares, each insulated laterally from its neighbors. The transparent coating is connected to a positive voltage through an electrical load resistor across which the signal voltage is developed. In the absence of

FIGURE 64.3 A schematic diagram of the major components of a vidicon camera tube. Many variants of this basic design exist utilizing different target materials to improve particular characteristics. The electron beam readout of the optically generated charge in the target makes the tube bulky and less reliable than solid-state sensors. Most tubes currently sold are for replacement in existing equipment rather than in new cameras, which almost always incorporate solid-state sensors.

light, the electron beam causes the external surface of the photoconductor to be charged to near zero potential. Light causes the resistance of the photoconductor to decrease, and its surface to acquire a more positive potential, due to the accumulation of positive charge. At each point on the surface touched by the electron beam, some of the beam current is deposited to neutralize the positive charge present due to the illumination. The rest passes through the load resistor generating an output voltage that is a function of the light intensity at that point. The precise timing of the scanning process ensures that the location of the beam is known at each instant in time.

Vidicons have some unique characteristics. They can have spectral responses extending into the ultraviolet and infrared regions of the spectrum, and they allow scan rate and adjustments in scan alignment to be made electronically by adjusting the scanning pattern. This allows very simple region-of-interest readouts. On the other hand, the electron beam readout method confers a number of disadvantages, which are not found in solid-state devices, including large size, fragility, susceptibility to shock and vibration, high power consumption and a high degree of sensitivity to external electric and magnetic fields. The principal imaging defects, which again are not present in solid-state devices, include

- lag when displaying changing images, due to slow response speed,
- image burn which is damage to the sensor surface caused by intense light,
- geometric distortion,
- drift in the apparent position of the image,
- a nonlinear relationship between signal output and light intensity which varies with target voltage.

The degree to which these effects are present depends on the type of tube and its particular construction.

The original vidicon tube design employed antimony trisulphide as the photoconductive material and a low-velocity electron beam and gave only adequate performance. Newer tubes employ the same basic design but use better electron beam readout techniques and target materials to improve characteristics such as spectral response, sensitivity, dark current, lag, and burn-in. Two tubes suitable for broadcast television use are the plumbicon developed by Philips and the saticon introduced more recently by Hitachi. The plumbicon employs a lead-oxide photoconductive target, while the saticon target comprises several layers with different combinations of selenium, arsenic, and tellurium. It can provide greater resolution than the plumbicon, but the lag performance and range of operating temperature are worse. Examples of nonbroadcast quality tubes are the newvicon, chalnicon, and the si-vidicon. The newvicon target has a double layer of cadmium and zinc tellurium, which achieves exceptional sensitivity, but lag and nonuniformity are excessive. The chalnicon employs a cadmium selenide target and provides good performance in most respects but has excessive lag. The si-vidicon target effectively consists of an array of silicon photodiodes that are reverse biased and store charge released by the incident light. The resulting tube has very high sensitivity and little lag, and it is virtually burn proof. However, it exhibits excessive blooming and nonuniformity. The silicon-intensified camera, or SIT camera, is a modification of the si-vidicon camera that employs a photocathode that generates electrons when struck by light photons. These electrons are accelerated by a voltage of several hundred volts and focused on the target of the si-vidicon sensor that produces an output in the normal way. The high-speed electrons landing on the target produce large numbers of electron-hole pairs and a corresponding larger response. The resulting SIT sensor is used in very low light level applications such as tracking satellite debris and can produce useful video images at illumination levels down to 0.001 lux. By comparison, a solid-state CCD sensor (without an image intensifier) typically requires about 1 lux to produce a useful video signal.

Charge-Coupled Devices

A CCD is fabricated on a single crystal wafer of *p*-type silicon and consists of a one- or two-dimensional array of charge storage cells on centers typically about 10 μm apart. Each cell has several closely spaced electrodes (gates) on top, separated from the silicon by an insulating layer of silicon dioxide. The charge is stored under one of the electrodes, and its location within the cell is defined by the pattern of positive voltages applied to the electrodes. By applying a coordinated sequence of clock pulses to all the electrodes

in the array, packets of stored charge (of between 10 and 10^6 electrons) are transferred from one cell to the next until they finally reach a sensing amplifier (floating gate diffusion) which generates a voltage signal proportional to charge, usually assumed to be $1 \mu\text{V}$ per electron. The result is a device that has an inherently linear variation of output voltage with light from the minimum useful level set by noise, to the maximum useful level set by saturation of the output amplifier, or the limited capacity of the charge storage cells. The dynamic range of the device is defined as the ratio of the maximum output signal to the output resulting from noise. Manufacturers published figures may use peak-to-peak or root-mean-square noise values (typically five times smaller) in this calculation, but the former is more relevant for imaging applications.

Any light penetrating into the underlying silicon generates electron-hole pairs. The holes are swept away to the substrate electrode while the electrons accumulate beneath the nearest electrode in a potential well created by the applied voltage. The sensitivity of silicon is of the order of $1 \mu\text{A}$ of generated charge per microwatt of incident light. The cells intended to function as light-sensitive photosites have electrodes made of semitransparent polysilicon so that the light can penetrate into the storage region, whereas those intended to function only as part of a shift register for charge transfer are covered by an opaque surface layer. Due to manufacturing imperfections, the photosites do not have perfectly uniform characteristics, and a photoresponse nonuniformity (PRNU) of about 5 to 10% is fairly typical. This is easy to measure using uniform sensor illumination and its effects can be removed if necessary by calibration. The basic spectral response of the silicon extends from 200 to 1100 nm, but the first figure is typically reduced to 450 nm by absorption in the surface layers of the CCD photosites. Infrared radiation penetrates deeper into the silicon than shorter wavelengths, and charge created by an infrared photon may be collected by a different cell to the one entered by the photon. This reduces the resolution of the device, and if infrared operation is not required but the illumination contains infrared (from a tungsten lamp for example), then an infrared reflecting filter (a hot-mirror filter) is often used. CCD cells also accumulate charge linearly with time due to thermally generated electrons produced within the cells and at electrode interfaces. Like the photoresponse, this dark signal varies from cell to cell and can be compensated for by calibration. These thermally generated contributions are most significant for low light level applications and can be reduced by cooling the sensor using either a thermoelectric cooler, a Joule Thomson cooler, or a liquid nitrogen dewar. The dark signal reduces by 50% for every 7°C reduction in temperature, and at -60°C , produced by a Peltier cooler, the dark signal is typically reduced to about one electron per pixel per second. Another important temperature dependent characteristic of the CCD sensor which improves with cooling is the noise floor of the output amplifier which is proportional to $T^{1/2}$ and typically equivalent to about 300 electrons at room temperature. A particular CCD device used in astronomy, for example, and operated at about -110°C has a readout noise of about 10 electrons, a dark current less than 0.3 electrons per minute, and a quantum efficiency for converting visible photons into electrons of between 70 and 80%. Light can be integrated for periods of hours, compared with the approximately 1/8 to 1/4 s integration period of the dark-adapted eye. Compared with photographic film previously used for low-light level imaging in astronomy, CCDs are from 10 to 100 times more sensitive, linear in response rather than nonlinear, and have a much greater dynamic range so that both faint and bright objects can be recorded in the same exposure.

The short-exposure, high-frequency performance of CCD devices is limited by another effect. The process of transporting charge in a CCD sensor is not 100% efficient and, in practice, a small amount of charge is left behind at each transfer to the next cell, contributing noise and degrading resolution. This effect limits the maximum clock frequency and the maximum number of transfers in a CCD sensor. Manufacturers' data sheets for commonly available CCD sensors quote values ranging from 0.9995 to 0.99999 for the charge-transfer efficiency or CTE of a single transfer. There are many variations in CCD technology. For example, virtual-phase CCDs [9] have some of the electrodes replaced by ion-implanted regions, resulting in improved blue response and higher sensitivity because of the removal of some of the blocking surface gates, and simpler drive circuitry because of the reduction in number of gates per cell. A manufacturing technique known as *pinning* can be used to passivate the interface states, which are the biggest contribution to the dark signal, producing an order of magnitude improvement in dark

signal as well as improved quantum efficiency and CTE. A signal-processing technique called *correlated double sampling* can also be applied to the output signal from the sense amplifier to improve the readout noise performance.

Linear Charge-Coupled Devices

The basic structure of a linear CCD sensor is shown in [Figure 64.4](#). It consists of a line of up to several thousand photosites and a parallel CCD shift register terminated by a sensing amplifier. Each photosite is separated from a shift register cell by a transfer gate. During operation, a voltage is applied to each photosite gate to create empty storage wells which then accumulate amounts of charge proportional to the integral of the light intensity over time. At the end of the desired integration period, the application of a transfer pulse causes the accumulated charge packets to be transferred simultaneously to the shift register cells through the transfer gates. The charges are clocked through the shift register to the sensing amplifier at a rate of up to 20 MHz, producing a sequence of voltage pulses with amplitudes proportional to the integrated light falling on the photosites. In practice, it is common for shift registers to be placed on both sides of the photosites, with alternate photosites connected by transfer gates to the right and left registers. This halves the number of cells in each register and the time required to clock out all the data. Another 2× reduction of transfer time is achieved if each shift register is split in two with an output amplifier at each end. There is a limit, typically between 10^5 to 10^6 depending on photosite size and dimensions, to the number of electrons that can be stored in a particular cell, beyond which electrons start to spill over into adjacent cells. The saturation charge in electrons is roughly 1000 to 2000 times the area of the photosite in square micrometers. This spread of charge or blooming is a problem with images containing intense highlights. It is reduced by about a factor of 100 by adding antiblooming gates between adjacent photosites and transfer gates and channel stops between adjacent photosites. The voltage on the antiblooming gates is set at a value that allows surplus charge to drain away instead of entering the transfer gates and shift register. By clocking this voltage, variable integration times that are less than the frame pulse to frame pulse exposure time can also be attained.

Area Charge-Coupled Devices

Three basic architectures are used in area CCDs and are illustrated in [Figure 64.5](#). The simplest is the full-frame CCD, consisting of an imaging area separated from a horizontal CCD shift register by a transfer

FIGURE 64.4 The architecture of a basic linear CCD showing the arrangement of photosites, transfer gates, shift register cells, and sensing amplifier. The latter produces a sequence of voltage pulses each proportional to the charge accumulated in one of the photosites. Although these pulses are often displayed on an oscilloscope during setting up of the optics and illumination, in normal use they are digitized to 8 or 12 bits, and the resulting values are stored in memory. In practice, most CCDs have two or more covered cells at each end of a line of photosites to allow the dark current to be monitored and subtracted during signal processing. Applying uniform illumination to the CCD enables the relative response of the individual photosites to be measured and compensated for.

FIGURE 64.5 The basic architectures used in area CCDs. FF devices fully utilize the available area for image detection and therefore achieve the largest number of pixels, currently about 5000×5000 , but need an external shutter. FT devices are normally used at standard video rates without an external shutter. The ILT architecture allows exposure times down to less than 0.1 ms. The lower fill factor of ILT devices compared with FF and FT devices results in higher values of modulation-transfer-function at the Nyquist limit. This increases the visibility of aliasing artefacts in images containing high spatial frequencies. A low-pass optical filter must be used if aliasing is a problem.

gate. In the imaging area, each photosite is one stage of a vertical shift register separated from neighboring shift registers by channel stops and antiblooming structures. During the light integration period, the vertical clocks are stopped, creating potential wells which collect photoelectrons. At the end of this period, the charge is clocked out vertically, one row at a time, into the horizontal shift register. The charge in the horizontal shift register is then very rapidly shifted toward the output amplifier by the application of a horizontal clock signal. An example full-frame CCD is the RA1001J from EG&G Reticon, which has pixels arranged in a 1024×1024 configuration and dual horizontal shift registers and outputs to achieve a 30 frame per second readout rate. To avoid image smearing during the readout period, full-frame CCD sensors must be operated with external shutters, as in digital cameras produced by Kodak and other companies, or used in low light level applications requiring very long integration times compared with the readout time, as in astronomy. The full-frame CCD is also the basis for time delay and integration (TDI) sensor manufactured by companies such as Dalsa and EG&G Reticon. In the application of this device, which may have 96 rows each with 1024 pixels, a moving scene illuminates a region on the sensor only one pixel high, and this is arranged to move vertically down the sensor at the same rate that the generated photocharge is shifted down the sensor. This mode of operation achieves an output signal identical to that from a linear CCD sensor except for a increased light sensitivity proportional to the number of horizontal rows in the TDI sensor. It can be appropriate in applications where both high speed and high sensitivity are required, providing a cheaper alternative to the combination of a line sensor and an image intensifier. An application of this technique to capturing images of web systems moving at up to 5 m/s is described in Reference 10.

The requirement for an external shutter is greatly reduced in the frame-transfer CCD sensor by the provision of a light-shielded storage section into which the entire two-dimensional image charge is shifted at a much higher rate (limited primarily by CTE considerations) than is possible in a full-frame CCD. The charge can then be read from the storage region during the next integration period without any further image smearing. Some sensors, such as the EG&G Reticon RA1102 device, have the storage area divided into halves placed on opposite sides of the imaging area. This improves performance by halving the maximum number of transfers required to reach the nearest storage region. The same reduction

occurs automatically in sensors designed for interlaced video applications where each integration period corresponds to one video field, and only half the number of rows in the frame is required at any one time. For example, to produce an interlaced video frame containing 576 image lines (CCIR standard), a frame transfer sensor with only 288 rows of storage is required. By changing the clock signals, the odd field can be displaced vertically by half a line width relative to the even field. This ensures that the odd and even lines contain different information and reduces aliasing, because the cell width is twice the separation between the lines in the frame. Some of the companies that produce frame-transfer CCD sensors and cameras include Cohu, Dalsa, EG&G Reticon, EEV, Kodak, Philips, and Thomson-CSF.

Image smear is virtually eliminated by the interline-transfer (ILT) architecture in which each column of photosites has an adjacent light-shielded vertical CCD shift register into which the charge is transferred by a transfer pulse. The contents of all the vertical shift registers are then shifted simultaneously one pixel at a time into a horizontal shift register where they are then rapidly shifted to an output amplifier. This approach makes it easy to implement exposure control and achieve short integration times, but it introduces *dead space* between the active pixels, reducing the sensitivity of the image sensing area and increasing aliasing effects compared with frame-transfer sensors. For the latter, the fill factor, which is the percentage of the imaging area which is light sensitive, can be close to 100%, whereas it is usually less than 50% for interline-transfer devices. Localized bright objects tend to produce vertical streaks in an ILT device because strong light can leak under the narrow light shield covering the vertical shift registers, causing image smearing similar to that in a full-frame device. This reduces the usefulness of ILT sensors for scenes containing pronounced highlights. For interlaced operation, two adjacent pixels, for example 1 and 2, 3 and 4, etc., are transferred to a single shift register cell on one field, and in the next field pixels 2 and 3, 4 and 5, etc., are transferred together. This is rather similar to the interlaced operation of a frame transfer CCD. The primary advantages of the ILT sensor are low noise and good exposure control, providing true *stop-motion* control on every field, because all photosites integrate light over the same period of time. Many companies manufacture ILT CCD sensors and cameras, including Hitachi, NEC, Panasonic, Pulnix, and Sony.

The frame transfer and interline transfer approaches both have performance advantages and disadvantages, and the hybrid frame-interline transfer (FIT) approach [11] combines some of the advantages of both. This architecture includes a light-shielded field storage area between an interline imaging area and the horizontal output shift register. With this arrangement, the charge associated with the whole image is first transferred horizontally into the interline storage area, which facilitates exposure control. The charge is then transferred at maximum speed (as in the FT sensor) into the field storage area, which minimizes the occurrence of vertical streaking. For example, the NEC microPD 3541 array clocks the vertical registers at 100 times the normal rate for an ILT sensor. This gives a 20-dB improvement in streaking threshold and an overall threshold of 80 dB, making streaking effects less than other optical effects such as lens flare. On the other hand, the FIT approach does not improve the fill factor, and aliasing artefacts associated with ILT sensors and the noise levels are somewhat higher, and the CTE reduced, because of the higher clock frequencies. Manufacturers of FIT sensors and cameras include JVC, Panasonic, and Sony.

Photodiode Arrays

Because photodiode arrays generally have less extensive electrode structures over each sensing element compared with CCD arrays, the spectral response is smoother and extends further at the blue end of the spectrum. The peak quantum efficiency is also higher ranging from 60 to 80% compared with 10 to 60% for photogates, leading to almost twice the electric output power for a given light input power. Photodiode arrays would therefore appear to be attractive alternatives to CCD array sensors but, in practice, CCD sensors have lower noise levels because they do not have reverse-bias leakage current. A photodiode consists of a thin surface region of P-type silicon formed in an N-type silicon substrate. A negative voltage applied to a surface electrode reverse-biases the P-N junction and creates a depletion region in the N-silicon containing only immobile positive charge. When the electrode is isolated, the P-N junction is left

charged and is effectively a charged capacitor. Light penetrating into the depletion region creates electron-hole pairs which, with dark current, discharge the capacitor linearly with time. The penetration depth in silicon increases with wavelength and the depletion region should be wide enough to absorb all wavelengths of interest. Dark current and most of the noise sources operating in the photodiode increase with reverse bias but can be reduced by employing a thicker P-type region which allows a wide depletion region to be achieved with low bias voltage. However, this also degrades the blue-end response of the photodiode. To achieve good blue and UV response along with low bias voltage operation, a three-layer structure comprising thin P-type, intrinsic, and N-type substrates is employed. The intrinsic layer is so pure that the depletion region extends halfway across it at zero bias and extends right across it at a small reverse bias voltage. This structure provides photodiodes with excellent linearity, noise performance, and speed of response at low operating voltages. At the end of an integration period, the states of charge of the photodiodes are measured, and image sensors based on two different types of readout approach are commercially available. These are the serially switched (sometimes called self-scanned) photodiode (SSPD) arrays and the charge-coupled photodiode (CCPD) arrays illustrated in Figure 64.6.

Serially-Switched Photodiode Arrays

Associated with each photodiode in the sensor array is an MOS (metal-oxide semiconductor) switch which, when turned on by a digital voltage level applied to its control line, connects the photodiode to a readout amplifier. Each control line is connected to one of the outputs of a digital shift register and, shifting a bit through the register, sequentially reads the charge on each photodiode in the array. This type of readout is very flexible, and random readout is achieved by replacing the digital shift register by an address decoder connected to an address bus as in the SR series linear arrays from EG&G Reticon. 2-D arrays of photodiodes are connected in a configuration similar to a cross-point switching matrix with a switch and diode at each cross point and separate vertical and horizontal shift registers. To scan the array, the vertical shift register turns on a complete row of switches, which causes the photodiodes in the corresponding row to dump their charge into vertical signal lines. These are in turn connected to the output amplifier by a set of horizontal switches controlled by the horizontal shift register. Switched arrays of photodiodes are made using processes similar to those employed in the manufacture of dynamic RAM, and this along with their simple structure and small size, yields higher densities and lower manufacturing costs. However, the SSPD approach has one shortcoming, namely the large capacitances of the readout buses. This reduces the speed of the device, increases the noise, and reduces the dynamic range, which are all generally significantly worse than those of CCD sensors. The dynamic range for

FIGURE 64.6 Readout architectures associated with photodiode array sensors. In the SSPD approach shown, each photodiode is connected in turn via an MOS switch to the sensing amplifier. This eliminates smearing, because the charge does not move between photosites. The device noise and speed characteristics are poorer than CCD sensors because of nonuniformity in the MOS switches and the large capacitance of the sensing bus. The CCPD approach combines the excellent blue end response of the photodiode with the low noise transfer characteristics of the CCD shift register to produce very high-quality linear devices.

example is typically 250 to 300 compared to more than 2500 for commercially available CCD sensors. SSPD arrays also suffer from fixed-pattern noise due to nonuniformities in the switches, which can be as high as 20% of the saturated output. The SSPD approach does have unique advantages:

- The readout method is extremely flexible and can be programmable.
- It is relatively free from blooming effects, because the sensors can be optimally isolated from each other.
- The blue response is good, which is particularly important for spectroscopic applications and for studio quality color television cameras.

Manufacturers supplying SSPD-based sensors include EG&G Reticon, Hamamatsu and VLSI Vision.

Charge-Coupled Photodiode Arrays

Although individual photodiode elements are superior to individual CCD photogate elements in terms of dynamic range, the dynamic range of the SSPD is limited by fixed pattern noise, switching noise and the difficulty of transferring charge packets over the high capacitance output bus. Replacing the horizontal digital shift registers by a low noise CCD shift register significantly improves the dynamic range of the device and the resulting hybrid design is the charge-coupled photodiode array. During operation, the charges on an entire row of photodiodes are simultaneously transferred via MOS switches into the analog CCD shift register and then shifted out in sequence to the output amplifier. By providing a reset pulse (from a second vertical digital shift register) to eliminate all pre-stored charge in one row a fixed interval before the charge is transferred to the CCD shift register, it is relatively easy to implement an electronic equivalent of a focal plane shutter [12] and control exposures in increments of one horizontal scan period. However, images of moving objects will be subject to distortions similar to those found using photographic cameras with focal-plane shutters. In the case of 2-D arrays there are inefficiencies in the movement of small charge packets over the vertical transport lines which get worse the smaller the packet. The solution adopted is to turn a small charge into a large one by pre-charging the lines with a priming charge equal to 10 to 15% of the maximum charge capacity before transferring the photo-charge to the CCD in a process known as charge-primed transfer. This requires several MOS switches forming a sequence of transfer gates and storage capacitors between each vertical transport line and CCD cell and depends critically on correct phasing of a large number of timing signals for proper operation. The CCPD approach appears to be most successful for linear arrays which do not require a vertical transport bus. Manufacturers supplying linear CCPD based sensors include Dalsa and EG&G Reticon.

64.3 Image Intensifiers

When the available solid-state image sensors do not have enough sensitivity for the scene illumination, it is necessary either to use a more sensitive tube camera or to amplify the available light. Companies supplying intensified cameras include Cohu, Kodak, Pulnix, and Philips. Intensified cameras are standard video cameras fitted with image intensifiers that increase the number of available photons falling onto the image sensor. In addition to allowing operation over a wide range of lighting of the order of 0.0001 lux from overcast starlight to 100,000 lux of full sunlight, intensified cameras can be used to stop motion in nanosecond frame times, count photons, and observe images with very high intrascene dynamic ranges. However, this increased flexibility is achieved at a considerable increase in cost, usually some loss in resolution, reduced lifetime, and increases in geometrical distortion, lag, and smear. Image intensifier tubes (IITs) are usually classified as generation I, II, and III devices.

Generation I Tubes

In a generation I intensifiers, illustrated in [Figure 64.7](#), the incoming photons strike a multi-alkali photocathode within a vacuum tube, and the resulting photoelectrons emitted into the vacuum are accelerated and focused onto a phosphor coating on the rear wall of the tube. The impact of the high-energy

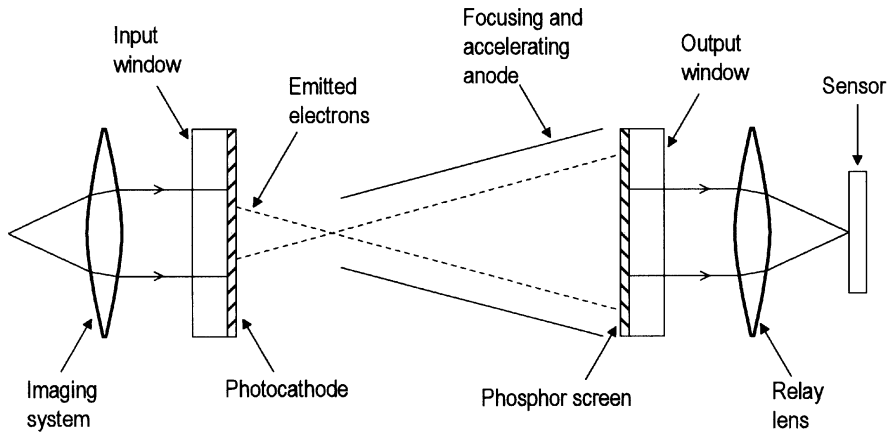

FIGURE 64.7 A schematic diagram showing the major components of a generation I image intensifier tube coupled to a sensor. Combined with a CCD sensor, the sensitivity of a SIT tube camera is achieved but with much higher reliability and greatly reduced lag, geometrical distortion, and power consumption. An example is the Cohu 5512 generation I optical-fiber coupled intensified CCD camera, sensitive down to 0.00015 lux and with 460 TV lines horizontal resolution, currently costing about \$12,000.

electrons on the phosphor creates many electron-hole pairs that in turn generate light at a higher level than that striking the photocathode. The electron gain depends strongly on the accelerating voltage and also on the photocathode and phosphor materials, and it is typically around 200 with a 12 kV accelerating voltage. These tubes tend to be bulkier than later-generation tubes and have relatively low gains, although tubes can be cascaded to achieve higher gains. They are also relatively intolerant of bright sources and rapid changes of scene illumination, with increased tendency toward highlight blooming. The light output from the intensifier tube is transferred to the solid-state sensor by either a relay lens or a fiber-optic coupler. The latter is shorter and much more efficient (typically 60% compared with 6%), but requires a sensor whose protective glass or quartz window has been replaced by the fiber-optic coupler resting against the sensor surface. The narrow gaps between couplers and between the coupler and sensor are filled by an index-matching optical grease. The spectral response of the photocathode should be chosen to match the scene requirements, while the narrower phosphor response should be optimally matched to the image sensor for greatest sensitivity [13]. In general, for largest output, a phosphor with the maximum persistence that is acceptable in terms of image lag should be selected. But, if the scene includes object motion, a shorter-persistence phosphor may be necessary to avoid image smear. For night vision, P20 and P39 phosphors are frequently used. The former emits 550 nm light with very high luminous efficiency (65%) and relatively short persistence (0.2 ms), while the latter has a persistence of about 80 ms, which reduces high-frequency jitters. For high-speed imaging, the yellowish-green P46 phosphor has a persistence of only 0.16 μ s, while the purplish-blue P47 phosphor has a persistence of only 0.08 μ s. However, both these phosphors have luminous efficiencies of only 3%. The resolution of an intensified camera is generally quoted in line pairs per millimeter (lp/mm) and is the harmonic mean of the individual resolutions of the intensifier (typically 20 to 30 lp/mm), the coupler (typically 80 lp/mm), and the image sensor (typically 20 to 50 lp/mm).

Generation II and III Tubes

Generation II intensifiers are similar to generation I devices except that gain is achieved using a micro-channel plate (MCP) instead of an accelerating potential difference in vacuum (see Fig. 64.8). Generation III intensifiers are similar to generation II except that the multialkali photocathode is replaced by a gallium arsenic solid-state structure. The resulting device has double the gain of a type II device and improved SNR and resolution. The heart of both types is an MCP disk about 25 mm dia. and 0.5 mm thick, consisting of an array of millions of glass tubes (called *microchannels*) with holes about 10 μ m diameter

FIGURE 64.8 The basic components of a generation II or III intensified-image sensor. These are typically two and four times more sensitive than generation I intensifiers. Narrow vacuum gaps between the photocathode, microchannel plate, and phosphor screen achieve proximity focusing. An example is the Philips I800 low-light video camera, which couples an XX1410 generation image intensifier with an FT800 1/2-in., 760×576 resolution frame-transfer CCD at a cost of around \$8000.

coated with a secondary electron emitting substance. The two faces of the MCP are coated with conducting layers, allowing a voltage (typically 50 to 900 V) to be applied between the entrance and exit of each microchannel. An energetic electron from the photocathode enters a microchannel and produces secondary electrons on striking the wall. These electrons are accelerated by the axial electric field and, in turn, dislodge more secondary electrons. This process is repeated many times down the channel. The number of electrons continues to increase until either the end of the channel is reached or current saturation occurs because the electron cloud is so dense that it inhibits further secondary emission. The electrons exit the MCP and may be accelerated further before striking a phosphor screen. The light generated is then transported to the image sensor by fiber-optic couplers. A thick phosphor layer increases light gain but allows electrons and light scattering in the phosphor, which causes some loss of resolution. Improved performance is achieved by integrating the phosphor into the fiber-optic bundle in a so-called *intagliated construction*. Each glass core in the fiber-optic bundle is etched out to a predetermined depth, leaving a small cup of cladding glass at the entrance to each fiber, which is filled with phosphor. Electrons striking the phosphor produce light that is confined to one fiber, minimizing crosstalk and improving resolution. The overall light amplification achieved is of the order of 10^4 , and higher gains can be achieved by stacking multiple MCPs and by increasing the accelerating voltages. The MCP has a nonlinear response, because the current density increases at an exponential rate until limited by saturation. The IIT can be gated in only a few nanoseconds by pulsing the cathode potential from the cutoff level (a few volts positive) to the normal operating voltage. This provides a high-speed shutter capability for stopping motion as well as a means of exposure control. Generation II devices have high gain and dynamic range and are easy to gate on and off, but they have relatively low output levels compared with generation I devices. The Kodak EktaPro 1000 high-speed video camera uses a generation II intensifier as a high-gain first stage coupled to a generation I intensifier to provide the required level of light output.

64.4 Fiber Optic Scopes

It is sometimes necessary to acquire images within confined and inaccessible spaces. In some cases, this can be achieved with the aid of mirrors, but when the image must be conducted around bends, a fiberscope may be needed. This consists of a semirigid flexible sheathing around a bundle of optical fibers, each about $10 \mu\text{m}$ diameter aligned coherently so that fibers have the same relative location at entrance and exit of the bundle. An image formed on one end of the bundle therefore appears undistorted but dimmer

at the other end. Between 20 and 35% of the bundle face area consists of fiber cladding and epoxy filler and does not transmit light. Light passing through fiber cores suffers Fresnel reflection losses of about 4% on entering and leaving, and attenuation within the fibers of the order of 10 to 15% for each meter of length. A 1 m fiberscope therefore transmits only about 40 to 60% of the incident light. Fiberscopes range in diameter from about 2 to 18 mm and in length from about 0.6 to 3 m, with a minimum bend radius of about 75 mm for an 8 mm insertion diameter tube. To illuminate the object, a coaxial arrangement of fibers is often used, as in the flexible boroscope marketed by Edmund Scientific. The inner fibers are used for imaging, while fibers in the outer, noncoherent bundle are used to transport light to the object. Alternatively, a separate fiber-optic light guide may be used. Fiberscopes may be fitted with optics for viewing in the forward, oblique, side, and rearward directions but may not allow easy quantitative measurements of distances and areas because of distortions introduced by wide-angle optics. Fiberscopes are generally supplied with an eyepiece for direct observation, but C-mount couplers are often available to allow a CCD camera to be connected.

64.5 Components and Trends

A wide range of image sensors and cameras based on tube and solid-state technologies is now available, and a few examples are listed in [Table 64.1](#) to give an indication of some of the currently available devices and their approximate prices, if purchased in the U.K. It is advisable to contact local suppliers to determine actual prices and availability. Contact information for some companies is listed in [Table 64.2](#). Manufacturers are continuing the incremental development of sensors with greater resolutions, readout rates, and signal-to-noise performances, and new application areas such as high-definition television (HDTV) and digital photography should cause prices to come down as the markets for these products expand. Some examples of this type of development are as follows.

- EG&G Reticon is currently developing a 1000 frames per second, 1024×1024 interline-transfer CCD sensor for high-speed imaging.
- Thomson Components (France) has developed the THX-31163 CCD sensor specifically for use in HDTV. This chip is designed to output 1152×1260 pixel frames in 40 ms at a transfer frequency of 47 MHz.
- Manufacturers such as Kanimage, Kodak, and Leaf Systems supply digital cameras based on very high-resolution area array sensors. The Kodak professional range of color and monochrome digital cameras, for example, incorporate CCD full-frame transfer sensors with resolutions ranging from 1024×1536 to 2036×3060 into standard 35 mm photographic cameras.

A separate trend is the development of smart cameras and smart sensors [14] for industrial and scientific applications. There are two basic motivations. One is to correct for imperfect behavior of sensors (such as pixel to pixel nonuniformity associated with MOS devices), and the other is to reduce the communications or processing bottlenecks associated with handling very large amounts of image data. A smart camera is a single-image acquisition subsystem incorporating image sensor, analog-to-digital conversion, and microprocessor that provides processed image data in a standard format such as SCSI or RS-423. Pulnix already supply a series of smart linescan cameras that implement application functions such as object detection, size measurement, and go, no-go comparison. Another example is the imputer 3 [15] from VLSI Vision incorporating a CMOS (complementary MOS) area sensor with 512×512 digital resolution and an i960 32-bit reduced instruction set processor. Using VLSI technology, but not CCD technology, it is possible to integrate both image acquisition and low-level processing onto a single chip to achieve a kind of electronic retina. One way of constructing such chips is to integrate photodetector and processing element at the photosite, but this produces very poor fill factors. This can be alleviated to some extent by using microlenses to focus the light onto the sensitive region. An alternative approach is to implement the photodetection and processing as separate arrays on the chip. This allows a large fill

TABLE 64.1 Cameras, Sensors, and Other Components

Manufacturer	Designation	Function	Specification	Approximate price
Cohu	4712	Monochrome TV camera	1/2-in. FT CCD, 754 × 484 pixels, 0.04 lux minimum, RS-170 output	\$2,000
Cohu	4110	Digital output camera	1/2-in. FT CCD, 755 × 484 pixels, 0.01 lux minimum, 8-bit per pixel RS-422 outputs	\$4,000
Cohu	4912	Monochrome TV camera	1/2-in. ILT CCD, 768 × 494 pixels, 0.02 lux minimum, RS-170 output	\$1,000
Cohu	2252	Color TV camera	1/2-in. microlens ILT CCD, CMYG mosaic filter, 0.3 lux minimum, NTSC/Y-C/RGB outputs	\$1,400
Edmund Scientific	A52999	Fiberscope	8 mm diameter, bend radius 75 mm, 60° field, 10 to 100 mm focus	\$1,200
EG&G Reticon	D Series	Line sensors	256, 512, 1024, or 2048 pixel CCPD arrays	\$80 to \$2,400
EG&G Reticon	LC1911	Line scan camera	10 MHz data rate, D series sensors, RS-422 outputs	\$2400
EG&G Reticon	RA1001	Area sensor	FF CCD, 1024 × 1024 pixels, dual outputs, 30 frames per second	\$2,500 to \$16,000, depending on grade
EG&G Reticon	TD Series	TDI CCD array	1024 × 96 pixels, single output	\$400
Hamamatsu	S5464-1024Q	Spectroscopic line sensor	CMOS SSPD 1024 array, 2.5 mm by 25 μm pixels, quartz window	\$1,600
Kodak	DCS 410	Color digital camera	FF CCD, 1524 × 1012 pixels, mosaic filter, Nikon N90S camera	\$8,800
Kodak	DCS 460	Color digital camera	FF CCD, 3060 × 2036 pixels, mosaic filter, Nikon N90S camera	\$4,0000
Panasonic	GP-US502	Remote head color camera	3 1/2-in. ILT CCDs, 768 × 494 pixels, 3 lux minimum, NTSC/Y-C/RGB outputs	\$7,500
Philips	XX1410	Intensifier	18 mm generation II	\$1,600
Philips	XQ3427	Tube	2/3-in. plumbicon, 400 TV lines at 55% modulation	\$3,200
Philips	XQ1270	Tube	2/3-in. vidicon, resolution 500 TV lines	\$120
VLSI Vision	Imputer 3	Intelligent camera	2/3-in. CMOS sensor, 512 × 512 × 8-bit, 32-bit RISC CPU	\$4,000
VLSI Vision	IDS	Development system	Software and hardware to create Imputer 3 applications	\$7,200

65.1 Radioactivity

Radioactivity is the phenomenon of emissions of neutral or charged particles, or electromagnetic radiations from unstable atomic nuclei. The more common types of radiations are listed in [Table 65.1](#). Several naturally occurring (primordial) radionuclides and some produced by cosmic rays in the earth's atmosphere are given in [Table 65.2](#). Methods of producing other unstable nuclei are discussed below. Radioactive isotopes from man-made sources and from naturally occurring nuclides are widely used in health sciences, industry, and academic research.

TABLE 65.1 Characteristics of Nuclear Radiations [8]

Type	Origin	Process	Charge	Mass [MeV]	Spectrum (energy)
α -particles	Nucleus	Nuclear decay or reaction	+2	3727.33	Discrete [MeV]
β^- -rays (negatrons)	Nucleus	Nuclear decay	-1	0.511	Continuous [keV-MeV]
β^+ -rays (positrons)	Nuclear	Nuclear decay	+1	0.511	Continuous [keV-MeV]
γ -rays	Nucleus	Nuclear deexcitation	0	0	Discrete [keV-MeV]
X-rays	Orbital electrons	Atomic deexcitation	0	0	Discrete [eV-keV]
Internal conversion electrons	Orbital electrons	Nuclear deexcitation	-1	0.511	Discrete [high keV]
Auger electrons	Orbital electrons	Atomic deexcitation	-1	0.511	Discrete [eV-keV]
Neutrons	Nucleus	Nuclear reaction	0	939.57	Continuous or discrete [keV-MeV]
Fission fragments	Nucleus	Fission	$\cong 20$	80-160	Continuous (bimodal) 30-150 MeV

Radioactivity was first discovered by Henri Becquerel in 1896. His student Marie Curie and her husband Pierre Curie were the first to chemically separate the radioactive elements polonium and radium. Becquerel and the Curies received the Nobel Prize in physics in 1903 for their pioneering work in nuclear and radiochemistry. The historical development of the field of radioactivity is covered in a number of

TABLE 65.2 Some Cosmogenic and Naturally Occurring Radionuclides

Radionuclide	Half Life
^3H	12.35 years
^7Be	53.3 days
^{14}C	5730 years

standard texts, including *The Atomic Nucleus* [1] and *Radioactivity and Its Measurement* [2], and in *Radioactivity Measurements: Principles and Practice* [3]. Other excellent texts are available for students in nuclear medicine [4], in radiochemistry and nuclear chemistry [5, 6], in nuclear and particle physics [7, 8], and a popular general textbook *Radiation Detection and Measurement* by Knoll [9] for nuclear engineering and health physics.

Radioactivity is defined by the International Commission on Radiation Units and Measurements [10] in terms of the *activity*, A , of an amount of a radionuclide in a particular energy state at a given time. Mathematically, it is defined as the quotient of dN by dt , where dN is the number of spontaneous nuclear transformations from that energy state in the time interval dt , thus

$$A = \frac{dN}{dt} \quad (65.1)$$

The unit of activity in the International System (SI) of units is the becquerel (Bq), which is equal to the unit reciprocal second (s^{-1}). In many fields the older unit, the curie (Ci), is still in use, where $1 \text{ Ci} = 3.7 \times 10^{10} \text{ Bq}$ (exactly).

The activity of an amount of radionuclide is given by the product of the decay constant, λ , and the number of nuclei present at time t , thus

$$A = \lambda N \quad (65.2)$$

The reciprocal of λ is the mean life of the nuclide. More commonly, one computes the time necessary for one half of the nuclei to decay, and since this is an exponential process, the half-life is given by

$$T_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.69315}{\lambda} \quad (65.3)$$

The activity at any time t can be computed using the initial activity A_0 and the decay time t according to

$$A = A_0 \exp\left(-0.69315 \frac{t}{T_{1/2}}\right) \quad (65.4)$$

The term *specific activity* is in use in several applied fields and one should be careful to look at the units in any particular application. It is normally defined in terms of the amount of activity per unit mass of the element. For example, the nominal activity of ^{14}C in modern carbon (that found in the biosphere) is 0.3 Bq g^{-1} . In nuclear medicine, however, specific activity is widely used to express the amount of activity per unit quantity of the radioactively labeled compound. For example, one might

produce ^{11}C in a cyclotron and oxidize it to carbon monoxide CO with a specific activity of $1 \text{ MBq } ^{11}\text{C } \mu\text{mol}^{-1}$ (CO) (megabecquerel of activity per micromole of substance).

Stable nuclei are those nuclei in their ground state that have a proper number of neutrons and protons to balance the nuclear forces between constituents and thus do not decay spontaneously. Radioactive nuclei may be divided into three categories:

- those that have an excess of neutrons over protons,
- those that are neutron deficient, and
- those that are in excited nuclear states.

A schematic showing the most prominent simple transformations between elements of atomic number Z and neutron number N are given in Figure 65.1. The atomic number Z is the number of protons, and the isotopic mass number A is the total number of nucleons (protons plus neutrons). The notation for an isotope—for example, one of krypton—is ^A_ZKr . In this chapter, isotopes will be identified only by the mass number and the element symbol, e.g., ^{241}Am .

Particle Emission Radioactivity

Alpha particles are ^4He nuclei (2 protons plus 2 neutrons) and are usually emitted by heavy nuclei ($A > 150$). Alpha particles are monoenergetic and usually have energies between 4 and 6 MeV. Table 65.3 lists several alpha emitters, including some at lower and higher energies that can be used for the energy calibration of instruments. Alpha particles carry a +2 charge, and their detection with a variety of instruments is described in detail in Chapter 67, on charged-particle detectors. Alpha-particle pulse-height distributions for several radionuclides of interest in the nuclear fuel cycle are shown in Figure 65.2. The alpha-particle pulse-height distribution for an ^{241}Am source obtained with a high-resolution detector is given in Chapter 66 (Figure 66.16).

TABLE 65.3 Alpha-Particle-Emitting Radionuclides

Radionuclide	Half-Life	Energies (MeV)
^{148}Gd	90 years	3.183
^{241}Am	432.2 years	5.486, 5.443
^{210}Po	138 days	5.305
^{242}Cm	163 days	6.113, 6.070

FIGURE 65.1 Characteristics of nuclear radiations [8].

FIGURE 65.2 Liquid-scintillation spectra of selected actinides using a single-phototube detector with the peak channel counts for each major peak preset to 40,000 counts [11].

Beta particles are high-energy electrons emitted by the nucleus as a result of the “weak force” interactions in nuclei that contain too many or too few neutrons. For a system with excess neutrons, the neutron is transformed into a proton and in the process an electron and an antineutrino $\bar{\nu}$ are emitted

The proton remains behind in the nucleus. The antineutrino is required to maintain the conservation of momentum, energy, and “weak-interaction” quantum numbers with respect to the emitted electron [5]. The emitted negatively charged beta particles, usually denoted as β^{-} , have a continuum of energies from zero to a maximum energy denoted by $E_{\beta_{\max}}$. $E_{\beta_{\max}}$ is the total energy available for the kinetic energy of the electron. The antineutrino carries away that portion not transferred to the electron. An example of an emission spectrum for ^{32}P is given in Figure 65.3. The mode of decay for neutron deficient nuclei is quite similar, except that the proton is converted to a neutron with the emission of a positive electron or *positron* (β^{+}) and a neutrino, which may be written as

FIGURE 65.3 Theoretical distribution of beta particles as a function of energy for ^{32}P [12].

Although it is unusual, some radioisotopes decay by both negatron β^- and positron β^+ emission. For example, in the decay of the 13-day half-life ^{126}I one has

Table 65.4 gives a short list of pure beta-particle emitters.

TABLE 65.4 Pure Beta-Particle-Emitting Radionuclides

Radionuclide	Half-Life	Maximum Energy (keV)	Average Energy (keV)
Negatron (β^-) Emitters			
^3H	12.35 years	18.6	5.69
^{14}C	5730.0 years	156.5	49.5

^{22}Na	2.602 years	545	216

a. These nuclides exhibit a small amount of electron-capture (EC) decay.

Neutrons are constituents of the nucleus that have a mass number of unity and carry no charge. In normal radioactive decay processes, neutrons are not emitted from the nucleus. With energies exceeding

a few million electron volts (MeVs), however, one can add sufficient energy to cause a neutron to be ejected from the nucleus. These energies can be attained by bombardment with alpha particles from radioactive decay, which is the basis for the common neutron source americium-beryllium (AmBe) in which the alpha particles from the ^{241}Am induce neutron emission from the ^9Be nucleus:

In this case, the ^{13}C nucleus is formed in a highly unstable excited state and rapidly disintegrates by several processes, all of which lead to neutron emission. The neutron spectrum from a $^{241}\text{AmBe}$ source is shown in Figure 65.4. It is very difficult to measure neutron spectra directly, because it is necessary to deconvolve a complicated detector response. Figure 65.4 is the “standard” spectral shape recommended in recent national and international standards [13, 14]. The units on the y -axis are explained in Reference 13.

Neutrons are also readily produced in high-energy particle accelerators. Various combinations of accelerated particles and target materials are used to produce neutron beams with selected energies (e.g., 2 and 14 MeV). Neutrons from isotopic sources, accelerators and nuclear reactors can then be used in such applications as boron neutron capture therapy to treat cancer, or in metal fatigue analysis. The neutrons can also be used to produce radionuclides for other applications.

Protons with unit positive charge and unit mass number are simply ^1H nuclei stripped of the single orbital electron. Spontaneous emission of protons by nuclei is an exotic decay mode that has been

FIGURE 65.4 Neutron spectrum of an $^{241}\text{AmBe}$ radioisotopic source as given in the American National Standard [13] and the International Standard [14]. The units used on the y -axis are explained in Reference 13.

observed in only a few cases involving extremely neutron-deficient nuclei [15]. However, beams of protons can be made in positive-ion, charged-particle accelerators by injecting high-purity hydrogen gas, stripping the electrons, and then accelerating the protons to high energies. When these protons are incident on stable target nuclei, a variety of nuclear reactions are possible. The product nuclides are normally radioactive and neutron deficient.

Fission fragments are the large-mass debris formed when a high-Z nuclide such as ^{235}U spontaneously (or by absorption of a slow neutron) breaks up into two or more smaller nuclides in a process known as nuclear fission. The best known fissionable nuclei ^{235}U and ^{239}Pu fission as a result of capturing a neutron. For a given nucleus, the fission fragments are distributed according to a mass distribution which has two maxima. For ^{235}U fission, the maxima occur at $A = 90$ and $A = 130$, resulting in fission-product radionuclides such as ^{90}Sr , ^{95}Zr , ^{131}I and ^{137}Cs . A small number of high-Z radionuclides decay by spontaneous fission (e.g. ^{248}Cm). This decay process usually competes with alpha-particle decay and is mostly limited to high-Z nuclides.

Electromagnetic Emission Radioactivity

Gamma rays are photons emitted during nuclear deexcitation processes. These gamma-ray transitions may be from a metastable excited state, or between levels in a daughter nucleus. Two examples are shown in Figure 65.5 for the 6-hour half-life $^{99\text{m}}\text{Tc}$ and the 2-day ^{111}In . The large majority of gamma rays from fission products and man-made radionuclides have energies between 20 keV and 2 MeV. A list of gamma-ray emitters used for instrument calibrations are given in Table 65.5. The probability of gamma-ray emission in a particular radionuclide decay (P_γ) is also given in the table. The rate of gamma-ray emission is given by the product $P_\gamma A_0$.

FIGURE 65.5 Simplified nuclear decay schemes for the radionuclides $^{99\text{m}}\text{Tc}$ and ^{111}In . The vertical arrows indicate transitions between nuclear excited states. Gamma-ray emission competes with internal conversion processes for each transition [8].

TABLE 65.5 Gamma-Ray-Emitting Radionuclides Used for Detector Efficiency Calibrations

Radionuclide	Half-Life (days)	Energy (keV)	Gamma Rays per Decay, P_γ
^{109}Cd	462.6	88	0.0363 ± 0.0002

Characteristic **X-rays** are photons emitted during atomic relaxation processes. X-rays are emitted from radionuclides when electrons are involved in the high-energy processes in the nucleus. In the *electron capture* process, for example, the nucleus captures an electron (usually a *K*-shell electron, since it is closest to the nucleus), and a proton and electron form a neutron. This process leaves a *K*-shell vacancy, and a characteristic X-ray from the daughter nucleus can be emitted as orbital electrons from higher shells fill the vacancy. An example is the decay of the 2.6-year half life ^{55}Fe

The rate of Mn *K* X-ray emission from an ^{55}Fe source of activity A_0 is

$$N_K = P_{KX} A_0 \quad (65.13)$$

where P_{KX} = probability of *K* X-ray emission.

Conversion electrons are monoenergetic electrons emitted from the nucleus in isomeric transitions between nuclear levels. Conversion-electron emission competes with gamma-ray emission as a mode of nuclear deexcitation.

Interactions with Matter

Before examining in detail the manner in which ionizing radiations can interact, consider two sources of photon radiations, annihilation radiation and bremsstrahlung, which are associated with radioactive decay but depend on the material in which the decay process occurs.

Annihilation radiation is a form of photon radiation associated with a class of radioactive decays. Positrons, since they are the antiparticles of ordinary electrons, cannot survive long in normal matter. Thus, positrons emitted during radioactive decay will slow down in matter until they reach thermal equilibrium. (Depending on the material, they may exist for some microseconds in a state of matter known as positronium.) Ultimately, they combine with an electron in an annihilation event in which their combined mass (1.022 MeV) is converted to energy. This takes the form of two annihilation quanta of 0.511 MeV each which are oppositely directed (to ensure the conservation of momentum). Depending on the positron energy and the density and thickness of the stopping material, there is a slight but calculable probability of *annihilation in flight* [1]. These decays do not result in characteristic 0.511-keV quanta.

Bremsstrahlung is the photon radiation emitted by the deceleration of an electron in the Coulomb field of an atom. Thus, bremsstrahlung radiation is present during all beta decay processes as the emitted β particles (both negatrons and positrons) slow down in matter; it has a continuum of photon energies extending up to the maximum beta-particle energy. The shape of this continuum depends on the nature of the stopping material, as is described in the following section. Bremsstrahlung radiation represents a

particular safety hazard for high-energy pure-beta particle emitters such as ^{32}P (14.4 day, 1.710 MeV β^- max). At higher energies, bremsstrahlung production is almost linear in electron energy and proportional to Z^2 of the stopping material. Thus, to minimize bremsstrahlung, one uses low- Z shielding materials such as plastic.

Now, consider the more general ways in which ionizing radiations from radioactive decay interact with matter. They interact by collisions with the electrons and nuclei along their path. The nature of these interactions is characterized by the charge, mass, and energy of the incident ionizing photon or particle, as well as the charge and mass of the traversed matter. In the energy region of interest, electromagnetic radiation (gamma-ray and X-ray photons) interact with matter principally by three processes: photoelectric absorption, Compton scattering, and pair production. In the photoelectric process, which dominates at lower energies, the photon transfers its energy to an atomic electron, which is then ejected from the atom with an energy equal to that of the incident photon minus the electron's binding energy. In Compton scattering (incoherent scattering), the photon loses a fraction of its energy to an atomic electron, and the scattered photon emerges generally in a direction different from that of the incident photon. Higher-energy photons will undergo multiple Compton scatter events until the process is finally terminated by a photoelectric absorption. For photons with energies exceeding 1.022 MeV, the process of pair production can occur whereby an electron-positron pair is formed. The positron produced will ultimately annihilate with the production of two 0.511-MeV photons (or in flight). The three interaction processes compete as a function of photon energy, electron density, and nuclear charge of the stopping material. Above 2.044 MeV, triplet production can occur [16], but this is a low-probability process, and few radionuclides emit gamma rays above 2 MeV.

Quantitative measures of the photon interactions in matter are attenuation coefficients based on cross sections for specific interactions [8,9]. The total narrow-beam attenuation coefficient μ is given by the sum

$$\mu = \mu_{\text{photoelectric}} + \mu_{\text{Compton}} + \mu_{\text{pair production}}$$

The attenuation process for a beam of photons traversing a slab of matter is an exponential function of the form

$$I = I_0 \exp(-\mu l) \quad (65.14)$$

where I and I_0 = intensities of the transmitted beam and the incident beam, respectively, l = distance traveled in matter, and μ = the linear attenuation coefficient. A useful procedure is to express distances in terms of the mass thickness—the product of density ρ and thickness l . The beam transmission equation can then be rewritten as

$$I = I_0 \exp\left[\frac{-\mu}{\rho}\right](\rho l) \quad (65.15)$$

where μ/ρ is the *mass attenuation coefficient*. The mass attenuation coefficient, in contrast to the linear attenuation coefficient, does not depend on the density of the absorber, but only on its composition. The mass attenuation coefficient as a function of energy for water and lead are shown in [Figures 65.6](#) and [65.7](#). This discussion of photon interactions has been limited to narrow-beam (or ideal) geometries. In practice, most radioactive sources emit a broad beam of radiation such that the detector registers not only events from the incident beam but also those scattered through large angles, and these effects must be included in computing detector response [9].

Charged particles interact with matter in many different ways. These include:

1. inelastic collisions involving ionization and excitation of atomic electrons of the material
2. inelastic collisions involving bremsstrahlung production in the field of the atom
3. elastic scattering in the field of the atom

FIGURE 65.6 Narrow-beam mass attenuation coefficients for water as a function of photon energy [17].

FIGURE 65.7 Narrow-beam mass attenuation coefficients for lead as a function of photon energy [17].

4. nuclear reactions
5. emission of Cerenkov radiation (photons in the visible and ultraviolet regions)

Electrons and positrons, due to their much smaller mass, behave differently from protons, alpha particles, and low- Z charged particles. Two quantitative parameters used to describe inelastic interactions of charged particles as they slow down in matter are *stopping power* and *range*. The total mass stopping power, S/ρ , is defined by the ICRU [10] as the quotient of dE by ρdl , where dE is the energy lost by a charged particle in traversing a distance dl in the material of density ρ . For energies for which the nuclear

interactions can be neglected, the total mass stopping power can be represented as the sum of an electronic (ionization and excitation) term and a radiative (bremsstrahlung) term as follows:

$$\frac{S}{\rho} = \frac{1}{\rho} \left(\frac{dE}{dl} \right)_{\text{elec}} + \frac{1}{\rho} \left(\frac{dE}{dl} \right)_{\text{rad}} \quad (65.16)$$

Figure 65.8 illustrates the contributions of the electronic term and the radiative term to the total mass stopping power for electrons in lead and water over the energy range from 10^{-2} MeV to 10^3 MeV. For alpha particles, the radiative term can be neglected, but the nuclear interactions cannot. The nuclear interactions are pronounced at lower energies, while at higher energies the inelastic collision process dominates. This is illustrated in Figure 65.9 for alpha-particle interactions in lead and water.

The range of a charged particle of a given energy in a material is an important parameter in designing detectors and shielding materials. In general, a charged particle does not travel in a straight line as it slows down. However, the total rectified path length traveled by the charged particle, called the mean range, is given by

$$r_0 = \int_0^E \frac{\rho}{S} dE \quad (65.17)$$

where E = incident electron energy. The range as given in Equation 65.17 has units of g cm^{-2} . Range in water and lead as a function of incident particle energy for electrons and for alpha particles is given in Figures 65.10 and 65.11, respectively.

Neutron Interactions

Since neutrons are uncharged, they can travel some distance in matter before they interact. This interaction is normally a “nuclear reaction” in which the neutron is absorbed, scattered, or produces a nuclear reaction. The probability of each of these interactions occurring is described by the capture, scatter, and nuclear reaction cross sections. Secondary particles produced by neutrons are usually high-energy charged

FIGURE 65.8 Stopping power for electrons in water and lead as a function of electron energy [18].

FIGURE 65.9 Stopping power for alpha particles in water and lead as a function of alpha-particle energy [19]

FIGURE 65.10 Range-energy curves for electrons in water and lead [18].

particles that are stopped in short distances in the stopping material. Neutrons from nuclear reactions normally start with energies of a few MeV. They are moderated by collisions with atomic nuclei until they experience a capture process. Capture cross sections for a given elemental stopping material exhibit resonances characteristic of specific nuclear excited states. The total neutron cross section of carbon as a function of neutron energy is shown in Figure 65.12 [20]. The structure in the cross section is the result of resonances in the compound nucleus formed by neutron interaction with ^{12}C . The intensity of a neutron beam in an absorber will decrease exponentially (analogous to a photon beam) with absorber thickness. The attenuation coefficient will include the scatter and capture components.

FIGURE 65.12 Total neutron cross section for carbon as a function of neutron energy [20]. The *barn* is the traditional unit of area used to describe neutron cross sections ($1 \text{ barn} = 10^{-28} \text{ m}^2$).

Radioactivity Measurements

Measurements of electromagnetic radiations and charged particles are discussed in Chapters 66 through 69. However, there are certain classes of instruments that are widely used for the measurement of radioactivity. Three examples will be dealt with here: alpha- and beta-particle liquid-scintillation spectrometers, high-purity germanium (HPGe) gamma-ray spectrometers, and gamma-ray dose calibrators.

Most liquid-scintillation spectrometers operate with two phototubes that view a cylindrical vial containing the radionuclide intimately mixed with an organic liquid scintillator [21, 22]. The radiations emitted during radioactive decay interact in the scintillator to produce light pulses that strike the photocathodes of the phototubes. The magnitude of the light pulse depends on the energy deposited by the radiation and on chemical and optical quenching processes [21]. The scintillation yield for high energy electrons (low dE/dx) for the best organic scintillators does not exceed 5 percent. That is, 5 percent of the deposited energy is emitted as photons in the near ultraviolet (~ 400 nm wavelength) and the remaining 95 percent is lost to radiationless transitions in the organic molecules. In real samples, this photon yield is reduced further through chemical processes (electron scavengers), and optical losses (colored samples, mismatches at vial interfaces, etc.). The counting efficiency for the two phototubes in coincidence is defined as the ratio of the counting rate to the activity. The counting efficiency approaches unity for beta particles with energies exceeding 20 keV [23]. For alpha particles, the efficiency is essentially unity (although the magnitude of the light pulse for alpha particles is less than that for beta particles due to the nature of the interactions of the particles with the organic scintillator). The counting systems are calibrated using standard solutions of known activity [22]. Since the pulse height is largely proportional to the energy of the incident particle, the signal from the counting system can be sorted according to pulse height in a multichannel analyzer (MCA). The pulse height spectra for a mixture of alpha-particle emitters is shown in Figure 65.13 [24]. In practice one obtains the area under the peak for a given radionuclide and divides by time to get the counting rate N_α . The activity A_0 is given by N_α/ϵ_c where ϵ_c is the coincidence counting efficiency.

The activity of mixtures of gamma-ray emitters is needed at many stages in the nuclear fuel cycle. For example, in measurements of environmental radioactivity, a gamma-ray spectrometer allows rapid determination of many fission and activation product nuclides in the presence of naturally occurring radioactivity. Both NaI(Tl) scintillation detectors and HPGe semiconductors are used for this purpose, and their design and operation are covered in Chapter 66. Gamma-ray spectra for a mixture of radionuclides with a semiconductor detector are shown in Figure 65.14 [22]. The detectors are calibrated using radioactivity standard sources prepared by the National Institute of Standards and Technology or one of the commercial secondary standards suppliers. A photopeak efficiency curve for a HPGe detector is shown in Figure 65.15.

FIGURE 65.16 A well-type ionization chamber used for the assay of single radionuclides in nuclear medicine [26].

Single radionuclides are widely used in many applications in health sciences. In nuclear medicine most samples are assayed in reentrant dose calibrators, which are essentially ionization chambers. In this counting geometry the sample is placed inside a well detector which is normally a sealed, pressurized argon gas, ionization chamber (See, for example, [Figure 65.16](#)). The photons emitted from the sample traverse the inner wall of the chamber and cause ionization events in the counting gas. The chambers typically operate at a few atmospheres pressure at a bias voltage of 600 to 1000 V. The charge created is subsequently collected at the anode. These chambers are designed to assay large amounts of activity such that the current from the device in picoamperes is proportional to the activity in megabecquerels. For a given radionuclide, the manufacturer can establish calibration factors for specific radionuclides in order to convert the current response of the chamber to a unit activity (pA MBq^{-1}). A dose calibrator response curve for gamma-ray emitters is shown in [Figure 65.17](#) [26].

Radioactivity was first discovered by Henry Becquerel in 1896 when he noticed that photographic plates became fogged after exposure to uranium atoms. In addition to uranium nuclei, many other naturally occurring and man-made isotopes are known to be radioactive and decay by emitting uncharged particles (gamma rays and neutrons) and charged particles (alpha or beta particles) from their nuclei. Over the past few decades, there has been a growing need for monitoring, locating, and imaging radioactive sources in a wide variety of medical, environmental, industrial, space, scientific, and national security applications. Many of the applications rely on the use of commercially available radiation detectors, whereas others require development of new detectors to meet system requirements related to sensitivity, power, size, portability, ruggedness, maintenance, radiation hardness, and energy resolution.

The signals generated by a radiation-sensing system depend on (a) the mechanisms in which the incident radiation interacts with the detector material and (b) the scheme used to readout the interaction. In general, there are three types of radiation sensors in use today: gas-filled detectors, scintillation devices, and semiconductor detectors. The types of radiation sensors can also be divided into two groups according to whether they can measure the energy of the emitted gamma-rays, X-rays, or charged particles. Whenever an energy-resolving capability is desired, a large number of information carriers must be generated for each absorbed pulse to reduce the statistical limit on energy resolution. This is best accomplished by use of semiconductor detectors, although some spectral information can be achieved through the use of scintillators and gas-filled detectors.

The typical unit of measure of radioactivity is the becquerel (Bq), which is defined as the rate of one disintegration per second of a decaying isotope. Another common measure of radioactivity is the curie, which can be obtained by multiplying the becquerel by 3.7×10^{10} .

This chapter is divided into sections on gaseous, scintillation, and semiconductor detectors. Separate sections describing semiconductor detectors that must be cooled to cryogenic temperatures for operation and those capable of operation at ambient temperatures are presented. There are several texts devoted to the subject of radiation detection [1–7], and the reader is directed to these books for more detailed information on the principles of detector operation, device performance, problems limiting detector performance, areas of current research and development, and applications.

66.1 Gaseous Detectors

Ionization in a gas resulting from the interaction of X and gamma radiation is the basis for a wide variety of radiation detectors. The versatility of gas phase detection arises from the great flexibility in detector sizes and shapes that can be produced, their relatively low production cost, and particularly, the ability to perform a multitude of measurement tasks. Gas detectors can be separated into three distinct types: ionization chambers, Geiger-Müller counters (tubes), and proportional counters with numerous variations of each type. All utilize the ions and electrons created by the interaction of an incident photon with the detector gas, directly or indirectly, to produce an output signal. They differ in the characteristics of the electric field and nature of the output signal.

Ionization chambers can be operated in either a current mode or pulsed mode, although the current mode is more common. They operate by collecting (with an applied electric field) all the charge generated by the original ionizing event and differ in this way from both proportional and Geiger-Müller counters. The latter, normally operated in a pulsed mode, have output signals that result from amplification of the original ion pairs by gas multiplication processes.

General Operating Principles

Fundamental to the operation of gas detectors is the generation of electron-ion pairs and their movement through the surrounding gas under the influence of an applied electric field. It is convenient to summarize basic features of these processes before turning to specific detector designs.

W Values

The energy (W) required to produce an electron-ion pair in a gas depends on the gas, the type of radiation (and its energy). W values for fast electrons in common filling gases range from 26.4 eV per ion pair in argon to 41.3 eV per ion pair in helium. The presence of nonionizing energy loss processes accounts for the W values greatly in excess of the ionization energy. Fluctuations in the number of pairs produced from photons of the same energy are of significance in pulse-mode operation. The variance is generally less than expected based on Poisson statistics and is accounted for by an empirical constant, the Fano factor (typically 0.1 to 0.2).

Charge Transport

The motion of free electrons and ions in the gas under the influence of the electric field (E) is quite different. The drift velocity (v) of the more massive ions is a linear function of E/p where p is the gas pressure. It can be expressed as

$$v = \frac{\mu E}{p} \quad (66.1)$$

The proportionally constant μ is the mobility, which depends on the type of gas and the charge of the ion. Values are typically in the region of 1000 cm²/V-s/mm Hg. The electron mobility is normally about 1000 times ion values; the electron drift velocity is not linear in E/p [8].

Electric Field Effects

The amplitude of a pulse resulting from the interaction of a photon with the wall or fill gas depends strongly on the voltage applied to the detector and serves to distinguish the three detector types. A plot of pulse amplitude as a function of applied voltage is shown in Figure 66.1. The plateau following the initial steep segment is the region of ion chamber operation. It is a region where the electric field is sufficient to reduce recombination of the original pairs to an acceptable value and further voltage increases yield no more charge (as it has all been collected) and ion saturation is established. Assuming complete charge collection, the output current accurately represents the rate ion pairs are being produced. This is the basis for ionization chamber operation.

The rapidly rising portion following the plateau marks the onset of gas multiplication (the initial electrons can acquire enough energy between collisions to generate further ionization). In the initial segment, the multiplication process is linear; that is, the charge collected is proportional to the number of original ion pairs. This is the defining characteristic of proportional counter operation. The proportionality eventually is ended at higher voltages by space charge effects caused by positive ions.

At yet higher voltages, the space charge becomes sufficient to reduce the electric field below the multiplication threshold and no further multiplication takes place. Thus, a condition is reached where the same number of positive ions are produced for all initial ion-pair populations, and the pulse amplitude is independent of the initial conditions. This characterizes Geiger-Müller counter operation.

Further details on the operation of these devices may be found in texts by Knoll [1], Price [9], Attix and Roesch [10], and Tait [11]. The monograph by Rossi and Staub [2] contains a lengthy discussion of ionization chambers together with data on the physics of the transport process.

Ionization Chambers

Ionization chambers have been designed for numerous X- and gamma-ray measurement applications. They are frequently employed in radiation survey instruments. They are found in parallel plate, cylin-

FIGURE 66.1 Distinct operating regions of gas-filled detectors. E_1 and E_2 depict pulses from photons of two energies.

drical, and spherical geometries. Essential features of their design can be found in the parallel plate chamber shown schematically in Figure 66.2. The design shown contains an optional guard ring that helps to define the active volume of the chamber. The ring is normally maintained near the collector electrode potential. (Guard rings are also employed in very low current designs to reduce leakage current.) Because the current for the ionization chamber is low, typically 1 nA or less, considerable care must be taken with the insulators to minimize leakage currents.¹

Because of the low output current, special care must be taken with the readout system. Both dc and dynamic-capacitor types are used. Only electrometers of the highest quality should be used. Dynamic-capacitor (or vibrating-reed) varieties provide more stable operation. They are normally the choice for very low current applications.

Several special-purpose ion chambers are notable. The “free air” chamber, a parallel-plate variant, is valued for accurate gamma ray exposure measurements, particularly when absolute measurements are required. This is achieved by collimation of the incoming gamma flux and by an internal design that ensures compensation for ionization produced outside the sensitive volume by secondary electrons. These chambers are limited to energies below about 100 keV, however. Cavity ionization chambers are widely used for dosimetry purpose. To function in this manner, it is necessary that they be designed to meet the requirement of the Bragg-Gray principle [12]. This states that the absorbed dose in a medium can be determined from the ionization produced in a small gas-filled cavity in the medium. The cavity dimension must be small compared to the range of the ionizing particles generated in the material so that the particle flux is essentially unperturbed. Of particular interest for health physics applications are

FIGURE 66.2 Schematic diagram of parallel-plate ionization chamber with guard ring defining active volume.

¹Note also that ionizing radiation can cause both permanent and transient resistivity losses in insulating materials and should be considered in high-flux or high-fluence applications.

tissue equivalent chambers where the wall material is a plastic that closely simulates the absorption properties of tissue.

Proportional Counters

Proportional counters utilize gas multiplication to amplify the charge of the initial ion pair population and have the important characteristic that the charge associated with the amplified pulse is proportional to the ion pairs produced initially. They are normally operated in a pulse mode. They can be operated sealed or in a gas flow mode. The sealed style is most common for X- and gamma-ray applications. While they are found in a number of geometries, cylindrical is the most common shape. A typical cylindrical design is shown in Figure 66.3. This relatively simple design features a central wire that is maintained at high voltage and a surrounding metal container that serves as the cathode. The electric field in this geometry is given by

$$E(r) = \frac{V}{r} \ln\left(\frac{b}{a}\right) \quad (66.2)$$

where V = anode-cathode voltage, a = anode wire radius, and b = inner radius of the cathode.

It should be noted that $E(r)$ depends on the diameter of the anode wire, allowing the threshold electric field needed for multiplication to be obtained at relatively modest voltages. The multiplication process is confined to a small volume surrounding the anode where the field exceeds the multiplication threshold. The characteristics of several common counting gases are given in Table 66.1.

TABLE 66.1 Characteristics of Common Proportional Counter Gases

Gas	W (eV per ion pair)	Fano Factor	Resolution (%) @ 5.9 keV	
			Calculated	Measured
Ne + 0.5% Ar	25.3	0.05	10.1	11.6
Ar + 0.5% C ₂ H ₂	20.3	0.075	9.8	12.2
Ar+ 10% CH ₄	26.0		12.8	13.2

Source: adapted from Knoll [1].

FIGURE 66.3 Schematic diagram of cylindrical proportional counter.

Proportional counters can be used for both photon and particle measurements. In photon applications they are particularly valued for spectroscopy in the low energy X-ray region. Their energy resolution and detection efficiency is generally inferior to semiconductor detectors such as lithium-drifted silicon or mercuric iodide but they offer large surface areas, reliable operation, and low cost. The energy resolution ΔE for given gas mixture for a specific photon energy can be estimated from the statistical limit given by

$$\Delta E = 2.35 \left[W \frac{(F + \beta)}{E} \right]^{1/2} \quad (66.3)$$

where F = Fano Factor, β = variance factor (typically about 0.5) [1], E = energy in eV, and W = energy in eV required to produce an ion pair.

Energy resolution for a proportional counter at 5.9 keV can be expected to be on the order of 10 percent (Table 66.1).

Geiger-Müller Counters

Geiger-Müller counters (more commonly known as G-M counters or tubes) remain among the most widely used means of detecting X and gamma radiation. They have high sensitivity, are rugged, and offer low cost. Also of importance is the large amplitude of the output pulse (several volts, typically), which greatly simplifies the readout. Because of these factors, they are the detectors of choice for a variety of commercial gamma survey instruments. Like proportional counters, they utilize gas amplification to generate an output pulse, although here the output is independent of the initial number of ion pairs. They are counters only and not applicable to spectroscopy. A G-M counter with typical readout is shown schematically in Figure 66.4.

G-M counters typically use a noble gas filling, most frequently argon or helium. The gas pressure is normally in the region of a few tenths of an atmosphere. At this pressure, a typical counter would require about 1000 V.

The process that terminates multiplication in a G-M counter has important counting implications. The positive ions space charge and resultant subthreshold electric field (for gas multiplication) persist for some time after the discharge is terminated. As a result, there is an interval following each pulse when pulses from subsequent input gamma rays are not produced or have less than full amplitude. This is

FIGURE 66.4 Typical counting circuit using a G-M tube. C_1 represents the combined tube and wiring capacitance, C_2 is a blocking capacitor that isolates the high voltage from the counter/scaler. The time constant of the circuit is RC_1 .

illustrated in Figure 66.5. The period between a full-amplitude pulse and the next discharge of any size is the dead time of the G-M counter (T_d). The time from the initial full amplitude pulse until another full amplitude pulse can be produced is the recovery time. Dead times in G-M counters are on the order of 100 μ s, with recovery time several times that. If the dead time is known and independent of count rate, the true count rate R_t may be determined in most cases from the observed rate R_o by the expression

$$R_t = \frac{R_o}{1 - R_o R_d} \quad (66.4)$$

Availability

Ionization chambers, Proportional counters, and Geiger-Müller counters are standard commercial products. They are available as stand-alone detectors requiring the user to supply ancillary electronics or as part of an instrument. Custom design devices are also available.

Scintillation Detectors

Scintillators, one of the oldest means of detecting gamma radiation, remain the method of choice for a multitude of counting and spectroscopy applications, particularly when counting efficiency rather than high-energy resolution is the primary objective. They are also widely used to record transient radiation events and in timing applications. While available in solid, liquid, and gas phases, solids and liquids are preferred for gamma-ray applications. Scintillators have the common property of converting energy absorbed from the incident gamma ray into visible or near visible light. The scintillation detector thus consists of a scintillator element, in which gamma ray energy is converted to optical photons, and some form of a photocell, normally a photomultiplier tube, to convert the optical photons into an electrical signal for processing by ancillary electronics.

Desired properties of a scintillator include high transparency to its own optical emission, efficient conversion of the absorbed gamma energy into optical output, short duration of the output, and output

FIGURE 66.5 Illustration of dead time (T_d) in a typical G-M counter.

that is proportional to the amount of energy absorbed. Other useful properties include the ability to be produced in large sizes, ability to be machined, stable output over a wide range of environmental conditions, and efficient gamma-ray absorption.

Scintillation Process

The excess energy contained by the scintillator as a result of the gamma-ray absorption is dissipated largely through nonradiative processes and appears as heat. A small fraction decays radiatively and appears as visible and near visible light. That fraction of the absorbed energy converted to optical photons is referred to as the scintillation efficiency, which varies from <1 to ≈10 percent for the more efficient scintillators.

The optical emission originates from electronically excited atomic and molecular states. The emission is broadband, frequently exceeding 50 nm at the half-intensity points. Temporally, it is characterized by a very fast rise, followed by exponential decay. For most purposes, the light pulse can be adequately represented by

$$I(t) \propto N \left[e^{-\frac{t}{\tau}} - e^{-\frac{t}{\tau_R}} \right] \quad (66.5)$$

where $I(t)$ is intensity at time t , and N is related to the total number of scintillation photons. τ_R is the time constant associated with the pulse rise time, and τ is the time constant for decay. The time required for the intensity to fall to $1/e$ of the maximum value is the pulse decay time. Optical pulses from organic scintillators are often described by the full width of the pulse at the half maximum of intensity. Further details of the scintillation process can be found in the text by Knoll [1] and, in particular, the treatise by Birks [13].

Scintillator Types

As previously noted, the scintillation process is observed in solid, liquid, and gas phases, but gamma applications are limited mainly to solids and liquids. This brief discussion is confined to the most common solid and liquid phase scintillants that are applicable to gamma ray detection. A number of scintillators, including pure organic crystals and gas scintillators used primarily for charged particles, are not considered. Those remaining fall into inorganic and organic types.

Inorganics

The most important of this group are crystals of inorganic salts containing trace quantities of activators to enhance the emission. Because of their high atomic number, high density, and light output, they are valued for gamma spectroscopy. They are available commercially in a variety of standard forms, including right cylinders and parallelepipeds, and are readily machined to custom shapes. Ruggedness varies considerably among crystal types; care in packaging and use is required. Encapsulated crystals are available, but integrated units comprising a scintillator and photomultiplier are also available and often preferable.

The most widely used of this group is sodium iodide activated with thallium, NaI(Tl). NaI(Tl) has high light output and is generally the choice for scintillator-based spectroscopy systems. This material is hygroscopic and must be encapsulated. A typical pulse height spectrum from a NaI(Tl) photomultiplier combination is shown in [Figure 66.6](#).

Also useful for spectrographic applications is cesium iodide, which is available with either a thallium or sodium activator. The optical output of CsI(Tl) is at substantially longer wavelengths than either NaI(Tl) or CsI(Na) and is well matched to the spectral response of silicon. This has been successfully exploited to produce small, rugged CsI(Tl)-Silicon PIN devices. A spectrum of Cs-137 obtained with a CsI(Tl)/PIN detector combination is shown in [Figure 66.7](#). Exceptional resolution can be obtained when CsI(Tl) is used with a mercuric iodide photocell. With this combination resolution at 662 keV of better than 5 percent has been reported [14].

FIGURE 66.6 Typical energy spectrum obtained with a NaI(Tl) scintillator/photomultiplier combination in response to a Cs-137 source (662 keV).

FIGURE 66.7 Energy spectrum of Cs-137 (662 keV) obtained with a CsI(Tl)/PIN combination. Specifications CsI(Tl): 1 cm \times 2 cm \times 2 cm; PIN: 1 cm \times 2 cm.

Two unactivated inorganic crystals, barium fluoride (BaF_2) and bismuth germinate ($\text{Bi}_4\text{Ge}_3\text{O}_{12}$), warrant comment. Barium fluoride has a weak subnanosecond component in the ultraviolet that is useful for timing and the recording of fast transients. With proper attention to ultraviolet transmission and photocell response requirements, gamma spectra can be obtained. Bismuth germanate has lower light output than either CsI or NaI and inferior energy resolution. However, because of its high density (7.1 g/cm^3) and the high atomic number (83) of bismuth, it is a good choice when high counting efficiency per unit volume rather than energy resolution is required.

Organics

Organic scintillators are available in both solid and liquid form. This group is characterized by very fast rise times (often subnanosecond) and decay times of a few nanoseconds. Their scintillation efficiency is about one-third that of the more efficient inorganics, however. Because of the low atomic number, photoelectric absorption is not significant. As a result gamma spectra consist mainly of a Compton continuum with, in large samples, a distinct Compton edge. Because of the absence of a photopeak, they are not well suited for spectroscopy applications. (High-Z additives such as tin or lead have been shown to enhance the photoelectric response but sometimes at the cost of light output.) They are particularly well suited for counting applications when very large detector volumes are required or for wide bandwidth measurements of fast transients. Because of the large number of available fluorescent organic compounds, organic scintillators are much more easily tailored to meet emission wavelength and decay time requirements than inorganics. The liquids typically consist of one or more fluorescent organic compounds dissolved in an aromatic solvent. A large number of formulations are commercially available. They can be obtained in sealed vessels suitable for mounting on a photomultiplier or as part of integrated scintillator–photomultiplier combination.

Solid organic solutions or plastic scintillator are prepared by dissolving fluorescent compounds in monomers of styrene or vinyl toluene, which then are polymerized. Like liquid organics, several different solutes can be used to achieve the desired wavelength and efficiency. Slabs of plastic scintillator several meters in length can be prepared in this manner. Alternatively, custom shapes can be either cast directly or machined.

Characteristics of several representative scintillators are shown in [Table 66.2](#).

TABLE 66.2 Properties of Common Scintillators

Scintillator	Wavelength of Emission Maximum (nm)	Density (g/cm^3)	Principle Decay Constant (ns)
NaI(Tl)	415	3.67	230.0
CsI(Tl)	530	4.51	1000.0
CsI(Na)	430	4.51	630.0
BaF_2	220	4.88	0.6
$\text{Bi}_4\text{Ge}_3\text{O}_{12}$	460	7.13	300.0
BC-505 (liquid)	425	0.88	2.5
BC-400 (plastic)	423	1.032	2.4

66.2 Germanium Detectors

High-purity germanium (HPGe) detectors are widely used for gamma-ray spectroscopy due to their combination of efficient absorption and high energy resolution. [Figure 66.8](#) shows the cross sections of germanium and silicon for photoelectric absorption, Compton scattering, and absorption by electron-positron pair production in several materials used for solid-state nuclear radiation detectors. Attenuation is significantly stronger in germanium than in silicon. Over much of the gamma spectrum, the dominant

FIGURE 66.8 Attenuation coefficients vs. energy in common semiconductor materials [4].

interaction is Compton scattering. However, it is principally the stronger photoelectric absorption in germanium that makes it more suitable than silicon for gamma-ray spectroscopy. In the typical size germanium detector, a gamma ray may be scattered several times before it is photoelectrically absorbed. Thus, the energy of the gamma ray is primarily transmitted directly to a small number of electrons. These energetic electrons in turn interact with electrons in the valence bands to create mobile pairs of electrons and holes. In a detector with sufficiently large volume, the average number of electron-hole pairs N produced by an absorbed gamma-ray of energy E becomes independent of the details of the initial reaction path and varies linearly with E as follows:

$$N = \frac{E}{\epsilon} \quad (66.6)$$

This relationship is more broadly valid and is the foundation of energy spectroscopy of gamma rays using semiconductors, gases, and cryogenic liquids (ϵ depending on the material). While ϵ is independent of the gamma-ray energy (and is also virtually the same for energy deposited by charged particles), ϵ in germanium does increase slightly with decreasing temperature, as does the energy gap. At 77 K, ϵ is 2.96 eV, and the energy gap is 0.72 eV.

Practical exploitation of Equation 66.6 depends on electronically detecting the motion of the ionized charge in an electric field. The signal-to-noise ratio is improved by reducing current flow in the detector from other mechanisms. In germanium, this is achieved by producing a rectifying and a blocking contact and by cooling to about 100 K. For a planar detector, a slice of high-purity germanium is diffused with the donor lithium on one side, forming a strongly n -type layer. The opposite side is implanted with the acceptor boron, forming a p + layer. When voltage is properly applied, the electric field direction prevents the majority carriers in the contact regions from being injected across the device. As the voltage is applied, a region depleted of holes will advance into the slice from the n + contact if the slice is p -type. If the slice is n -type, a region depleted of electrons will advance from the p + contact. At the depletion voltage V_d , the depletion region reaches the opposite contact. For germanium,

$$V_d = 565 V \times \frac{N_e}{10^{10} \text{ cm}^{-3}} \times \frac{d^2}{\text{cm}^2} \quad (66.7)$$

N_e is the net charge density in the depleted or active region of the detector, and d is the thickness of this region. This is a key relationship in high-purity germanium technology, as it quantifies the effect of the residual impurity concentration on device size and depletion voltage. Techniques to grow germanium pure enough for gamma detectors were pioneered by Hall [15] and the detector group at Lawrence Berkeley Laboratory (Haller, Hansen, and Goulding [16]), based on purification methods of Pfann [17] and crystal-growing techniques developed by Teal and Little [18] to produce crystals for germanium transistors.

Leakage Current

Germanium detectors need to be cooled to reduce leakage current. There are several potential sources of leakage current, including

- Diffusion of minority carriers from either doped contact into the depletion region
- Thermal generation of carriers at either bulk or surface defects in the depletion region
- Electrical breakdown at points where the electric field is concentrated due to irregularities in the contact geometry, large-scale inhomogeneities in the bulk, or surface states.

Current will also be generated if the detector is not shielded from room-temperature infrared radiation. Background nuclear radiation from materials near the detector and cosmic radiation also generate leakage current.

Germanium detectors are typically liquid-nitrogen cooled and operated between 85 K and 100 K. In this temperature range, leakage current is typically less than 40 pA in “good” detectors and is not a significant contributor to system noise (400 to 900 eV). Leakage current increases with temperature and eventually becomes the predominate noise component. Pehl, Haller, and Cordi [19] reported a leakage current driven system noise of 2 keV at 150 K and 7 keV at 170 K for an 8 cm³ planar detector. These authors also reported that, above about 120 K, the leakage current had an activation energy of approximately one-half the bandgap and attributed this to generation at mid-gap surface states. Below 120 K, the temperature dependence was milder.

A typical detector/cryostat configuration is shown in [Figure 66.9](#). The detector resides in an evacuated cryostat and is cooled by means of a copper rod inserted into a liquid-nitrogen dewar. The first stage of amplification is an FET, also cooled, positioned nearby the detector. Mechanical fixturing is designed to stabilize the detector and the mechanisms for contacting it, to provide a cooling path from the detector to liquid nitrogen, and to electrically insulate the high-voltage contact.

A variety of detector geometries are shown in [Figure 66.10](#). These different electrode configurations allow efficiency and energy resolution to be optimized for different gamma-ray energies and applications. For example, the detector in [Figure 66.10\(c\)](#) minimizes noise by the lower capacitance of its electrode

FIGURE 66.9 Schematic cross section of a dipstick cryostat. (Darken and Cost, 1993, reprinted with permission of Oxford Instruments, Inc.)

configuration at the expense of the reduced stopping power. Thus, this detector would be more suitable for lower-energy gamma rays.

Coaxial Detectors

The detector type shown in Figures 66.9 and 66.10(e) has a closed-end coaxial geometry. Nearly all of the largest-volume (active volumes of 100 cm³ to 800 cm³) HPGe detectors are of this type. This electrode geometry reduces both capacitance and depletion voltage with respect to a planar detector of the same volume. This latter benefit relaxes the constraint on material purity. In addition, charge collection distances are shortened, and the uncontacted surface area, frequently troublesome in processing, is reduced. Also, the HPGe is grown by the Czochralski technique and is therefore nearly cylindrical, even before machining. It is important, however, to note that the reduction in depletion voltage is realized only when the device is contacted so that it depletes from the outer contact to the inner contact. Thus,

FIGURE 66.10 Schematic cross section and electrostatic field distribution in high-purity germanium detectors. The dark line represents the p - n junction: (a) true planar, (b) grooved planar, (c) low capacity planar, (d) truncated coaxial, (e) closed-end coaxial, and (f) well geometry.

p -type HPGe to be fabricated into a coaxial detector is lithium diffused on the outer diameter and, in the case of n -type HPGe, the outer diameter is boron implanted.

The boron-implanted contact (depth approximately $0.2\ \mu\text{m}$) is thinner than the lithium-diffused contact (depth approximately $750\ \mu\text{m}$), so the n -type coaxial detector can detect lower-energy radiation and is usually built with a beryllium window in the aluminum end cap to take full advantage of this feature. The difference in the range of use is illustrated in Figure 66.11. The geometric asymmetry of the

FIGURE 66.11 Relative absorption efficiencies for typical n - and p -type detectors. (Darken and Cox, 1993, reprinted with permission of Oxford Instruments, Inc.)

contacting electrodes in the coaxial detector makes charge collection more dependent on the carriers (electrons or holes) traversing to the inner contact. As more gamma rays are absorbed near the outer contact, the carriers traversing to the inner contact must travel on average a longer distance. Also, charge traversal near the inner contact is particularly effective in inducing current in the external circuit [20]. Thus, the *p*-type coaxial detector with positive bias on the outer electrode is more sensitive to hole collection, and the *n*-type coaxial detector with negative bias on the outer electrode is more sensitive to electron collection. This is a crucial consideration in applications where the hole collection is going to be degraded during use by exposure to fast neutrons or other damaging radiation. The superior neutron damage resistance of the electrode biasing polarity on *n*-type coaxial detectors was demonstrated by Pehl et al [21].

A typical gamma-ray spectrum of a Co^{60} source taken with a coaxial HPGe detector is shown in Figure 66.12. The salient features are the full-energy peaks at 1.17 MeV and at 1.33 MeV, and the lower energy plateaus due to incomplete energy absorption of Compton-scattered gamma rays. The peak-to-Compton ratio [22] is generally 40 to 100, depending on the size and quality of the detector. The 1.33 MeV peak is shown separately in Figure 66.13. The energy resolution measured as the full width at half the peak maximum (FWHM) for typical coaxial germanium detectors is between 1.6 and 2.1 keV for 1.33 MeV gamma rays, again depending on the size and quality of the detector. The variance in the peak L^2 (FWHM = $2.35 \times L$, L being the standard deviation for a Gaussian distribution) can be divided into three additive components: the electronic noise component L_N^2 , a component reflecting the variance in the number of electron-hole pairs created L_F^2 , and a component due to incomplete charge collection L_T^2 ,

$$L^2 = L_N^2 + L_F^2 + L_T^2 \quad (66.8)$$

$$L_F^2 = \epsilon EF \quad (66.9)$$

FIGURE 66.12 A Co^{60} spectrum collected with a 15% *p*-type detector showing typical features of germanium detector spectrum.

FIGURE 66.13 A ^{60}Co spectrum collected with a 22% relative efficiency *p*-type detector. (Darken and Cox, 1993, reprinted with permission of Oxford Instruments, Inc.)

F is called the Fano factor and has been experimentally determined to be no greater than 0.08 for germanium [23]. $F < 1$ implies that electron-hole pair creation events are not uncorrelated. L_T^2 is usually dominated by the trapping of electrons and holes at defect sites. However, shorter electronic shaping times, lower electric fields, and larger detectors accentuate ballistic deficit (loss of collected charge in the external electronics due to the finite traversal time of the electrons and holes across the detector). L_N^2 is independent of gamma ray E and is the dominant resolution limiting factor at low energies. L_F^2 depends linearly on E and, for a coaxial detector, usually dominates L_N^2 for E over a few hundred keV. The energy dependence of L_T^2 is not given simply from first principles for an arbitrary trap distribution, but an E^2 dependence seems to fit under many circumstances. Thus, at high enough E , L_T^2 is expected to be the largest component. For “good” detectors at 1.33 MeV, however, L_T^2 is always smaller than L_F^2 . In addition, the magnitude of L_T^2 is variable enough between detectors that it distinguishes between acceptable, very good, and excellent detectors. L_T^2 is usually also the only component of resolution drawn from a nongaussian distribution and is thus responsible for any low-energy tailing of the peak.

X-Ray Detection

Both silicon and germanium detectors are used in low noise systems for the detection of fluorescent X-rays produced by electron beams (usually in an electron microscope) or X-rays (XRF). For both materials the detector is liquid-nitrogen cooled to reduce leakage current, and small volume devices [Figure 66.10(b), typically 10 mm² active area, and 3 mm depth] are used to decrease capacitance and therefore to further reduce electronic noise. Lithium-drifted silicon (SiLi) detectors were used first for these applications. Early germanium detectors displayed poor peak shape for X-ray energies just above the L absorption edges (attributed to diffusion against the field to the front contact by some electrons and their resulting loss to the photopeak [24]). However, as was first demonstrated by Cox et al., [25] this is not a fundamental problem but can be solved by the contacting technology. An X-ray spectrum taken with a HPGe detector is shown in Figure 66.14. Germanium has the advantages with respect to silicon of a smaller ϵ (2.96 eV per pair versus 3.96 eV per pair at 77 K) for better energy resolution and a higher Z (32 versus 14) for better photoelectric absorption of higher-energy X-rays.

FIGURE 66.14 Manganese X-ray spectrum from ^{55}Fe source collected with an HPGe detector. (Darken and Cox, 1993, reprinted with permission of Oxford Instruments, Inc.)

Current Status of HPGe Detector Technology

High-purity germanium detectors are a mature commercial technology. Process development in crystal growing and diode fabrication have been conducted in private industry where significant advances are proprietary. However, the results of technological advances in these areas are quite evident in the continual improvement in the size, performance, and availability of HPGe detectors. Maximum photopeak efficiency for HPGe gamma-ray detectors is doubling every 6 to 8 years. Concurrently, energy resolutions are moving toward the theoretical limits of Equation 66.8 as the concentrations of trapping centers are reduced.

The reliability as well as the performance of germanium gamma-ray detectors has also continued to improve, although this is harder to quantify. Cryostats have been redesigned to reduce virtual and direct leaks, reduce microphonics, implement modular design, and to improve ruggedness. Detector makers are also making more serious attempts to offer models with reduced backgrounds by judicious design changes and careful selection of materials.

New applications for gamma-ray spectroscopy have emerged. The HPGe detector industry has recently supplied over 100 detectors each to two different experimental facilities (GAMMASPHERE in the United States, and EUROBALL in Europe), where they were arranged spherically in a modular fashion around the target of an ion accelerator to study the decay of nuclei from excited states of high angular momentum.

For users of single-detector systems, developments in the pulse processing electronics necessary for data acquisition and in the hardware and software for data analysis have resulted in both more compact and more flexible systems. Plug-in cards for a personal computer are available that not only contain the functions of the ADC and multichannel analyzer, but the high-voltage power supply and amplifier as well. Software developments also allow for control of many pulse-processing parameters that were previously set manually.

66.3 Silicon Detectors

As with germanium for gamma-ray spectroscopy, the impurity requirements on silicon for nuclear radiation detectors are also stringently low—and difficult to obtain. Such silicon must be grown by the float zone technique to eliminate contamination from a crucible. Unlike with germanium, little dedicated effort has been expended trying to improve silicon growth techniques to achieve superior detector characteristics. Most progress in material quality has come from technology improvements aimed at other applications. The purest silicon commercially available typically has a net electrically active impurity concentration of a few times 10^{11} cm^{-3} (compared to 10^{10} cm^{-3} for HPGe), which usually limits device thicknesses to less than 1 mm. However, this thickness is sufficient for many applications. Silicon detectors are widely used for heavy charged particle (alpha, proton, ion) spectroscopy. When thicker silicon devices are required (X-ray spectroscopy, beta spectroscopy, or medium-energy protons: $E > 25 \text{ MeV}$), silicon of higher net purity may be obtained by lithium drifting [26], but such material cannot be subsequently processed above room temperature.

In contrast to germanium detectors, silicon detectors can be operated at room temperature. Compared to gas and scintillation detectors, silicon detectors have good energy resolution and are reasonably compact. They are fabricated from slices of a silicon single crystal and are available in a variety of areas (25 to 3000 mm^2), and the active thickness is usually a few hundred micrometers. Specialized detectors have been developed for a wide variety of applications.

Energetic heavy charged particles lose kinetic energy continuously along a linear path in an absorbing material. Energy is transferred primarily to the electrons in the absorbing material but to a lesser extent to the nuclei also, via Rutherford scattering. Although only energy transferred directly to the electronic system generates electron hole pairs, Equation 66.6 (with $\epsilon = 3.62/\text{pair}$ for silicon at 300 K) is still a good approximation. Energy loss is characterized by two parameters: specific ionization loss dE/dx , which depends on the incident particle, its energy, and the absorbing material, and the range R (i.e., the penetration depth of the particle), which determines the detector thickness required for complete energy absorption. The continuous nature of energy loss leads to substantial window effects.

Diffused Junction Detector

Silicon detectors can be generically categorized by the type of rectifying contact employed. The diffused junction detector is fabricated by diffusing phosphorus from the gas phase into p -type silicon. This is a high-temperature (900 to 1200° C) operation that is prone to introducing faster diffusing metals into the bulk that can act either as generation centers increasing leakage current, or as trapping centers degrading charge collection. The thickness of the diffused region, from 0.1 to 2.0 μm , also presents a dead layer to incident particles that is reduced in alternative technologies. Nonetheless, these detectors find use due to their ruggedness and economy.

Surface Barrier Detector

Surface barrier junctions are fabricated by either evaporating gold onto n -type silicon or aluminum onto p -type silicon. A typical entrance window is equivalent to 80 nm of silicon. The rectification properties depend on the charge density of surface states of the silicon and of the thin oxide layer over the silicon, as well as on the evaporated metal. The wafer is epoxied in an insulating ring before metallization. The finished detector is encapsulated in a can that has a front window for particle entry and a single contact in the back for the combined function of applying bias and for extracting the signal pulse. Devices can be operated either in the partially depleted or totally depleted mode. As fabrication is entirely at room temperature, there is no opportunity for metal contamination by diffusion. Generally, surface barrier detectors have lower leakage current, and less system noise than a diffused junction detector of comparable area and depth. However, detectors currently fabricated by ion implantation have still lower leakage current and electronic noise, together with a thinner and more rugged front contact. On the other hand, implanted detectors are not available in the same range of active thicknesses as surface barrier detectors. Below 100 μm and above 500 μm , only surface barrier

detectors are currently available. Surface barrier detectors can be made in small quantities with rather simple equipment.

Ion Implanted Detectors

A simplified representation of ion implanted detector fabrication is shown in Figure 66.15. The first successful implementation of silicon planar processing to silicon detectors was reported by Kemmer [27]. The procedure starts with the thermal growth of an oxide film on a high-purity, *n*-type silicon wafer. Windows are then opened in the oxide by photolithographic techniques. The front contact area is implanted with boron to form the rectifying contact, and arsenic is implanted into the backside. The wafer is then annealed to activate the implant, and aluminum is evaporated on both sides to reduce sheet resistivity. Typical entrance windows are 50 nm silicon equivalent. Electrical connections are made by wire bonding to the aluminum layers. Finished detectors are canned in a manner similar to surface barrier detectors. More than one detector can be fabricated on the same wafer using the appropriate masks during photolithography. In fact, quite elaborate detector geometries can be achieved via photolithography. The detector in Figure 66.15 is actually a strip type.

This ion implantation planar process technology is well suited for mass production of wafer sizes compatible with the rest of the silicon industry. Minimum wafer diameters are now 4 or 5 in. At this diameter, breakage during fabrication is an issue for thicknesses less than 150 μm. For thicknesses greater than 500 μm, the availability of enough sufficiently pure material to justify the cost of photolithographic masks is an issue. Ion implanted detectors can be baked at 200° C to reduce outgassing. This is a significant improvement over surface barrier detectors, which irreversibly degrade by device processing above room temperature. This is a useful feature, as most heavy charged particle spectroscopy is done in a vacuum.

Leakage currents, at room temperature, are typically 1 to 10 nA per cm² active area and per 100 μm depletion depth. These values represent an order of magnitude reduction in leakage current with respect to surface barrier detectors. Two factors are relevant. Passivation of silicon surfaces by thermal oxidation

FIGURE 66.15 Steps in the fabrication of passivated planar silicon diode detectors. (From Ref. 30.)

is extremely effective in reducing leakage current around the rectifying contact. Also, the bulk generation current is reduced by the gettering of metal impurities during the high-temperature oxidation. Float zone silicon for radiation detectors usually has a minority carrier lifetime longer than 1 ms and this can be increased an order of magnitude during detector fabrication [28]. Thus, not only is leakage current reduced, but potential charge collection problems are also eliminated.

Energy Resolution

A typical spectrum of an Am-241 alpha particle source taken with an ion implanted detector is shown in Figure 66.16. While the factors considered in Equation 66.8 for germanium gamma-ray spectrometers are still valid, additional considerations also apply. In particular, if the source is moved closer to the detector to improve collection efficiency, larger differences in the angle of incidence will produce peak broadening due to larger variation in effective window thickness. Even when the source is sufficiently distanced from the detector, there will still be spatial variations in window thickness, as well as some variation in energy lost escaping from the source and traversing to the detector.

Another source of peak broadening is the variation in the small amount of particle energy lost during Rutherford scattering. This energy is transmitted directly to the scattering nuclei and does not generate electron-hole pairs, and a small pulse deficit results. These events are relatively few but large and therefore contribute disproportionately to peak variance. The FWHM contribution of this effect on a 6-MeV alpha particle peak has been estimated to be 3.5 keV [29].

Spatial Resolution

The uninterrupted progress of the semiconductor silicon industry in achieving both larger wafers and smaller device features has allowed the development of larger and more complex silicon detectors that can provide position information in addition to (or instead of) energy information. Spatial detection can be obtained by fabricating detectors as pixels (two-dimensional) or strips (one-dimensional) on the same wafer. For penetrating radiation, two strip detectors, one behind the other but with the strip pattern rotated 90°, provide two-dimensional positioning. Frequently, such detectors are individually designed and fabricated for a particular application. Strip detectors, drift detectors, and CCD (charge-coupled device) detectors will be discussed here.

FIGURE 66.16 Spectrum of a ²⁴¹Am alpha-particle source (log scale) measured with an IP detector (25 mm² area, 300 μm thick) at room temperature. Resolution at 5.486 MeV is 10.6 keV (FWHM). (From Ref. 30).

Strip Detectors

Silicon strip detectors are currently fabricated on silicon wafers (typically approximately 300 μm thick) by using photolithographic masking to implant the rectifying contact in strips [30]. The strips usually have a pitch on the order of 100 μm and a width less than half of this size to minimize strip-to-strip capacitance and hence electronic noise [31]. The device is biased past depletion, and the back blocking contact is continuous. Each strip requires, in principle, its own signal processing electronics; however, charge division readout (capacitive or resistive) can reduce the number of amplifiers by a factor of 10. Detectors are fabricated in rectangular segments from a single wafer and can be ganged together if a larger area is needed.

Strip detectors are well established in high-energy physics experiments for reconstruction on the micron scale of the tracks of ionizing particles. The particles being tracked result from the collision of accelerated particles with a target and are highly energetic ($>10^{10}$ eV). Frequently, experimental interest is focused on short-lived particles created in the collision but which decay before they can be directly detected. Spatial resolution of the decay vertex from the original collision is necessary to detect such a particle and to determine its lifetime.

The requirements of new high-energy experiments and advances in silicon technology have produced much evolution and innovation in the strip detector concept. For example, a double-sided microstrip detector with an oxide-nitride-oxide capacitor dielectric film has been reported [32]. The use of intermediate strips to improve spatial resolution has become common [33], and the biasing network has been integrated onto the detector [34].

Drift Detectors

Silicon drift detectors were first proposed by Gatti and Rehak [35] as an alternative to silicon strip detectors in high-energy physics experiments. The primary motivation was to significantly reduce the number of readout channels. Drift detectors have subsequently been adapted for X-ray spectroscopy. These detectors are usually fabricated on n -type silicon wafers with holes collected to either a p^+ contact on the back side of the detector, or to concentric annular p^+ contacts on the front side. The detector is depleted from both sides. The reverse bias applied to the p^+ annular rings is varied in such a way that electrons are collected radially in a potential energy trough to an n^+ anode at the center of the detector on the front side.

A cross section through a circular drift detector is shown in Figure 66.17. The electron collecting anode ring surrounds the integrated FET used for the first stage of signal amplification. Enough negative bias

FIGURE 66.17 Cross section of a cylindrical silicon drift detector with integrated n -channel JFET. The gate of the transistor is connected to the collecting mode. The radiation entrance window for the ionizing radiation is the non-structured backside of the device.

is applied to the back contact (actually the entrance window) to deplete the wafer to the anode, which is near ground potential. At the same time, negative bias, progressively increasing in magnitude, is applied from the ring next to the anode (near ground potential) to the outermost ring, which is maintained at about two times the bias of the back contact. These applied biases deplete the detector in such a way that there is an electrostatic potential minimum for electrons that varies in depth across the detector from right under the front surface at the anode to near the back contact at the last ring. Ionized electrons will drift first to this minimum, then drift radially to the anode as shown in Figure 66.17. A feature of this contacting arrangement is that the anode capacitance, and hence amplifier series noise is low and nearly independent of the active area of the detector.

Silicon drift detectors have been designed in several different topologies of various sizes for different experimental needs. Spatial resolution for tracking and vertexing of high-energy particles is obtained by segmenting the cathode (for angular position) and analysis of signal rise time (for radial position [36]). Drift detectors with integrated electronics have been demonstrated for high-resolution room-temperature X-ray spectroscopy [37].

CCD Detectors

The design of CCD (charge coupled device) detectors has similarities to the silicon drift detector [35]. The CCD detector is normally fabricated on an *n*-type silicon wafer depleted both from the backside with a continuous *p*+ contact on the back, and from *p*+ CCD registers on the front. Reverse bias voltages are such that the wafer is totally depleted and the electron potential minimum is about 10 μm below the CCD registers. After an ionizing event, holes are collected to the *p*+ contacts, and electrons are trapped under a nearby register, then transported down a channel of registers by properly clocked voltage pulses to the registers. Each channel has its own readout anode, which can be made small to minimize capacitance, a prerequisite for minimizing noise. The first stage of amplification is frequently integrated onto the same wafer. Spatial resolution is limited to the register (pixel) size. Brauniger et al. [38] described initial results on a 6×6 cm CCD array of 150×150 μm pixels intended for satellite X-ray imaging. The system also had an energy resolution of 200 eV FWHM for 5.9 keV X-rays at room temperature.

Silicon pixel detectors have also been designed using other highly integrated device structures to optimize particular performance aspects such as timing resolution. Pixel detectors using MOS transistors [39] and using reverse-biased diodes with individual readout circuitry [40] have been described.

Present Status of Silicon Detector Technology

The simple structured silicon detectors fabricated with parallel contacts on a silicon wafer continue to serve a well established need for charged particle spectroscopy. Where economies of scale can be applied, ion implanted detectors have replaced surface barrier detectors. In X-ray spectroscopy for microanalysis (SEM and XRF), liquid-nitrogen-cooled Si:Li detectors are being challenged by similarly sized HPGe detectors, but Si:Li are still more widely used. In projects of sufficient size to support their development, specialized low-noise silicon drift detectors and CCD-based detectors have been designed and fabricated with promising room-temperature energy resolution: 200 eV FWHM at 5.9 keV. These highly structured detector technologies may find future application in liquid-nitrogen-cooled or room-temperature systems for microanalysis using X-ray spectroscopy.

In high-energy physics, the use of various strip, drift, and pixellated detectors for tracking and vertex determination has flourished. These efforts will intensify as experimental requirements for spatial resolution increase. However, radiation damage to the detector is already an issue in this application, and higher luminosity beams will only increase the problems. Nevertheless, it appears that the continuing need of the high-energy physics community for a higher number and density of signal paths forecasts continued reliance on the ever-improving integration technology of the semiconductor silicon industry.

66.4 Room-Temperature Semiconductors

Applications arise that require energy resolution beyond the capability of scintillator systems and where cryogenically cooled semiconductors are not suited. Examples include detector probes for monitoring restricted areas, monitoring at remote sites where replenishing the coolant is impractical, spectral imaging, and many portable instrument applications. There is available a class of semiconductor detectors that satisfy many such needs by providing energy resolution substantially better than the best scintillators (although inferior to cooled semiconductors) while operating at ambient temperature. In addition to spectroscopy, these devices are also useful for counting applications where high detection efficiency per unit volume is required. In these applications, the devices are operated in pulse mode wherein the charge associated with single-photon absorption events is recorded. They also can be operated in a current mode in the manner of a solid-state ion chamber. In their current stage of development, room-temperature detectors are limited in size and best suited for the energy region below 1 MeV.

The room-temperature detectors are distinguished from cryogenic semiconductors by the magnitude of the energy gap that separates the normally vacant conduction band from the highest filled band. If this energy gap is small, as is in the case of silicon (1.14 eV) and germanium (0.67 eV), electrons can be thermally stimulated across the bandgap at room temperature. The resultant current competes with the gamma-ray-generated signal precluding room-temperature operation of germanium and high-resolution applications of silicon. Thermally stimulated current is reduced to acceptable levels at bandgap energies of about 1.4 eV and above. This phenomenon has been successfully exploited in the development of room-temperature detector materials including cadmium zinc telluride (acronym, CZT), cadmium telluride (CdTe), and mercuric iodide (HgI₂).

Theory of Operation

Operating principles of room-temperature detectors are similar to those governing the more familiar cryogenic semiconductor devices. Gamma radiation is absorbed in the material and generates electron-hole pairs that move under the influence of an applied electric field to contacts and external electronics for processing and production of the familiar pulse-height spectrum. The process is shown schematically in Figure 66.18. Fundamental to the charge transfer process is the carrier mobility (μ) and the carrier life time (τ). The product $\mu\tau E$ defines a drift length (λ) that should be long compared to the intercontact dimensions. Owing to the substantially higher average atomic number of the room-temperature detector materials in the gamma absorption cross sections, the probability of gamma ray absorption is much

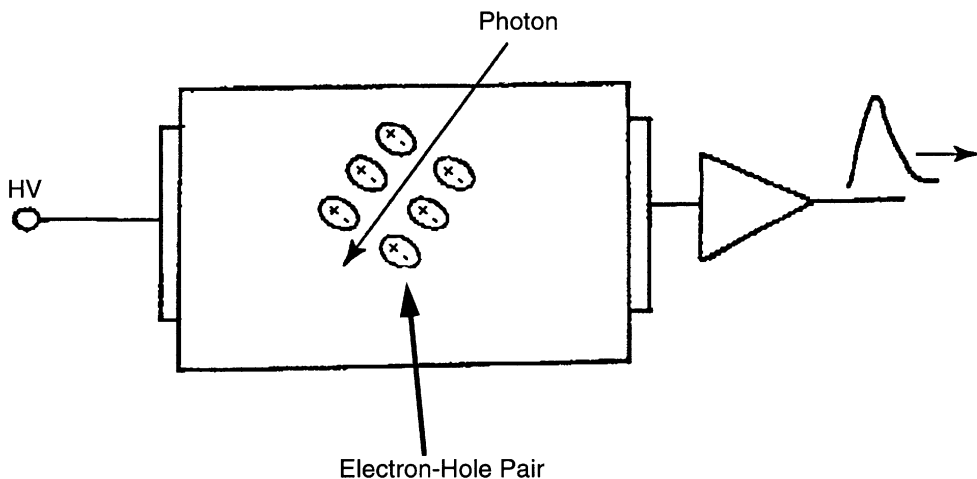

FIGURE 66.18 Schematic illustration of charge generation in a planar detector.

higher than in silicon or germanium (Figure 66.8). As a result, room-temperature detectors provide greater detection efficiency per unit thickness.

The energy required to produce an electron-hole pair (ϵ) is typically a few times the energy bandgap of the material. In silicon where the bandgap is 1.14 eV, the energy to produce an electron-hole pair (ϵ) is about 3.5 eV. The absorption of a 1 MeV photon in silicon thus produces about 285,000 pairs. Values of ϵ for room-temperature materials are in the region 4.2 to 5.0 eV per e-h pair (see Table 66.3) and, consequently, fewer electron-hole pairs are generated per unit of absorbed energy. Complete collection of the charge is desired, although charge trapping, which may not affect the two carrier types equally, prevents this in most cases. The drift length for holes (λ_h) in these materials is often less than the intercontact dimensions and creates a condition where the collection efficiency depends on the photon interaction depth. This is phenomenon is illustrated in Figure 66.19, where induced charge from single gamma absorption events originating at various depths in the material is plotted as a function of time. The initial fast-rising segment is due to the more mobile electrons; the slower component is due to holes. In this example, hole trapping is assumed and is manifest in the curvature of the hole segment. The charge collection efficiency (η) can be derived from the Hecht relation [41]. For a photon absorbed at a distance x from the cathode of a planar detector of thickness L operated with a uniform electric, the relationship becomes

$$\eta = \frac{\lambda_e}{L} \left[1 - \exp\left(-\frac{L-x}{\lambda_e}\right) \right] + \frac{\lambda_h}{L} \left[1 - \exp\left(-\frac{x}{\lambda_h}\right) \right] \quad (66.10)$$

FIGURE 66.19 Charge collection in planar detector for single-photon interaction in a planar detector. Curves a through d depict the charge from photon interactions at increasing depths below the cathode.

TABLE 66.3 Physical Parameters of Common Room-Temperature Semiconductor Materials

Material	E_g (eV)	Z	ϵ (eV)	ρ (Ω)	$(\mu\tau)_e$ (cm^2/V)	$(\mu\tau)_h$ (cm^2/V)
Cadmium zinc telluride	1.65	48	5.0	10^{11}	1×10^{-3}	6×10^{-6}
Cadmium telluride	1.5	50	4.4	10^9	3.5×10^{-3}	2.3×10^{-4}
Mercuric iodide	2.13	62	4.2	10^{13}	1×10^{-4}	4×10^{-5}

Note: E_g = bandgap energy, Z = average atomic number, ϵ = energy to create an electron-hole pair, and ρ = resistivity.

Source: *Semiconductors for Room-Temperature Radiation Detector Applications*, R.B. James, T.E. Schlesinger, P. Siffert, and L.A. Franks (eds.), Materials Research Society, Vol. 32, Pittsburgh, PA, 1993.

The dependence of the collection efficiency on interaction depth reduces energy resolution and without mitigation would limit high resolution to thin devices. Fortunately, methods have been developed that permit high-energy resolution to be achieved in relatively thick samples. As with cooled semiconductor detectors, the energy resolution of the combined detector-electronics system is normally specified by the full width of a monoenergetic spectral peak at its half amplitude points (ΔE). The FWHM is in turn related to the variance in the peak L^2 (see Equation 66.8). It is useful to note that the energy resolution is related to the reciprocal of the product $\mu\tau$.

Operational Considerations

Important physical parameters for the leading room-temperature detectors are summarized in [Table 66.3](#). Detectors are available with surface area of a few square centimeters and thicknesses up to about 1 cm. The performance of detectors based on the different materials varies considerably, as can the performance for detectors of the same material. The choice of specific detector material is normally dictated by the application. The exceptionally high resistivity and high photoelectric cross section in mercuric iodide permit good resolution and high efficiency in the X-ray region, particularly below 10 keV. For example, ΔE of 4 percent has been reported [42] with typical values in the region of 10 percent. For applications in the region of 0.5 MeV, trade-offs between efficient gamma absorption and resolution may be required. If energy resolution is the primary concern, thinner devices that minimize charge trapping are generally required. Considerable progress is being made in achieving both high efficiency and resolution in the region of 0.5 MeV, particularly with CZT. For example, resolution of better than 3 percent has been achieved in 1-cm thick detector at 511 keV, and about 5 percent at 662 keV in a 2.5 cm thick device [4]. Improvements in material quality can be expected further improve the performance of thick detectors, as the $\mu\tau$ values are further increased.

Procedures have been developed to overcome many of the thickness and surface area limitations of currently available devices. For instance, electronic circuits have been developed that permit the operation of planar arrays that provide spectral resolution approaching that of single units while providing substantially greater area [43]. Similarly, high gamma absorption efficiency with useful spectral resolution has been obtained with stacks of thin spectrometer-quality detectors [44]. Additionally, pulse processing and single charge collection procedures have been demonstrated that enhance spectrometer performance. This development can be expected to substantially improve the availability and price of spectrometer grade devices. Further details concerning the performance of these devices, as well as electronic processing and design details, are available in the literature [2, 3, 45, 46].

Detectors based on the materials in Table 66.3 are available commercially. Due to the evolving nature of this technology, it is recommended that buyers' guides be consulted for suppliers and current availability.

66.5 Prices and Availability

The detectors described in this chapter are available commercially. Their prices vary widely, depending on type, size, and performance. Gaseous detectors are normally in the range of a few hundred dollars for standard designs. Scintillator-photomultiplier combinations range from about a thousand to several thousand dollars, depending on size and resolution. Room-temperature semiconductor detectors range from less than one hundred dollars for small, low-resolution devices to over a thousand dollars for large (1 cm^3), high-resolution devices. Pricing of coaxial HPGe detectors is based largely on their gamma ray efficiency, which is specified relative to a 3×3 -in. sodium iodide scintillator at 1.33 MeV. Coaxial detectors are available with relative efficiencies up to about 150 percent with cost in the area of several hundred dollars per percent efficiency. Planar HPGe detectors are normally less expensive than coaxial designs. In either case, the price includes cryostat, dewar, and preamplifier. Cryogenic silicon detectors are available in area up to several tens of square millimeters. Cost ranges to $> \$10,000$, depending on size, performance, and complexity of design.

67.1 Introduction

Interaction of Charged Particles with Matter

There are a number of subatomic charged particles that can be detected by their interaction with matter. These include protons (hydrogen nuclei), β particles (fast electrons), α particles (helium nuclei), light ions, heavy ions, and fission fragments. Some of these particles are emitted by natural radioactivity on Earth or originate from space and reach the Earth in the form of cosmic rays; others are due to human activities (nuclear industry, accelerators). The kinetic energy of charged particles is given in units of electron-volts (eV), where $1 \text{ eV} = 1.6 \times 10^{-19} \text{ J}$. Naturally occurring α and β particles from radioactive decay have energies up to 10 MeV. Ions, such as Cl^+ , are accelerated to 35 MeV and higher in beam analysis procedures. Energetic particles that originate from space can have energies up to 10^{12} GeV. Charged particles traversing matter lose kinetic energy until they eventually come to a halt. In the case of electrons, protons, α particles, or light ions, most of this energy is lost through interactions with the electrons of the target. Heavier ions also lose a significant amount of kinetic energy through direct collisions with the nuclei of the constituent atoms. However, for all types of charged particles of concern here, ionization of the target atoms is the dominant mode of excitation of the detection medium. This process is also the main source of radiation damage in biological tissue.

Energy Loss of Protons and Ions

The quantity of energy deposited by an incident energetic charged particle in a detection medium is a function of the atomic mass, A_{med} , the atomic number, Z_{med} , and the density of target atoms that it meets

FIGURE 67.1 The electronic energy loss curves for protons in three different absorber elements are shown as a function of kinetic energy. The target element with the lower Z_{med} displays the highest stopping power due to its low average ionizing potential. These curves were obtained using the SRIM computer program. (Reference 2.)

along its path. Hence, the unit of dimension used in this field is the mass thickness, and it is measured most often in units of g cm^{-2} . This is equal to the geometric thickness or path length x , multiplied by the density of the detector volume, ρ . It follows that the rate of energy loss of a particle in the detection volume is $dE/(\rho dx)$ and it is given in units of $\text{keV (g cm}^{-2})^{-1}$ or $\text{MeV (g cm}^{-2})^{-1}$. The energy loss due to ionization is characterized by the Bethe-Bloch equation:

$$-\frac{1}{\rho} \frac{dE}{dx_{\text{ion}}} = D \frac{z^2 Z_{\text{med}}}{A_{\text{med}}} \frac{c^2}{v^2} \left[\ln \frac{2m_0 v^2}{I_{\text{med}}} - \ln \left(1 - \frac{v^2}{c^2} \right) - \frac{v^2}{c^2} \right] \text{MeV} / (\text{g cm}^{-2})^{-1} \quad (67.1)$$

with $D = 0.307 \text{ MeV}/(\text{g cm}^{-2})$, c is the velocity of light ($3.0 \times 10^8 \text{ m s}^{-1}$). The incident ion is described by z and v , its charge and velocity, respectively. The atoms of the target are further defined by I_{med} ($\sim 16 Z_{\text{med}}^{0.9} \text{ eV}$), their mean ionization energy. The energy loss is characterized by a peak at low energy and a minimum at higher energies where a particle of $z = 1$ is referred to as a minimum ionizing particle (MIP). The energy loss curves of protons in Si, Ar, and Au are shown on [Figure 67.1](#). The energy loss expressed in $\text{MeV (g cm}^{-2})^{-1}$ is lower for higher Z_{med} materials, where the ratio $Z_{\text{med}}/A_{\text{med}}$ becomes less than 0.5 and I_{med} is large. However, when multiplied by the material's density, the energy loss in MeV cm^{-1} shows a reverse trend; it is greater for high Z_{med} materials because they have a high density. The rate of energy loss varies to the second power of the charge z of the incident ion and as the inverse square of its

kinetic energy ($1/v^2$ term). Equation 67.1 holds for protons and α particles of energy above 500 keV and 1 MeV, respectively, in Si where the target is described by an average ionization energy. It is not applicable for ions for which $z > 2$, where stripping must be considered. Ziegler and co-workers [1] give a very useful description of scaling rules that allow the proton energy loss to be scaled to any incident ion and target atoms. They have included these rules in a software package called SRIM [2]. Their empirical relations allows for ion stripping and gives a more exact representation of the energy loss than Equation 67.1 in the case of heavy ions and for low-velocity light ions. Alternatively, one can use published $dE/(\rho dx)_{\text{ion}}$ plots [3]. Interaction of fast charged particles with the nuclei of the constituent atoms of a target produces an additional contribution to the energy loss, $dE/(\rho dx)_{\text{nuc}}$, the nuclear stopping power. For protons and α particles, the electronic stopping power dominates by a factor of 1000 over the nuclear stopping power for most energies of interest. For ions, the nuclear stopping power may dominate at low energies (<1 MeV), with its contribution decreasing at higher energies and becoming negligible. The range of a particle, or its path length, is also a very important parameter in the selection of a detector. It is given by:

$$R(E_0) = \int_0^{E_0} \frac{dE}{dE/dx} \quad (67.2)$$

where dE/dx in this case is the total stopping power $dE/dx_{\text{ion}} + dE/dx_{\text{nuc}}$. Range-energy curves for various ions in silicon are shown on [Figure 67.2](#).

Energy Loss of Electrons

The case of electron propagation through matter is more complicated. The electron collides with bodies having a mass equal to it (other electrons) or much heavier (nuclei). The collisions cause it to undergo many changes in direction. This “random walk” type of behavior is superimposed on the forward motion of the electron. Along its random path an electron loses energy through ionization in a way similar to ions. At increasing kinetic energy, electrons also lose energy through the emission of X-rays, called bremsstrahlung radiation. In a target constituted of atoms of charge Z_{med} and below a critical energy $E_c \sim 817/Z_{\text{med}}$ MeV, electrons lose a greater fraction of their energy through ionization. Above E_c , the energy loss due to bremsstrahlung X-ray emission dominates and is given by:

$$-\frac{1}{\rho} \frac{dE}{dx_{\text{rad}}} = B \frac{Z_{\text{med}}^2 E}{A} \left(\ln \left(\frac{183}{Z_{\text{med}}^{1/3}} \right) + \frac{1}{18} \right) \text{MeV} / (\text{g cm}^{-2})^{-1} \quad (67.3)$$

where $B = 1.40 \times 10^{-3}$ for E in MeV, and for the molar weight of the target A in grams. Equation 67.3 applies for specified energy ranges, and the interested reader should consult the available literature [4].

The electron range is defined as the distance separating the point of entry in the detection medium to the point where the electron stops. It is much shorter than its actual pathlength and can be approximated by $R(E)$ (Equation 67.4) for E ranging from 0.01 MeV to 3 MeV [5]. Ultimately, the problem of electron propagation through materials has to be addressed using Monte Carlo programs (see References 6 and 7), which follow the individual electron histories to a specified energy or geometrical cutoff.

$$R(E) = 0.2115 Z_{\text{med}}^{0.26} E^n (\text{g cm}^{-2}) \quad (67.4)$$

$$n = 1.265 - 0.0954 \ln(E)$$

FIGURE 67.2 Ions of widely different masses have widely different ranges in a target element such as silicon. These curves for protons (p), α particles, boron ions (B), and iron (Fe) were obtained using the SRIM computer program. (Reference 2.)

Technologies

The most appropriate detection technique selected depends on the particle under study, its energy, and the type of information sought, such as source activity, position or energy measurement, or particle identification. For all cases reviewed here, except nuclear emulsions, the detection process is active and accompanied by electronic signal processing. Nuclear emulsions permanently record the ionization tracks left by traversing particles and can only be examined after their development. The active technologies include: gas-filled detectors (ionization chambers, proportional counters, Geiger-Müller counters), scintillators, and solid-state detectors. The active volume consists of a radiation-sensitive material that is raised to an excited state through ionization by the passage of charged particles. For active detectors, this ionization is sensed by the external electronics as an induced charge in the case of gas-based and solid-state detectors, or as visible or near-visible light in the case of scintillators. The sensors described here are the front-ends of complex detection systems.

Nuclear emulsions are a special preparation of photographic emulsion designed to record “tracks” left by ionizing particles as they traverse the emulsion. The emulsion is sensitive up to the time it is processed, and the image is latent for many months or years if the emulsion is cooled. Once processed, the emulsion is a permanent record of the ionizing radiation that traversed it. In a situation where a prompt signal is not required, the nuclear emulsion may be a suitable detector. Its primary advantage is that it is compact, is self-contained, and has high spatial resolution. Since no associated equipment is needed during exposure, it is well suited for remote applications, such as studying cosmic rays and for recording the cumulative exposure to ionizing radiation in space.

Gas-filled detectors were among the first instruments designed for radiation detection. A charged particle passing through a gas-filled container leaves a trail of ionization electrons and ions. With a suitably configured external electric field, the ionization can be used to produce an electrical signal for charged particle detection. Depending on the magnitude of the applied electric field, a variety of ionization phenomena can arise in gases which have been used over the years to develop different types of gaseous charged particle detectors; for example, ionization chambers, proportional counters, Geiger-Müller counters, spark chambers, etc. Spark chambers are rarely used these days because of electrical noise and limited counting rate ability. The other three devices are used primarily as instruments for radiation protection and monitoring. Their advantage is that they are inexpensive, easy to operate, and are available commercially. In addition, many variants of gas-filled proportional counters have been developed for use in experimental nuclear physics and elementary particle physics. These, however, need to be specifically designed and fabricated for particular applications.

Scintillation counters consist of a scintillation material, a photodetector, and a light guide to link the two. Charged particles crossing the scintillator material deposit energy in the material, which responds by emitting light isotropically. A large fraction of the light can be trapped in the material by internal reflection and directed toward a photodetector, such as a photomultiplier tube. This kind of detector can be used at very high counting rates and can achieve efficiencies approaching 100%. Components for scintillation counters are readily available and it is possible to purchase assembled counters.

Solid-state detectors are large semiconductor diodes made of very high resistivity material and are operated under reverse-bias. The small bandgap in these material ensures that the kinetic energy of the incident charged particle is efficiently converted into an electric signal through the creation of electron-hole pairs. A signal is induced on the metal contacts as the charge carriers drift under the applied electric field present in the depletion region. Their advantages include a fast response, good energy resolution, and compact size.

Table 67.1 presents some radiation sensing applications, the particles under study, and the suggested sensor–system combination. The following subsections present each sensing technology in more detail.

TABLE 67.1 Detection Applications and Suggested Instruments

Detector Type	Typical Applications	Advantages	Shortcomings
Nuclear emulsion	Cosmic ray studies, dosimetry, low statistic (single track) studies	Passive detector, high spatial resolution, unattended operation, particle identification, and energy measurement	No time information, manual scanning, chemical development
Gas-filled counter	Radiation monitoring, dosimetry	Low density, large area at low cost, nuclear and particle physics experiments, realtime particle identification	Needs ultra-pure flammable gases, high voltages required, signals need amplification
Scintillation counter	Energy measurement, particle counting, triggering	Large volumes, flexible shapes, fastest timing, high efficiency	Poor spatial resolution, poor energy resolution
Solid-state detector	Energy measurement, particle identification, position measurement, radiation monitoring, beam analysis techniques	High-energy resolution, compact size	High cost per area, signal needs amplification

67.2 Nuclear Emulsions

Nuclear emulsions are a suspension of silver halide grains, primarily AgBr, in a gelatin medium. The silver halide grains are small, on the order of 0.2 μm to 0.5 μm and constitute about half the volume and 80% of the total weight. The “pellicles” of nuclear emulsion range from 25 μm to 600 μm in thickness and can be as large as 70 cm by 30 cm. The pellicles may be supported on a glass or plastic plate during exposure, or stacked to increase the thickness of the emulsion detector, in which case the pellicles will be placed on a supporting plate as part of processing. If pellicles are stacked for an exposure, then a reference grid is usually printed on the bottom surface of each pellicle to assist in following tracks from one pellicle to the next.

The ionizing radiation crossing a grain of silver halide leaves the grain in an excited state. During development, the excited grains are reduced to elemental silver. The undeveloped grains are washed out during the fixing process. Due to their thickness and to ensure uniform response, a special development process, involving presoaking the emulsions at a reduced temperature, must be used. After development, the nuclear emulsion will have shrunk to about 40% of its original thickness. The thickness is also sensitive to the ambient humidity, and the plates are normally kept in humidity controlled storage (~50% relative humidity). The shrinkage needs to be taken into account for most measurements.

The track image in the emulsion is viewed with a microscope with magnification in the range of $10 \times$ to 10×100 . With the aid of a special microscope, having a calibrated micrometer vertical focus adjustment and a special high-precision stage with calibrated micrometer x - and y -movements, the characteristics of the tracks can be determined and used to identify most particles and to measure their momentum. The dE/dx is measured by determining the grain density along the track. The energy or momentum is determined from the range of the particle or from multiple scattering. Additional information can also be obtained from the density of associated delta rays. These measurements can usually be combined to uniquely determine the charge (but not the sign) and momentum of the particle and the mass in the case of a singly charged particle. The interested reader may find additional information in References 8 through 10.

Nuclear emulsions are currently produced by Ilford Photographic (Ilford Research Laboratory, Ilford Ltd., London, England) and Fuji Photo Film Co. Ltd. (Tokyo, Japan). Several types of emulsion are available with different sensitivities to ionizing radiation.

67.3 Gas-Filled Charged Particle Counters

A gas-filled counter detects the ionization electrons and positive ions produced by a charged particle passing through a gas volume. An electrostatic field established between a pair of electrodes in a gas-filled container causes the electrons to move toward the anode and the ions toward the cathode. The charge movement produces an electrical pulse that can be detected using suitable electronics. A gas-filled counter can operate as an ionization counter, a proportional counter, or a Geiger–Müller counter. [Figure 67.3](#) shows the three operating regions with characteristics determined by the electric field region in which they operate.

Ionization Counter/Chamber: At low fields, the recombination of electron-ion pairs reduces the detector signal, making it electric field dependent. With increasing field, nearly all the charges can be collected before they recombine. In an ionization counter, the signal-to-noise ratio is quite unfavorable, except when used for the detection of heavily ionizing particles (e.g., alpha particles). For radiation monitoring, the device is generally used in integrating mode as an ionization chamber. The current signal in an ionization chamber is proportional to the rate of ionization produced by charged particles interacting in the detector gas volume.

Proportional Counter: At still higher fields, the electrons acquire enough energy between collisions with gas molecules to produce secondary ionization in the gas. The secondary electrons in turn can produce further ionization along their path, leading to an electron avalanche that stops only when all the electrons are collected at the anode. This large increase in the number of primary electrons leads to

FIGURE 67.3 Typical behavior at atmospheric pressure for a gas-filled counter. Three principal operating regions are identified: ionization region, proportional region, and Geiger-Müller region. The lower curve is for minimum ionizing charged particles and the upper one for heavily ionizing ones. At low operating voltages, the ions and electrons recombine. Continuous discharge occurs at high voltages above the Geiger-Müller region of operation.

a detector signal substantially larger than that produced by a pulse ionization counter. The signal amplitude in a proportional counter is directly proportional to the ionization energy deposited in the gas by the ionizing particle. The proportional counter can detect charged particles without loss of gain at incident particle rates approaching 10^4 s^{-1} for each millimeter of anode wire length.

Geiger-Müller Counter: Increasing the electric field still further results in increasing loss of proportionality until the counter enters the Geiger-Müller region of operation. In the Geiger-Müller region of operation, a single ionizing event induces an electrical discharge along the entire length of the anode wire. The output pulse amplitude is large and independent of the energy deposited by the ionizing particle in the gas. The Geiger-Müller counter has a relatively long dead time of a few hundred microseconds, and the detector saturates at counting rates above a few thousand particles per second.

Proportional counters have many advantages over ionization chambers and Geiger-Müller counters, both of which are now used mainly as radiation monitors in the laboratory. A gas flow proportional counter is sensitive to the ionization produced in a gas volume by a single charged particle. It can be used for counting charged particles, to measure their energy loss in the gas, and to measure their track coordinates. The proportional counter is more sensitive than an ionization counter because of a built-in

FIGURE 67.4 Schematic diagram of a gas-filled proportional counter and measurement system.

gas multiplication process that amplifies the initial ionization pulse. Because of its relatively short pulse duration, a proportional counter recovers quickly and can count particles at higher rates than a Geiger-Müller counter with its long dead time.

Gas-Filled Proportional Counters

Basic Design and Operating Principle

Figure 67.4 shows the schematic diagram of a gas-filled proportional counter and associated readout electronics. An electrically conducting gas-filled tube serves as the proportional counter cathode. A fine wire 20 to 25 μm in diameter (usually made of gold-plated tungsten) at the center of the tube, supported by insulators on both ends, forms the anode. For reasons of mechanical and electric stability, the anode wire is strung under a tension of several tens of grams, depending on the wire length and operating voltage of the detector. Mylar windows thin enough to allow passage of α and β particles close the gas volume. The cathode is usually kept at ground potential and a positive voltage V_0 is applied to the anode. The electrostatic field is radial with magnitude given by:

$$E = V_0 / \left(r \ln(b/a) \right) \quad (67.5)$$

where r is the distance from the central axis, a is the radius of the anode wire, and b is the radius of the tube. The $1/r$ dependence leads to the existence of an intense electric field near the anode wire; for example, at $r = 20 \mu\text{m}$, the electric field is 25 MV m^{-1} for a $20\text{-}\mu\text{m}$ diameter anode wire held at 1.5 kV within a cathode tube of radius 1 cm. A charged particle passing through the detector ionizes the gas molecules along its path. Under the influence of electric field, the primary ionization electrons start drifting toward the anode. In the strong anode field region a few wire radii from the anode surface, the electrons produce additional ionization along their paths, which leads to the production of an electron

avalanche. The large increase in number of primary electrons is called gas multiplication or gas gain, which becomes significant in the high-field region near the anode. The gas gain is related to the mean free path of the electrons in the gas for secondary ionizing collisions. The electron mean free path is a function of the electric field and the gas pressure. Gas gains as high as 10^8 can be achieved by proper choice of gas mixture and mechanical construction before reaching the limit imposed by electric breakdown in the gas. Most commonly used proportional counter systems have gas gains in the range of 10^4 to 10^6 [4,11,12,].

The voltage pulse observed on the anode is the result of a change in the electrostatic potential energy of the system. Most of the potential energy change is due to the movement of positive ions away from the high anode field region. The contribution of electrons to the total signal is quite small since most of the avalanche electrons traverse only a short distance before being collected by the anode. The fast movement of the ions away from the intense electric field region near the anode produces an initial rapid rise of the signal. About 50% of the pulse height is reached in roughly 0.1% of the total time, followed by a slow logarithmic rise lasting a few hundred microseconds. The signal is proportional to the total amount of ionization produced in the gas; that is, the product of the gas gain and the number of primary electron-ion pairs. The proportional counter energy resolution is determined by statistical fluctuations in the number of ions and by the statistical nature of the gas gain process itself. Deviations from proportionality occur when the space charge density of the positive ion sheath around the anode wire becomes large enough to locally reduce the electric field. The space charge effects become appreciable, depending on the gas gain at counting rates above $10^4 \text{ s}^{-1} \text{ mm}^{-1}$ of anode wire length.

Fill Gases for Proportional Counters

The choice of proportional counter fill gases is dictated by practical considerations. If low gas gain is acceptable, such as for the detection of α particles or heavy ions, both of which produce extremely high specific ionization (initial number of electron-ion pairs produced per cm), almost any gas (even air) can be used. For other particles, one requires a gas that has high specific ionization, high gas gain, low operating voltage, good proportionality, high single particle counting rate ability, and long operating life time. Noble gases such as argon meet the criteria of reasonable gas gain at low operating voltage and high specific ionization. However, the ultraviolet photons produced by excited argon atoms can cause secondary electron emission from cathodes, leading to electrical breakdown at higher operating voltages. The problem can be cured by adding a quenching polyatomic gas with rotational and vibrational levels that can readily absorb the ultraviolet photons. The addition of a quenching gas permits stable high gain operation of proportional chambers. A mixture of 90% argon and 10% methane (CH_4) called P10 is a commonly used proportional counter gas. Several different gas mixtures exist that are capable of achieving proportional gas gains in the neighborhood of 10^6 .

The specific ionization for a gas can be calculated from a knowledge of dE/dx_{ion} , the rate of charged particle energy loss in the gas and W the mean energy needed to create a single electron-ion pair. The properties of some common proportional counter gases are shown in Table 67.2. The values of dE/dx_{ion}

TABLE 67.2 Characteristics of Gases Commonly Used in Proportional Counter Gas Mixtures

Gas	W (eV)	dE/dx_{ion} (keV/cm)	Specific Ionization (ion pairs/cm)
Ar	26	2.44	94
Xe	22	6.76	307
CO_2	33	3.01	91
CH_4	28	1.48	53
C_4H_{10}	23	4.50	195

Note: dE/dx_{ion} and specific ionization values are for minimum ionizing charged particles in gas at atmospheric pressure.

and the specific ionization shown in the table are for minimum ionizing charged particle tracks. The specific ionization for a gas mixture is the average specific ionization calculated with partial pressures of the component gases as weights.

The use of organic quenching gases as quenchers in proportional chamber gas mixtures can lead to the formation and deposition of polymers on the electrodes that reduce the operating life of a proportional chamber. To improve chamber lifetime and reduce aging, nonpolymerizing agents such as methylal are frequently added in small quantities to the gas mixture. For proportional counters with sealed gas volumes, the detector performance will degrade due to the contamination of gas in a sealed volume caused by component outgassing. Cleanliness and careful choice of components during fabrication can minimize these effects. The performance of a sealed proportional counter will also degrade with the degradation of the quenching gas component, which can happen when the device is exposed to large fluxes of radiation or after prolonged use. To minimize these problems, proportional counters are often used with external gas supply systems capable of refreshing the gas continuously.

Proportional Counter Operation and Readout

It takes a few hundred microseconds to develop the full voltage pulse in a proportional counter after a leading edge risetime of a few hundred nanoseconds. Even with a gas gain of 10^4 to 10^5 , the pulse amplitude is only a few millivolts. Further amplification and shaping is needed to obtain signals suitable for measurements. Often, low-noise amplifiers with built-in *RC* differentiation to shorten the output pulses to 1 μ s or less are used (see Figure 67.4). These improve the ability of proportional counters to measure particles at high counting rates without pulse pileup distortions caused by closely spaced pulses overlapping in time. The energy loss of a charged particle in a gas can be measured by measuring the pulse height of the anode signal with an oscilloscope or a multichannel analyzer. For charged particle counting, a discriminator can be used to produce logic pulses that can be counted with a scaler. For coincidence applications, timing resolution of a few nanoseconds is typical for a proportional counter. Good RF shielding and careful electric grounding are essential to maximize the sensitivity of most proportional counters.

The performance of a proportional counter is determined by operating voltage. At lower operating voltages, the best linearity is achieved at the expense of lower gas gain and, consequently, a low signal-to-noise ratio and low efficiency for particle detection. Increasing the voltage leads to larger gain, better signal-to-noise ratio, reduced linearity, faster aging, and susceptibility to electric sparking and damage. In general, the lowest possible anode voltage consistent with achieving good particle detection efficiency is preferred for the operation of proportional counters. This can be accomplished by choosing the operating voltage roughly in the middle of the high-voltage (HV) plateau for the device. On the HV plateau, the counting efficiency of the device remains constant for any variations of anode high voltage [12]. Typical proportional counter operating voltage plateaus are reached in the voltage range of 1.5 kV to 2.5 kV.

Proportional Counters: Advanced Techniques

Many variants of the simple, single wire design have been developed for nuclear physics and particle physics experiments [4,11,12]. Multiwire proportional counters were invented by George Charpak in 1968. In a multiwire proportional chamber, a parallel equidistant row of anode wires is enclosed between two cathode planes. Each anode acts as an independent proportional counter which is read out using suitable electronics. Segments of charged particle tracks can be localized in a multiwire proportional counter in the anode wire plane in a direction perpendicular to the anodes with accuracies on the order of 0.5 mm. A second coordinate along the length of the anode can also be obtained by a measurement of induced signals on a cathode that is segmented in strips in a direction normal to the anode wires. Much more precise particle track coordinate measurements with accuracies of tens of micrometers are possible in another variant called the drift chamber. This is achieved from a knowledge of drift velocities of electrons in the chamber gas as a function of electric field and by measuring the drift time of the ionization electrons to the anode. Complete three-dimensional determination of particle tracks is possible

in a device known as the time projection chamber, which is a combination of a multiwire proportional chamber and a drift chamber. Gas microstrip detectors [13] improve on the high count rate abilities and spatial resolution of a multiwire proportional chamber using closely spaced anode strips that are printed photolithographically on a rigid substrate. Gas microstrip detectors with anode spacings of 200 μm are able to achieve spatial resolution of under 40 μm and count rate abilities in excess of $10^6/(\text{s mm}^2)$.

Geiger-Müller Counters

Basic Design and Operation

A Geiger-Müller counter [14] is similar in construction to a proportional counter. Operating at electric fields above the proportional region, it is a controlled discharge counter that produces a large output pulse of a few volts for every ionizing event in the gas independent of the amount of energy deposited in the gas. The ultraviolet photons from the electron avalanche in a Geiger-Müller counter induce an electrical discharge along the entire length of the anode wire. Gas mixtures used in Geiger-Müller counters generally contain a noble gas mixed with ethyl alcohol or halogen containing a vapor such as ethyl bromide, which acts as a quencher and eventually stops the discharge. After the discharge, the Geiger-Müller counter has a large dead time on the order of a few hundred microseconds, while the excess ionization is swept out of the chamber, during which it cannot register another pulse. If ethyl alcohol is the quenching agent, the gradual decomposition of molecules causes the counter characteristics to degrade with usage and the counter eventually ceases to function. Counters with a halogen compound used as a quenching agent do not suffer from this defect; however, because halogens are electronegative and capture electrons, such counters suffer from the problem of variable output signal delays. Since the Geiger-Müller counter pulses are several volts high, they require no further amplification for measurement purposes.

Proportional Counter and Geiger-Müller Counter Applications

Proportional counters and Geiger-Müller counters are often used in instruments for radiation protection and monitoring. Depending on the construction, they can be used for both the detection of α and β particles. The simple Geiger-Müller counter is perhaps more commonly used as a radiation monitor because it is easier to use and it has high efficiency, close to 100%. However, because of its relatively long dead time, a Geiger-Müller counter becomes less useful as a monitor in high radiation environments where particle rates exceed a few thousand counts per second. Also, a Geiger-Müller counter provides no energy information. For high counting rate applications or when energy discrimination is needed, it is better to use a proportional counter. Unfortunately, they can be cumbersome to use if an external gas supply is required. Geiger-Müller counters and proportional counter systems can be purchased from many different vendors (see [Table 67.3](#)). Prices vary from \$100 to \$500 for Geiger-Müller and proportional tubes, and up to \$2000 for complete systems and accessories (e.g., survey meters, scalers, ratemeters, analyzers, etc).

67.4 Scintillation Counters

Introduction

The use of scintillation light is one of the original methods used to detect charged particles. In 1911, Rutherford used an activated zinc sulfide screen to detect α particles. The flashes of light produced in the screen were counted by a dark-adapted observer. Today, scintillation counters are usually made of either plastic, liquid, or crystal materials, and the resulting signal is detected electronically. The principle of operation of these devices is that the energy deposited by charged particles moving through the scintillator material causes some of the molecules to be raised to an excited state. On returning to the ground state, the molecules emit light. The decay time of the light emitted depends on the fluorescence

time of the scintillator. This can be very short, producing signal pulses as short as a few nanoseconds and thus allowing this type of detector to be used at very high counting rates. The light produced by the scintillator is usually detected using a photomultiplier. An appropriate choice of scintillation medium and detection method can produce a highly effective charged particle counter with an efficiency of essentially 100%.

Scintillation Counters: A Detailed Description

A scintillation counter consists of the scintillation medium, a light detector, and a light guide to transfer the light from one to the other (see Figure 67.5). Information on each of the components of a scintillation detector follows [4].

FIGURE 67.5 A typical scintillator system consisting of a scintillation medium, light detector, and light guide.

Scintillation Medium

Plastic or liquid scintillators are usually used for the detection of charged particles. Crystal scintillation media such as sodium iodide or BGO (bismuth germanate) are normally used for photon detection or applications in which energy resolution is important. Plastic detectors are inexpensive and have proved to be a reliable way of detecting charged particles. Large areas can be covered using adjacent sheets of plastic scintillator. Such an array of detectors is known as a hodoscope. Primary light output from a plastic scintillator is at short wavelengths, below 400 nm. Light at these wavelengths has a short attenuation length in the plastic, so wave-shifting dyes are employed to convert the light to longer wavelengths. Thus, a plastic scintillator contains two or more additives such as polystyrene doped with *p*-terphenyl and tetraphenyl-butadiene. Proprietary scintillators are available in a large variety of shapes and sizes from companies such as Bicron Corporation. Plastic scintillators will darken upon exposure to radiation in excess of about 10^3 grays, which will lead to inefficiencies. Liquid scintillation materials, such as toluene, are useful for constructing large volume detectors. Such devices are used in high radiation areas as liquid scintillators are inherently more radiation resistant. It is also possible to replace the liquid if radiation damage occurs. The main problem with this kind of device has been maintaining a leak-proof container and the resulting hazard associated with the toxicity of the liquid.

Light Coupling to Photon Detectors

The light produced in the scintillator is emitted isotropically. A portion of this light is trapped in the scintillator by total internal reflection. For a small detector, it is possible to couple the end of the scintillator directly to a phototube. For larger detectors (exceeding the width of the photodetector), a light guide made of a UV-transparent acrylic plastic is recommended. Acrylic plastic is widely available; Plexiglas by Rohm is one example. Light guides can be made of one piece of shaped plastic but maximum efficiency can be realized using adiabatic (constant area) light guides that minimize light losses. These light guides are quite artistic (see [Figure 67.6](#)) and are made from acrylic strips heated and then bent to the appropriate shape. The cut edges are flame polished to produce a smooth surface for good internal reflection. To

FIGURE 67.6 Photograph of adiabatic Plexiglas light guide. (Courtesy of Science and Technology Centre, Carleton University, Ottawa.)

match large scintillators to a small area detecting device, a light guide known as a “Winston cone” [15] is used on the light detector. The shape of the Winston cone minimizes light losses.

Light Detection and Readout

The standard method of detecting light from a scintillator is the use of photomultiplier (PM) tubes. These consist of a light-sensitive photocathode and an amplification stage. The photocathode is a thin layer deposited on the inside of a vacuum tube that has a good probability (>10%) of emitting an electron when struck by a photon. These electrons are electrostatically focused on a secondary electrode (dynode), which is the first element of the amplification structure. The voltage between the photocathode and this first dynode is sufficient to give the electrons enough energy to eject two to four electrons from the dynode. This process is continued through a series of dynodes resulting in a large gain, up to 10^8 in a tube with 14 dynodes. The output pulse is read out from a connection to the anode or the last dynode. The photomultiplier has connection pins corresponding to each dynode. Voltages are supplied to these via a resistive divider network contained in a “base” or “divider.” The base requires one HV input and provides one or two signal outputs. Details of divider networks are available from PM tube manufacturers. Further information on the operation of phototubes can be found in Reference [16].

In operation, PM tubes are sensitive to magnetic fields and it is usually necessary to provide magnetic shielding. A tube of a single layer of mu-metal is often sufficient to shield the PM tube from the Earth’s magnetic field. For applications where there are higher ambient fields, a shield of layered tubes can be used consisting of two mu-metal shields and up to two soft iron shields. They should extend approximately one tube diameter beyond the PM tube. In applications where an axial field is unavoidable, a bucking coil can be inserted between the two iron layers. A suitable choice of coil current can counteract the axial field.

Scintillator Detector Construction

Assembly of scintillators, light guides, and PM tubes is usually done with an optical cement. It is important in the preparation of the adhesive to remove air bubbles which would scatter the light. It is also possible to make a demountable joint using optical grease or vacuum grease and a mechanical fixture. Such a joint can be used to simplify the replacement of phototubes. Light levels produced in the scintillator are extremely low; therefore, detector assemblies must be enclosed in light-tight envelopes. For plastic scintillators, this is most easily arranged by wrapping with aluminum foil and protecting the foil with black plastic sheets held in place with black adhesive tape. In large systems of counters, it is useful to install LEDs in each scintillator to monitor the operation of the counter. A system for powering the LED with a short duration pulse allows a test of the counter and readout system.

Components for scintillator systems can be purchased from many manufacturers, some of which are listed at the end of this section. Prices vary widely, depending on both the details of the detector and the quantity of components ordered. Typical prices would be \$600 for a piece of scintillator $0.5\text{ cm} \times 45\text{ cm} \times 60\text{ cm}$, \$200 for a voltage divider and \$500 to \$1200 for a 12-stage, 5-cm diameter phototube. Liquid scintillators are available for \$145 per liter. Prices are in U.S. dollars. The cost of custom light guides is dominated by the available labor rate. There are some suppliers (such as Bicron) that will provide complete custom detectors consisting of scintillator, light guide, PM tube, and divider.

Operating Information

A minimum ionizing particle crossing a 1-cm thick scintillator will liberate about 10^4 photons. With typical scintillators and light guides, about 10% of these will reach the photocathode. The efficiencies of photocathodes to produce photo-electrons is usually greater than 10%. Given PM tube gains of 10^8 , this leads to 10^{10} electrons at the anode, allowing analog pulses of about a volt to be produced. The pulses typically have a rise time of about 1 ns and a fall time of 5 ns. The trailing edge of the pulses can be shortened to approximately 2 ns by attaching a short grounded line to the output (clip line). The anode outputs are normally connected to a discriminator that produces a standard digital pulse for all analog

pulses exceeding a fixed threshold voltage. More sophisticated circuits, such as constant fraction discriminators, can be used for best timing resolution. Using these devices along with a scintillator geometry that provides good light output, a timing resolution of the order of 300 ps (1σ) can be achieved. The excellent signal characteristics of scintillation counters allow them to count efficiently at rates exceeding 10 MHz.

Background counts in a scintillator are caused by cosmic rays and noise in the tube. An average rate from cosmic rays is $1 \text{ min}^{-1} \text{ cm}^{-2} \text{ sr}^{-1}$. Tube noise tends to have a lower amplitude than pulses resulting from the scintillator and will have a rate dependent on the choice of threshold. A counter should be checked to see if its count rate is consistent with cosmic ray backgrounds. High count rates are indicative of a light leak, which can be detected by shining a flashlight on the counter in a darkened room. Diligent use of aluminum foil and black tape will fix the leaks. In applications measuring particles that are energetic enough to pass through a counter, system noise can be reduced by using two layers of scintillator and putting their signals in coincidence. Noise can also be minimized by optimal setting of the tube HV and discriminator threshold. If the discriminator threshold is too low, then a large number of tube noise pulses are picked up.

Advanced Techniques

A plastic scintillation counter hodoscope can also be used to obtain position information. The spatial resolution of such a device is limited by the size of the individual detectors. For example, thin finger-shaped counters can be used for measuring beam profiles. Larger “paddles” 10 or 20 cm wide can be used to cover large areas. It is also possible to measure impact position along a counter using phototubes at both ends of a long scintillator and measuring the difference in arrival time of the pulses at the two tubes. Higher precision spatial resolution is possible using scintillating fibers with diameters of around 1 mm. Such a device has a large number of channels and requires segmented cathode phototubes or solid-state readout devices. One such device is the VLPC (visible light photon counter), which is a product of Rockwell International and is a development from a solid-state photomultiplier. To keep noise low, VLPCs are used at cryogenic temperatures.

List of Manufacturers

Table 67.4 shows a selection of potential suppliers of components for scintillator systems.

67.5 Solid-State Detectors

Solid-state detectors have proved to be very versatile in the detection of charged particles. They have been particularly useful for energy measurements of α and β particles, light and heavy ions, and fission fragments in applications that include nuclear spectroscopy, radionuclide identification both in the environment and laboratory, dosimetry, radiation level monitoring, and non-destructive testing using particle beam techniques. In high-energy physics, solid-state detectors are used mainly as high-precision tracking detectors in a particle counting mode. Most of the devices used in all these applications are based on silicon technology except for energy measurements of β particles ($>250 \text{ keV}$), where germanium-based detectors are also used.

Signal Generation

A charged particle moving through a semiconductor crystal loses energy according to the stopping processes described previously (Equation 67.1). The energy lost is spent promoting electrons from the valence band to the conduction band of the crystal. This leaves free electrons in the conduction band and free holes in the valence band. Under the action of an electric field, the free electrons and holes drift in opposite directions and give rise to an electrical current that can be sensed by external electronics.

The amount of charge produced is very small and the semiconductor must be depleted of majority carriers in order for the signal to be measurable. This is accomplished using a diode structure operated with a reverse-bias voltage. A profile of a “typical” diode detector is given in [Figure 67.7](#). The size of the active region of the detector, the depletion region, is determined by the reverse bias applied and the residual fixed charges. In the case where the material has a very high resistivity ($\sim 500 \Omega\text{cm}$ or more), the built-in field of the junction can be sufficient to generate a useful depletion layer without any reverse bias.

For a quantity of energy E_0 deposited through electronic interactions, the number of free electron-hole pairs created is $N_p = (E_0)/\epsilon$, where ϵ is the average energy to produce one pair, a characteristic of the semiconductor, similar to the W value for gas detectors. Typical values of ϵ are small, 3.62 eV for Si at 300 K and 2.96 eV for Ge at 77 K. The variance of the number of pairs created is FN_p , where F is the Fano factor [17], which is of the order of 0.1 for Ge and Si. Hence, semiconductor materials are very efficient in converting radiation energy to an electric signal and the pulse-to-pulse variation in the signal size is smaller than predicted by Poisson statistics, where $F = 1$. When all the charge carriers are collected (i.e., the electrons reach the anode side while the holes reach the cathode side), a total of N_p electrons are available to the front end-electronics for amplification and shaping.

Categories of Detector

Device Details

Commercial solid-state detectors (i.e., silicon or germanium devices) are available from a number of manufacturers (see [Table 67.5](#)). The following silicon devices are available: silicon surface barrier detectors (SSBD), ion-implanted silicon detectors, diffused junction silicon detectors, *pin* photodiodes, and lithium drifted silicon detectors (Si(Li)). Some of the manufacturers rename the different types using their own

FIGURE 67.7 A solid-state diode detector consists of a thin current blocking layer, a sensitive volume of high resistivity material, and a back ohmic contact. A near uniform field may be established in the sensitive volume.

TABLE 67.5 Device Details

Type	Area (mm ²)	Sensitive thickness (μm)	Dead Layers* (nm)	Particles detected	Prices 1996 US\$	Manufacturers
SSBD	10–1000	10–5000	80 225 (back)	p, α, β light and heavy ions	400 to 6000	a b c d

brand names. The first three types actually lend themselves to nearly the same applications: ion detection. Si(Li) detectors are mostly used for soft X-ray detection, but can also be used for full energy measurement of β particles from 250 keV to 3 MeV. Germanium devices are available as lithium-drifted germanium detectors (Ge(Li)) and high-purity germanium detectors (HPGe). As with the Si(Li) detector, the primary function of germanium detectors is for photon detection but they can also be used to detect β particles. Solid-state detectors are either *pn* or *pin* diodes. Silicon devices fabricated from a starting material of about 500 Ωcm (i.e., ion-implanted Si and diffused junction Si) have the *pn* structure. The SSBD, also made from Si of a few 100's Ωcm, is in fact a hybrid of Schottky junction and *pn* junction due to its

gold-on-*n* type Si interface as well as “*p*-like” surface defects introduced during manufacture. Devices that have a bulk resistivity in excess of 1 kΩcm, whether it is due to a high-resistivity starting material (such as is used for pin Si and HPGe) or compensated material (Si(Li) and Ge(Li)), are *pin* junctions.

Many aspects dictate the choice of a detector for a given application. To measure the full energy of highly ionizing particles, it is important to keep the surface dead layer of the detector as thin as possible to limit the loss of undetected energy. The dead layer is the combination of the entrance metal electrode and the underlying, radiation insensitive, heavily doped top Si layer (usually *p*-type). The required depletion region thickness is determined by the range in Si of the particles of interest. A sufficiently wide depletion region is required for full energy measurements of ions, or to obtain a large signal in the case of energetic particles, such as minimum ionizing particles, which traverses the whole detector without stopping. Energy measurements of β particles often require an active volume that is larger than can be achieved with a standard *p-n* junction and so Ge(Li), Si(Li) or HPGe detectors are used. Varnish-coated detectors can be obtained to withstand exposures to rugged environments. Bakeable devices, which allow partial recovery from damage, or inexpensive and replaceable photodiodes can be used in situations of heavy radiation damage. For the detection of heavy ions, devices that can be operated at high electric fields (>15 kV/cm) can be used to overcome recombination effects. One of the most widely used Si detectors is the SSBD. It offers a thin entrance window of less than 100 nm. The diffused junction is the original type of Si detector and it has a rather thick dead layer of 250 nm Si. It is still useful in applications that require a light-insensitive device or for particle physics applications. The implanted junction Si detector results from the implantation of boron ions in an *n*-type Si wafer. It is the most recent addition to commercial Si detectors and it offers a thinner entrance window (less than 50 nm) and a larger surface area than SSBD (see Table 67.5). All these devices can be operated in either partially or fully depleted mode. The thickness of the back dead layer is only relevant to fully depleted, transmission type detectors for energy loss (ΔE) measurements. Recently, high-quality, inexpensive Si *pin* diodes for visible and UV photon detection have been found to be suitable replacements for SSBD in many applications. The thickness of the dead layer is 100 nm, twice that of ion implanted Si detectors, and the resistivity is as high as 2 to 8 kΩcm for the more expensive versions.

Detector Systems

Three practical systems of increasing sophistication are considered next. The first setup, depicted in Figure 67.8, is used to measure the energy spectrum and the rate of incoming charged particles. One

FIGURE 67.8 Using a pulse counter, this simple setup is used to measure the activity of a radioactive sample or the intensity of an accelerator beam. With the addition of a storage oscilloscope or an MCA (multichannel analyzer), the energy deposited in the detector by each incoming charged particle may be measured.

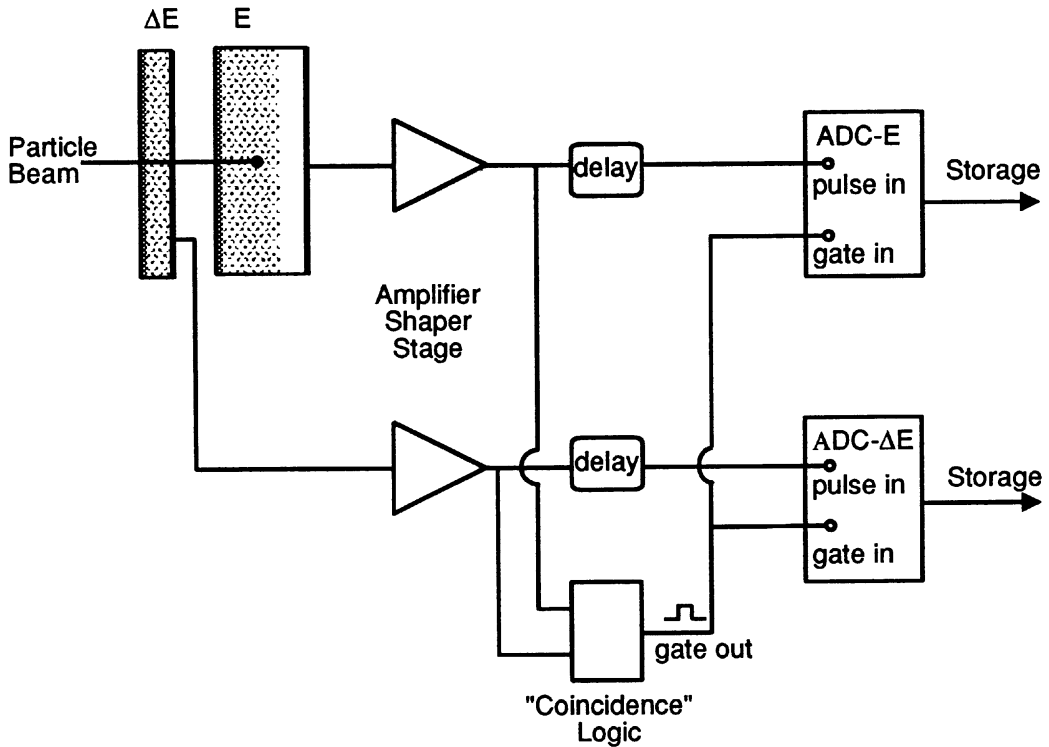

FIGURE 67.9 Knowledge of the amount of energy deposited in a transmission-type detector (ΔE) positioned in line with a full energy measuring detector (E) allows the identification of a particle due to the unique nature of dE/dx and E combination.

possible application is the measurement of the α activity from a natural source or from a wipe test sample. This simple count rate measurement requires a pn silicon detector or photodiode, a discriminator, and a pulse counter. By adding a pulse analyzer, called a multichannel analyzer (MCA in Figure 67.8), the same system can be used to record the energy of the α particles or the full energy of light ions, such as those encountered at an accelerator site where beam analysis of materials is performed. In this case, the suggested detector is a good quality SSBD or an ion-implanted detector with a thin window and operated at a voltage sufficient to generate a depletion region at least as wide as the range of the ions of interest. The second setup (Figure 67.9) shows a thin transmission type (ΔE) detector (open front and back), in front of a thick, fully stopping, (E) detector. This configuration is called a ΔE - E telescope and it supplies a simultaneous measure of the energy loss and the full energy of particles going through both devices. This information then uniquely identifies the particle. Finally, Figure 67.10 presents a position-sensitive silicon strip detector for which the localization of a particle hit to better than $5\ \mu\text{m}$ in one dimension is possible [18]. Such a detector is used in particle physics experiments. In many applications, combinations with other detector types, such as scintillators, are also possible.

Detectors with sensitive thicknesses of $100\ \mu\text{m}$ to $300\ \mu\text{m}$ are used in many nuclear spectroscopy and high-energy physics applications. For typical values of applied voltages, full electron collection occurs in less than $10\ \text{ns}$, while hole collection takes less than $20\ \text{ns}$. The amount of charge in a pulse is very small, of the order of $1.5 (10^6) e$ for the full energy of an α particle and $100 e$ per μm of path in silicon of a minimum ionizing particle. Depending on the application, the signal processing electronics can be optimized for low noise or fast response. In spectroscopy applications, where precise measurement of the total charge is important, one uses low noise, charge integrating preamplifiers, which offer output gains of the order of $1\ \text{mV fC}^{-1}$. The preamplifiers are optimized for specific ranges of detector capacitance. For detectors of $5\ \text{pF}$ and smaller, noise values of less than $1\ \text{keV}$ (equivalent energy loss signal in Si)

FIGURE 67.10 A silicon strip detector, such as the one depicted here, can be used to localize the hit position of a minimum ionizing particle.

can be achieved. In the case of preamplifiers optimized for larger detector capacitances (200 to 1000 pF), the noise increases with a slope of $\sim 0.02 \text{ keV pF}^{-1}$. Preamplifiers produce a “step” pulse with an amplitude proportional to the input signal charge. The rise time of the pulse varies with the detector capacitance, from 5 ns to 10 ns for $<10 \text{ pF}$ to 100 ns for 1000 pF. The pulse decay time is determined by internal circuit components and usually falls in the range of 50 μs to 300 μs . The signal is further amplified and shaped using an integrating-differentiating amplifier to provide a pulse of gaussian shape whose width is of the order of 1 μs . This pulse duration limits the counting rate to much less than 10^5 cps before an unreasonably high counting deadtime is encountered. In high-energy physics experiments, the signal processing electronics coupled to position-sensitive detectors are optimized for a high counting rate capability and good timing resolution. Silicon integrated circuits containing a large number of amplifiers are specially designed for such applications. The individual amplifiers provide large output gain (15 mV fC^{-1}) and output pulses whose width can be as small as 20 ns (baseline to baseline), at the cost of an increase in noise (6 keV Si-equivalent). Count rates near 10^6 cps for every detection channel can be achieved with such systems.

Plasma Effects and Pulse Height Defect

Under some conditions, one may observe a loss in proportionality between the energy lost by the particle crossing the detector and the signal. This is called the pulse height deficit (PHD) and it is the sum of

three components: E_W , E_N , and E_R , where E_W is the energy lost in the window or dead layer of the detector and E_N is the energy lost to nuclear scattering (nonionizing). The third term, E_R , is harder to define and is due to a deficit in the charge collection. Ions heavier than the proton create a plasma with a charge density as high as 10^{19} e⁻/cm³ which shields the charge from the collecting field and causes charge loss through electron-hole recombination in the plasma to occur. The PHD increases roughly with the particle mass and energy, and ranges from 1% to 3% for ions such as oxygen at 20 MeV.

New Structures

Modern silicon processing technologies allow the design of intricate structures which find applications in charged particle detection, particularly in high-energy physics experiments. These include position sensitive detectors, with strip electrodes or pixel segmentation, and large-volume silicon drift chambers. Front-end electronics can also be fabricated on the same wafer as the detecting structure itself. Close coupling provides noise reduction. The reader should be aware that new materials, such as GaAs, CVD diamond, natural diamond, cadmium telluride, HgI₂, and hydrogenated amorphous silicon, are being used in prototype detectors. These are beyond the scope of this chapter.

Manufacturers and Prices

A list of typical devices and pricing for each category of solid-state detector is given in Table 67.5. The names of some manufacturers are given but the interested reader is also encouraged to consider other sources.

Neutron Measurement

68.1	Detector Types Detectors Based on Elastic Scattering • Detectors Based on Capture Reactions • Detectors Based on Fission • Counters Based on Inelastic Scattering • Detectors Based on (n,p) or (n, α) Reactions
68.2	Efficiency Calculations
68.3	Summary

Steven M. Grimes
Ohio University

Neutrons have characteristics that make them of particular importance in technology and research. Since they are uncharged, they are able to enter the nucleus at very low energy. Furthermore, the lack of energy losses through ionization permits deep penetration into materials.

This latter characteristic makes detection of neutrons more complicated than detecting protons or alpha particles. The energy of these charged particles can easily be determined by detecting them in [ionization chambers](#), [proportional counters](#), or [scintillators](#), and ultraprecise measurements can also utilize the steering effect of magnetic fields. Detection efficiencies approach 100%. Neutrons, on the other hand, are not directly detected by these detectors and some means of converting the neutron through a nuclear reaction to a charged particle or gamma ray must be used.

Nuclear reactions occur when neutrons interact with nuclei (including protons). When a neutron interacts with a nucleus, the following processes are possible:

1. Elastic scattering occurs if the neutron simply changes its direction without giving the nucleus any intrinsic excitation energy. The transfer of energy is analogous to that in a collision of two billiard balls and is governed by the laws of mechanics.
2. Capture reactions are those in which the neutron is absorbed by the nucleus to form a heavier nucleus. In this case, the energy released comes in the form of one or more gamma rays.
3. Fission occurs in many cases if a heavy nucleus (mass $> A = 230$) is struck by a neutron. The nucleus divides into two smaller nuclei with a huge energy release ($E > 100$ MeV, where $1 \text{ MeV} = 10^6 \text{ eV} = 1.6 \times 10^{-13} \text{ J}$).
4. Inelastic scattering occurs if a neutron transfers energy to the target nucleus and leaves it in an excited state. This energy is usually emitted in the form of a gamma ray, although in some cases positron-electron emission occurs, and in many cases, a number of low-energy gamma rays are emitted rather than one higher-energy gamma ray.
5. (n,z) reactions can also occur, where the neutron is absorbed by the nucleus and a charged particle (usually a proton or alpha particle) is emitted.

Each of these processes could, in principle, be used to detect neutrons. Unfortunately, in many cases, one cannot ensure that only one type of reaction occurs and even when this condition is met, the resulting pulse spectrum does not always allow determination of the energy of the neutron.

68.1 Detector Types

Detectors Based on Elastic Scattering

Detectors based on elastic scattering are attractive because the elastic scattering cross-section is large (usually about half of the total interaction cross-section). A fundamental problem with elastic scattering is that the recoil energy as a fraction of the incident energy ranges from 0 (at 0° scattering angle) to $4A/(A+1)^2$ (for 180° scattering angle), where A is the mass number of the target. For $A = 1$ (hydrogen), this recoil energy ranges from 0% to 100%, but for even as light a target as carbon ($A = 12$), the maximum energy of recoil is less than 30%. The fact that a continuous range of energies is produced even from a monoenergetic neutron beam makes the efficiency difficult to calculate, since it depends on accurate knowledge of the cutoff threshold of the electronics. The same feature complicates determining the energy distribution of neutrons when a range of energies is present.

Hydrogen-containing counters are nonetheless frequently used in neutron physics. Below about 500 keV, the pulse height is usually too small to be useful, but above this energy this type of counter is effective. Proportional counters or ion chambers filled with methane can be used in situations where fast timing is not required. Hydrogen-containing scintillators have poorer energy resolution but better timing information and are available in large volumes. Scintillators are subject to a threshold but can be made highly efficient ($\epsilon > 50\%$) if the volume is sufficiently large. For either proportional counters or scintillators, gamma rays can produce background pulses through the [Compton effect](#), but some liquid scintillators have the capability of identifying the two types of pulses produced by neutrons and gamma rays, respectively, allowing discrimination against gamma rays. The excellent timing characteristics of scintillators have resulted in extensive use of these detectors for [time-of-flight spectrometers](#). In these spectrometers, the energy of the neutron is deduced by timing the neutron over a measured flight path. For typical flight paths ($L < 10$ m), a precision of a few nanoseconds is required.

The fundamental limitation of counters of this type is that the pulse height in the detector is not uniquely related to the neutron energy. If the detector is not used in a time-of-flight spectrometer, the energy of the neutron cannot be deduced. A related problem is that the efficiency is determined by an electronic cutoff, which is difficult to determine accurately. Finally, detectors that include the entire angular distribution do not have directional sensitivity.

All of these drawbacks can be removed if only a limited portion of the angular range is sampled. This is the case in a recoil counter telescope. The spectrometer consists of a polyethylene radiator at one end of an evacuated cylinder. Near the other end are either one or, more typically, two detectors. Neutrons enter the telescope from the end holding the radiator. A small fraction of them produce recoil protons at small angles to the beam. A two-detector system is arranged so that the particles traverse both. Requiring a coincidence in pulses reduces backgrounds. These detectors register protons scattered by the neutron beam at angles near 0° to the original beam. The recoil energy of such protons is $E_n \cos^2 \theta$, where E_n is the neutron energy and θ is the angle of recoil. This implies that for a telescope which subtends an angle θ around 0° , the energy range of recoil protons will be E_n to $E_n \cos^2 \theta$. It can be shown that the average energy is simply $(1/2) E_n (1 + \cos^2 \theta)$. Obviously, as θ becomes small, the proton energy reflects the neutron energy. The smaller θ becomes, however, the lower the efficiency of the telescope. Typical telescopes of this type have efficiencies of 10^{-5} to 10^{-6} . It is obvious that only neutrons arriving along the axis will give protons of the right energy. Neutrons coming from the backward hemisphere will not be able to produce protons that traverse the spectrometer. The drawback of a low efficiency is partly compensated by the fact that the efficiency can be accurately calculated and the fact that the energy spectrum can be deduced.

Detectors Based on Capture Reactions

Capture reactions have small cross-sections at energies above 1 MeV. At lower energies, the cross-section typically varies as $1/\sqrt{E}$, so it can be very large at low energies. Further, the capture process is exoergic,

typically yielding about 7 MeV. This energy is usually divided among two to four gamma rays. The efficiency of gamma-ray detectors is usually much less than 100% and detecting the gamma rays in coincidence requires large solid angles. It is essentially impossible to use the capture process to determine the energy of individual neutrons in a flux of neutrons of varying energies.

An alternative use of the capture process is in a passive detector. A foil of the appropriate material can be placed at the location where the flux is to be determined. The target must be one that produces a radioactive residual nucleus when a neutron is captured. Thus, ^{28}Si would not be appropriate, since ^{29}Si is stable, but ^{27}Al would be a possibility, since ^{28}Al is radioactive. After the measurement is complete, the foil is removed and placed in a counting area. A detector then counts the beta particles or gamma rays emitted. Of particular importance is the choice of target to ensure an appropriate half-life. A very short half-life would allow the decay of the radioactive nuclei before they could be counted, while a very long half-life (>1 month) might require an excessive length of time to be counted.

The complicated energy dependence of the capture cross-section makes use of the capture process mostly useful for relative measurements. If two measurements are made of spectra with the same relative distribution of neutrons with energy, a measurement of the ratio of activities will give the ratio of neutron intensities. An important advantage to this technique is that small foils can be used, allowing the determination of the flux in a small volume. Other radiation, such as gamma rays, usually does not interfere in such a measurement. An important disadvantage is that the flux is not obtained until after the counting is completed; this might be as long as a month after the measurement. An additional disadvantage has already been mentioned. If the relative energy dependence of the two spectra is not the same, the relative ratio of neutrons will not be correct.

Detectors Based On Fission

The fission process is relatively unique, since an energy release of over 100 MeV occurs even when the incoming neutron has an energy below 1 eV. Fission cross-sections for gamma rays are small, so most of the pulses will be due to neutrons. There are two types of fission targets. Those with even proton number (Z) and even neutron number (N) have an energy threshold for fission. The cross-section for fission is normally negligible below 2 to 3 MeV. Other targets for which either N or Z or both are odd have no threshold energy. These isotopes (e.g., ^{235}U) normally have a low energy cross-section dependence of $1/\sqrt{E}$, giving a very large efficiency for neutrons below 100 keV. Fission detectors are designed either for $E_n > 2$ MeV (in which case ^{238}U would be an appropriate choice) or for the entire energy range, in which case the efficiency is highest at low energies.

Fission foils must be fairly thin to allow the escape of the fission fragments into the counting volume. This typically results in low efficiencies (<10⁻⁶). Fission chambers also require the license to possess radioactive isotopes. The energy release in the fission process is so large that the pulse height in the counter cannot be used to infer the neutron energy. Reasonably good timing information ($\Delta t < 5$ ns) allows the use of fission chambers in time-of-flight spectrometers.

Counters Based on Inelastic Scattering

Inelastic scattering results in a transfer of energy from the neutron to the target nucleus through excitation of an excited energy state. This will then result in the production of one or more gamma rays. Gamma rays can be detected in germanium detectors with good energy resolution. Unfortunately, the efficiency of a spectrometer utilizing a germanium detector and inelastic scattering is quite small. This technique is being examined as a possible approach to identifying contraband materials in luggage, since both the neutrons and the gamma rays they produce are highly penetrating.

Although most gamma ray decays occur rapidly (<10⁻⁶ s), some gamma-ray decays are inhibited by angular momentum coupling and have half-lives longer than 1 s. These could be used in a detector based on inelastic scattering just as the capture reaction is used. Two nuclei with such states are ^{89}Y and ^{103}Rh . Unlike the capture reaction, such isomeric transitions will not be effective in detecting low-energy

neutrons, since there is a threshold for populating such states (approximately equal to the energy of excitation, ignoring recoil effects).

Detectors Based on (n,p) or (n, α) Reactions

Detectors utilizing (n,p) or (n, α) reactions can be passive, in which a final product nucleus is radioactive, or active, in which a proton or alpha is detected. For a discussion of the passive type, see Section 68.2. Direct detection of the charged particle can occur in a proportional counter or a scintillator. As in the case of fission, many (n,p) and (n, α) reactions have an energy threshold, which prevents their occurring until this energy is exceeded. Others have no threshold (they are exoergic) and have low energy cross-sections that vary as $1/\sqrt{E}$. These targets and the reactions that occur are:

1. ${}^3\text{He}(n,p){}^3\text{H}$
2. ${}^6\text{Li}(n,\alpha){}^3\text{H}$
3. ${}^{10}\text{B}(n,\alpha){}^7\text{Li}$

Reaction (1) is often utilized in a proportional counter filled with ${}^3\text{He}$. The second reaction can be used in a scintillator made of glass which has a loading of up to 9% ${}^6\text{Li}$. For reaction (3), the gas BF_3 can be used in a proportional counter.

Each of these reactions is particularly effective in detecting neutrons below 1 MeV and especially thermal neutrons ($E \sim 0.025$ eV). Few charged particles are produced by neutrons at these energies from the counter housing or glass constituents, so the spectra are characterized by minimal interference from other materials. A common problem is that the low-energy neutrons that one seeks to measure are accompanied by a flux of thermal neutrons, which one does not wish to measure. In this case, the counter efficiency will be so high for the thermal neutrons that they may swamp the events one wishes to detect. An obvious solution to this problem is to use a thin layer of cadmium or boron to shield the detector, since these materials have very high thermal absorption cross-sections. Each of these reactions is much less effective at energies above 10 MeV, since backgrounds due to charged particles in the housing or in the glass can be comparably large. Although counters utilizing these reactions can be approximately 100% efficient at thermal energies, they are often less than 5% efficient at energies above 3 MeV.

There is an interest in having a counter that can detect neutrons with virtually constant efficiency independent of energy. A counter that approximately meets this characteristic is the long counter. This counter consists of a BF_3 -filled proportional counter embedded in a polyethylene moderating cylinder. Those neutrons directly incident on the BF_3 chamber with very low energies will be detected with approximately 100% efficiency, while neutrons with $E_n > 1$ MeV will be detected with much smaller efficiency (<10%). By surrounding the BF_3 counter with polyethylene, the higher energy neutrons can be slowed down and the net efficiency increased, although some may be captured in the polyethylene. Very low energy neutrons will be more likely to be captured in the polyethylene, so the detection efficiency for these neutron energies is reduced. Study of the detailed energy dependence of the efficiency of such counters has resulted in a design that has certain cavities cut in the shielding on the side from which the neutrons enter. This allows some of the lower energy neutrons a shorter path to the counter. The fact that neutrons are detected after moderation means that the counter cannot give precise timing information, nor can it be used to determine neutron energy spectra. It also cannot determine the neutron flux over a small cross-sectional area but gives an average over 40 to 100 cm^2 . It also will have a slightly different efficiency for neutrons coming from different directions. A sample design is shown in [Figure 68.1](#). Note that since the counting element needs only to have an efficiency that rises sharply at low energy, a long counter can be designed using a ${}^3\text{He}$ ion chamber instead of a BF_3 tube.

Other (n,z) reactions do not have positive Q values (are not exoergic). These have thresholds and, in fact, usually have small cross-sections for a few MeV beyond the threshold. An example is ${}^{27}\text{Al}(n,\alpha){}^{24}\text{Na}$. This reaction cannot occur for neutrons of less than 3 MeV and has a very small cross-section below 4.5 MeV. It does lead to a radioactive final nucleus and can be used as a passive detector. Unlike the detectors based on (n, γ) reaction, it will not detect low energy neutrons.

FIGURE 68.1 Cross-section of a typical long counter (described in M.H. McTaggart, AWRE NR/A1/59 (1958)). Neutrons incident from the right are scattered by the paraffin, causing them to lose energy. The BF_3 counter is efficient primarily for neutrons below 1 keV. The holes and the B_2O_3 sections balance the efficiency as a function of energy.

An alternative reaction that can be used in a passive detector is the $(n,2n)$ reaction. This typically has a threshold of about 8 MeV but has a large cross-section once the threshold is exceeded. Note that just as is found for (n,γ) or (n,z) reactions, not all nuclei reached in $(n,2n)$ reactions are unstable.

68.2 Efficiency Calculations

Detectors based on np scattering have an efficiency that depends on the n-p elastic cross-section. For a proportional counter or scintillator, an approximate expression for the efficiency is

$$\epsilon = \left(1 - e^{-n\sigma_H L}\right) \left(1 - \frac{B}{E_n}\right) \quad (68.1)$$

This expression involves the parameters n , the number of hydrogen atoms per cm^3 ; σ_H , the n-p elastic cross-section; B , the electronic cutoff (in energy equivalent units); and E_n , the neutron energy. This expression ignores multiple scattering, so it would not include pulses produced by two scattering events in succession. It also does not include carbon interactions. For energies below 4.4 MeV, carbon interactions are almost entirely elastic and do not result in absorption or pulses large enough to detect. Particularly at energies above 10 MeV, carbon interactions not only remove neutrons from the beam but also, through (n,α) or $(n,3\alpha)$ events, can produce pulses that can be detected. Calculating the efficiency in this energy range can be done with Monte Carlo codes, but the efficiency will depend on knowledge of the $^{12}\text{C}(n,\alpha)$ and $^{12}\text{C}(n,3\alpha)$ cross-sections as well as the relation between alpha pulse heights and proton pulse heights as a function of energy.

Recoil telescopes have an efficiency which has the form:

$$\epsilon = \frac{n\sigma(0^\circ)LA}{d^2} \quad (68.2)$$

Here, n is the number of hydrogen atoms per cubic centimeter, $\sigma(0^\circ)$ is the n-p elastic-cross section at 0° (in units of $\text{cm}^2/\text{steradian}$), L is the thickness of the radiator, A is the area of the detector, and d is the distance between radiator and detector. Note this assumes that $n\sigma L \ll 1$ and that θ is small. A corrected version based on the assumption that the n-p cross-section is isotropic in the center of mass has:

$$\sigma(0^\circ) = \frac{\sigma_{\text{np}}}{\pi} \quad (68.3)$$

where σ_{np} is the total elastic cross section and, if θ is not sufficiently small, $\sigma(0^\circ)$ is replaced by:

$$\frac{\sigma_{\text{np}}}{2\pi} (1 + \cos\theta) \quad (68.4)$$

Note that the efficiency can be increased by increasing L or A or reducing d . All of these changes degrade the energy resolution.

Efficiency of passive detectors is a function of many variables. The total activity of a sample after being struck by N_n neutrons will be:

$$n\sigma L N_n \frac{\tau}{T} \left[1 - e^{-\frac{T}{\tau}} \right] \quad (68.5)$$

where n is the number of atoms per cm^3 , σ is the appropriate cross-section (e.g., for n, γ), L is the thickness of the foil, T is the time over which the irradiation took place, and τ is the average lifetime of the radioactive nuclei produced. This expression assumes that $n\sigma L \ll 1$ and that the source strength was uniform over the time T .

If the counter has an area A , is at a distance d from the activated foil, has an efficiency ϵ_r , and measures the activity from a time t_1 after the bombardment to a time t_2 , the efficiency ϵ_n will be

$$\epsilon_n = (n\sigma L) \frac{\tau}{T} \left(1 - e^{-\frac{T}{\tau}} \right) \left(\frac{A \epsilon_r}{4\pi d^2} \right) \left(e^{-\frac{t_1}{\tau}} - e^{-\frac{t_2}{\tau}} \right) \quad (68.6)$$

Each of the factors in parenthesis is less than one, so the typical efficiency of such a monitor is 10^{-4} to 10^{-6} .

Fission chambers have an efficiency of:

$$\epsilon_n = n\sigma_f L \quad (68.7)$$

where n is the number of atoms per cm^3 in the foil, σ_f is the fission cross-section, and L is the thickness of the foil. At low energies, σ_f may be large enough so that the above expression is greater than 0.1. In that case,

$$\epsilon_n = (1 - e^{-n\sigma L}) \frac{\sigma_f}{\sigma} \quad (68.8)$$

where σ is the total cross-section for neutrons.

The efficiency for a lithium- or boron-containing scintillator is:

$$\epsilon_n = \left(1 - e^{-(n_1\sigma_1 + n_2\sigma_2)L}\right) \left(\frac{n_1\sigma_1}{n_1\sigma_1 + n_2\sigma_2}\right) \quad (68.9)$$

n_1 is the density of lithium or boron atoms per cm^3 , σ_1 is the (n,α) cross-section, n_2 is the density of atoms other than lithium or boron in the scintillator, and σ_2 is the average absorption cross-section for these atoms. If $(n_1\sigma_1 + n_2\sigma_2) L \ll 1$, this becomes:

$$\epsilon_n = n_1\sigma_1 L \quad (68.10)$$

Note that in each case where a term of the form $(1 - e^{-n\sigma L})$ appears, the average of this quantity is not $(1 - e^{-n\langle\sigma\rangle L})$ if σ has energy fluctuations over an energy bin that are substantial. Here, $\langle\sigma\rangle$ is the average cross-section over the energy bin. This limit is particularly important at low energies, where isolated resonances cause large fluctuations in σ and where the limit of small $n\sigma L$ may not be appropriate. In this case, the expression for the efficiency should be evaluated separately for individual energies in the bin and the resultant efficiencies averaged.

68.3 Summary

A summary of the features of various counters is presented in [Table 68.1](#). More exhaustive treatment of the subject of neutron detectors can be found in References 1 and 2. [Table 68.2](#) lists some suppliers of neutron detectors.

TABLE 68.1 Characteristics of Various Neutron Detectors

Detector Type	Gives Energy Spectrum	Small Size	Directional Information	Insensitive to Gamma Rays	Detects Neutrons Below 500 keV	Timing Information	High Efficiency
Hydrogen-containing counters							
Proportional counter	No	Yes	No	Somewhat	No	No	Yes
Scintillator	No ^a	Yes	No	Liquid Scintillator Can Reject Gamma Rays	No	Yes	Yes
Proton recoil telescope	Yes	Yes	Yes	Yes	No	Yes	No
Passive (n,γ) detector	No	Yes (smaller than others)	No	Yes	Yes	No	No
Fission detector	No ^a	Yes	No	Yes	Yes	Yes	No
Passive inelastic-scattering detector	No	Yes	No	No	No	No	No
Detectors based on (n,z) reactions							
Passive detector	No	Yes	No	Yes	Yes	No	No
Scintillator (lithium glass)	No ^a	Yes	No	No	Yes	Yes	Yes
Long counter	No	No	No	Yes	Yes	No	Yes

^a Can give energy information when used in time-of-flight spectrometer.

^b Timing information is considered to be available if the time is determined to within less than 10^{-6} s.

^c High efficiency means $\geq 1\%$.

Defining Terms

Ionization chamber: A detector that collects the charge produced by ionization as a charged particle passes through the chamber.

Proportional counter: A detector that collects the charge produced by ionization with linear amplification as a charged particle passes through the chamber.

Scintillator: A detector that converts ionization energy to a short light pulse.

Compton effect: A process by which a gamma ray scatters from an electron on an atom. As a result, the electron is given a recoil velocity, producing ionization and yielding a pulse in an ionization chamber or proportional counter.

Isomeric transaction: A gamma ray decay of a nucleus in which the rate of decay is greatly slowed by restriction imposed by angular momentum coupling.

Time-of-flight spectrometer: A detection device for neutrons in which a neutron detector is placed a known distance from the neutron source and the energy of the neutron is deduced from the time the neutron takes to traverse this path.

Q value: A parameter expressing whether a nuclear reaction leads to a final state of higher final mass ($Q < 0$) or of lower final mass ($Q > 0$) than the initial state. Elastic scattering reactions have $Q = 0$.

Efficiency: The efficiency of a neutron detector is its probability of detecting a neutron incident on the detector. Efficiency is obviously a number between 0 and 1 and generally depends on neutron energy.

Radiation dosimetry is a field of radiation detection devoted to the quantitative measurement of the physical changes that occur in matter upon exposure to ionizing radiation. Radiation dosimetry is performed on a routine basis to ensure the occupational safety of workers when there exists a risk of radiation exposure. Such routine personal dosimetry is used to monitor and limit the long-term occupational exposure to workers and to assist with the assessment of the dose received in the event of an accidental exposure. Some occupations that have an associated risk of radiation exposure include medical personnel performing clinical X-ray diagnostic and radiotherapy procedures, and military and civilian personnel involved in power plant maintenance and operation. Radiation dosimetry is also an important tool in a wide range of environmental monitoring and industrial processing applications. The scope of this chapter is limited to discussion of the most widely used and commercially available technologies for dosimetry of ionizing radiation for personal protection; however, it should be recognized that many of the same technologies are used with equal effectiveness for other dosimetry applications.

69.1 Radiation Dosimetry Quantities and Units

The goal of radiation dosimetry is to quantify the amount of energy that is deposited in matter upon interaction with ionizing radiation. Ionizing radiations fall into three categories: charged particles such as beta and alpha particles, neutral particles such as neutrons, and electromagnetic radiation such as gamma rays and X-rays. The mechanism and the efficiency of the energy deposition depends on the type and the energy of the radiation as well as on the composition of the absorbing material. In particular, the biological consequences to living tissue following radiation exposure are quite dependent on the type of radiation. In order to provide a useful measure of the biological damage that might be expected to occur upon energy deposition in tissue, a system of units and standards has been developed that takes into account the differing biological effectiveness of different types of radiation. Over the years, these units and standards have undergone extensive revision and this process is still evolving. However, the units and standards in current use have been defined in detail in recent reports [1,2] published by the

TABLE 69.1 Radiation Weighting Factors for Various Types of Radiation

Type of Radiation	Quality Factor
Photons, all energies	1
Electrons and muons, all energies	1
Neutrons, <10 keV	5
Neutrons, 10 keV to 100 keV	10
Neutrons, >100 keV to 2 MeV	20
Neutrons, >2 MeV to 20 MeV	10
Neutrons, >20 MeV	5
Protons, other than recoil protons, >2 MeV	5
Alpha particles, fission fragments and heavy nuclei	20

International Commission on Radiation Units and Measurements (ICRU) and the International Commission on Radiological Protection (ICRP) and are the subject of a recent review article [3]. A brief summary of the fundamental units is provided below.

The quantity of primary interest in radiation dosimetry is the amount of energy that is absorbed per unit mass. The amount of energy imparted to a volume of matter is the difference between the sum of the energies of all the charged and uncharged particles entering the volume and the sum of the energies of all of the charged and uncharged particles leaving the volume, plus any change in the rest mass of the matter. The mean energy imparted per unit mass is defined as the **absorbed dose**, D , expressed in (SI) units as J kg^{-1} . The special name for the unit of absorbed dose is the gray (Gy). If the mass exposed to radiation is at a point in tissue, knowledge of the amount of absorbed dose alone is not sufficient to judge the biological effectiveness of the charged particles producing the absorbed dose. A quality factor, Q , is used to weight the absorbed dose to provide an estimate of the relative hazard of different energies and types of ionizing radiation. Q is a dimensionless factor that converts absorbed dose to **dose equivalent**, H , at a point in tissue. The dose equivalent has the same (SI) units, J kg^{-1} , as the absorbed dose, but the special name for the unit of dose equivalent is the sievert (Sv). If the amount of absorbed dose received on average over a specific tissue or organ is of interest, the quality factor is called the radiation weighting factor, w_R [1]. **Table 69.1** lists values of w_R for various types and energies of radiation. The equivalent dose, H_T , in a tissue or organ is defined as the average absorbed dose in the given organ due to a particular type of radiation and is scaled by w_R . Thus, the total equivalent dose in a specific organ, T , due to exposure by each radiation type, R , is given by:

$$H_T = \sum_R w_R D_{T,R} \quad (69.1)$$

The **equivalent dose** also uses the special unit of sievert. For example, if an organ is exposed to neutrons of energy less than 10 keV, and receives an absorbed dose of 10 Gy (10 J kg^{-1}), the equivalent dose is determined, using **Table 69.1** and **Equation 69.1**, to be 50 Sv (50 J kg^{-1}). Since the biological effectiveness of the exposure also depends on the specific organs targeted, dimensionless tissue weighting factors, w_T , have been defined that reflect the probability of damage resulting from a given equivalent dose. The **effective dose**, E , for an exposed individual is then the sum of the weighted equivalent doses for all tissues and is given by the expression:

$$E = \sum_T w_T H_T \quad (69.2)$$

The effective dose also uses the special unit of sievert. It should be pointed out that despite the adoption of nomenclature and definitions for equivalent dose and effective dose, for all practical purposes the

quantities measured and reported for dosimetry applications are the dose equivalents defined in terms of the quality factor, Q . A further quantity for reporting purposes is the **personal dose equivalent**, $H_p(d)$, the dose equivalent in soft tissue, at an appropriate depth, d , below a specified point in the body. For weakly penetrating radiation, such as beta particles, a depth of 0.07 mm, or $H_p(0.07)$ is used. Eye doses are reported for 3 mm depth ($H_p(3)$) and deep doses are reported for 10 mm depth ($H_p(10)$). The personal dose equivalent is typically measured with a dosimeter that is covered with the appropriate thickness of tissue equivalent material. The dosimeter is worn on the surface of the body and is calibrated in a phantom. A phantom is a medium, such as poly(methyl methacrylate), that mimics the attenuating characteristics of the human body.

Another unit for absorbed dose, found in older publications and in current use in the United States, is the rad. One rad equals 100 erg g^{-1} . Similarly, another unit for dose equivalent is the rem. To convert from this system to the international standard (SI) units, the following conversions are used: $1 \text{ Gy} = 100 \text{ rad}$ and $1 \text{ Sv} = 100 \text{ rem}$.

When an ionization chamber is exposed to X-ray or gamma ray photons, the amount of ionization produced in the air inside the chamber is called the exposure, X . The (SI) unit of exposure is C kg^{-1} and the special unit is called the roentgen, R . Originally, R was defined as the amount of X-ray or gamma radiation that produces 1 esu of charge of either sign in 0.001293 g of air (the mass of 1 cm^3 of air at STP). The conversion from R to C kg^{-1} is $1 \text{ R} = 2.58 \times 10^{-4} \text{ C kg}^{-1}$. When air is exposed to radiation, the average energy required to form an ion pair is 33.97 J C^{-1} . For an exposure of 1 R , the absorbed dose in air is $8.77 \times 10^{-3} \text{ J kg}^{-1}$.

69.2 Thermoluminescence Dosimetry

Thermoluminescence dosimetry is perhaps the most widely used and cost-effective technique for radiation dosimetry. It is for many organizations the technique of choice for routine monitoring of occupational radiation exposure. Thermoluminescence dosimetry is also widely used in medicine to determine patient exposure as a result of X-ray diagnostic procedures and cancer radiotherapy treatments. The dose ranges of interest for these applications can be roughly defined as 0.1 to 1 mGy for personal dosimetry applications, 1 to 100 mGy for clinical X-ray diagnostics, and 1 to 10 Gy for medical radiotherapy applications. Thermoluminescence dosimeter (TLD) phosphors are commercially available that exhibit a linear dose response and are capable of accurately measuring the absorbed dose for all the applications and doses mentioned above. The radiation-sensitive element of a TLD is a small quantity, typically less than 100 mg, of an inorganic crystal doped with metal impurities, called activators. The activators provide the crystal with the energy storage capacity as well as the luminescent properties that are required for the crystal to function as a thermoluminescent phosphor upon exposure to ionizing radiation. The details of the energy storage and thermoluminescence mechanisms, despite intense research over many decades, are not well understood. Complex, long-range, many-body interactions between activator sites and their immediate environment may be involved. Despite this mechanistic uncertainty, the thermoluminescence phenomenon has been used reliably by following well-established heuristic procedures and by referring to a simple and intuitive model. This model assumes that the activators provide point defects, known as traps and luminescence centers, in the crystal lattice. Upon exposure to ionizing radiation, electrons and holes are captured in metastable states at the trap centers by local potential minima until such time that the electrons and holes are thermally stimulated to overcome the electric potential. The electrons and holes can then recombine, with the emission of photons, at the luminescence centers. It is apparent from this model that thermoluminescence dosimetry is a passive, integrating technique. Further, the technique shows no dose rate dependence and for most applications the TLD phosphors can be reused many times.

A comprehensive review of the properties and applications of a wide range of TLD phosphors has been published recently [4]. The characteristics of the phosphors that are of most interest for dosimetry applications include the sensitivity and the dynamic range of the TL response, the response to different types of radiation over a broad energy spectrum, the fading characteristics, reusability, and the reproducibility of the response. The TL response of the phosphor to ionizing radiation is indicated by measurement

FIGURE 69.1 Thermoluminescence glow curve of LiF phosphor activated with trace amounts of Mg^{2+} and Ti^{4+} (TLD-100). The phosphor was exposed to a 2-Gy dose of ^{60}Co gamma rays and the glow curve was read using a Harshaw 2000 A/B TLD reader.

of the glow curve. A glow curve is a plot of the TL intensity vs. temperature, measured as the phosphor is heated. A representative glow curve of a commercially available LiF TLD is shown in [Figure 69.1](#). The glow curve usually exhibits one or more glow peaks that correspond to the release and recombination of electron and hole traps of differing trap depth and stability. Thermoluminescence dosimetry is best accomplished using phosphors having glow peaks in the range 200°C to 250°C. Peaks in this temperature range are necessary to provide room-temperature trap storage times of several months. Although all traps fade with time, rapid fading of the stored information occurs from traps having glow peak temperatures below 200°C, effectively precluding practical dosimetry. Glow peaks having temperatures greater than 250°C require quite high temperatures (>300°C) to release all the filled traps. In this case, blackbody radiation from the hot phosphor and other ancillary hot matter within the sample readout chamber (sample planchet, hot gas) interferes with and can easily overwhelm the TL signal due to actual trap recombination. The response of TLD phosphors as a function of absorbed dose must be carefully calibrated for all doses of interest. This is necessary because the response deviates from linear above a threshold dose, different for each phosphor, and, ultimately, the TL signal saturates and the phosphors suffer irreversible damage at very high doses. The TL response per absorbed dose as a function of energy, for low-LET electromagnetic radiation (gamma ray and X-ray), is generally fairly uniform. The efficiency for higher LET radiation can vary and should be calibrated as a function of energy. Since personal dosimetry applications require the measurement of doses absorbed by human tissue, tissue equivalent TLDs (effective atomic number closely matches that of tissue) are attractive because the energy dependence of the TL response closely matches that of tissue.

The most commonly used TLD phosphors are lithium fluoride (LiF), calcium fluoride (CaF_2), lithium borate ($\text{Li}_2\text{B}_4\text{O}_7$), calcium sulfate (CaSO_4), and aluminum oxide (Al_2O_3) activated with trace quantities

FIGURE 69.2 Thermoluminescence dosimeter body badge. A standard TLD badge contains three LiF phosphor chips. A fourth chip and a fast neutron track-etch foil can be added if required. (Courtesy of Landauer, Inc.)

of transition metal or rare earth metal ions. TLD phosphors are available in a variety of forms, including powders, compressed chips, Teflon-impregnated disks, single crystals, extruded rods and thin films. TLD phosphors have been developed that respond primarily to gamma- and X-radiation, while others have been developed that, in addition, respond strongly to thermal neutrons. Unfortunately, there are no TLD phosphors having neutron sensitivity without gamma sensitivity. Therefore, in a mixed field of neutrons and gamma rays, TLDs are used in pairs, with one TLD having primarily gamma-ray sensitivity and the other having gamma-ray and thermal neutron sensitivity. The difference in the TL signal between the two TLDs of such a pair is assumed to represent the thermal neutron dose. Neutron sensitivity is enhanced, for example, in LiF phosphors by incorporating a high concentration of ${}^6\text{Li}$ since ${}^6\text{Li}$ has a much higher thermal neutron cross-section than ${}^7\text{Li}$ (TLD-600 contains 96% ${}^6\text{LiF}$ while TLD-700 has essentially no ${}^6\text{Li}$). The manufacturers of TLDs exert considerable effort to maintain the uniformity of their products from batch to batch, a task of some difficulty since the characteristics of phosphors are a sensitive function of not only the composition but also the details of the manufacturing process. Thus, the properties of TLD phosphors of similar composition can vary considerably, and both the manufacturers of phosphors as well as the dosimetry service industries typically test and sort chips into groups based on their measured parameters. A representative commercially available TLD badge is shown in [Figure 69.2](#). This standard badge contains three LiF TLDs and is capable of measuring gamma- and X-ray doses from 0.1 mGy to 10 Gy and energetic beta radiation doses from 0.4 mGy to 10 Gy. These badges are typically returned to the manufacturer on a monthly or quarterly basis for readout.

The actual practice of thermoluminescence dosimetry requires some care to achieve accurate and reproducible results. For example, TLD-100 traditionally has been a very widely used phosphor, due to

its tissue equivalence, that can yield accurate and fairly sensitive dose information. However, the energetics of the trap population in TLD-100, as well as the trap dynamics and intertrap communication with time, are extremely complex phenomena. Reproducible dosimetry requires that the sensitivity remain unchanged after each use. This is accomplished by careful adherence to a detailed protocol that may include a pre-irradiation anneal (for example, 400°C for 1 h followed by 80°C for 10 to 24 h), a post-irradiation anneal to 125°C, and finally heating to readout the TL signal. It is common for individual TLD users to develop their own unique protocols for annealing and reading TLD chips. Excellent dose reproducibility (<5%) can be expected with care by following a well-defined protocol and using a set of individually calibrated TLD chips on a single, well-maintained TLD reader.

TLD instrumentation is commercially available from a number of suppliers. The choice of instrumentation depends largely on the form of the dosimeter phosphor chosen (compressed chip, Teflon disk, etc.), the desired sensitivity, and the degree of automation desired. The key element in any TLD reader is the heating method. The heating method should provide for controlled, reproducible heating and, if speed of processing is important, rapid cooling. Contact heating of the TLD on a planchet through which an electric current flows is a widely used heating technique. Because the surface of the TLD is not perfectly smooth, more uniform heating can be performed using noncontact methods, such as heating with a stream of hot gas or heating with infrared light. Laser heating is another noncontact method that permits rapid heating ($>1000^{\circ}\text{C s}^{-1}$) using small quantities of TLD phosphor, yet permits very high signal-to-noise ratios [5]. Regardless of the heating method, blackbody radiation from the metal planchet and/or the TLD chip must be attenuated by colored glass and dielectric coated optical filters. The signal-to-noise ratio is also improved by the elimination of spurious TL signals that arise due to static charges or contamination on the surface of the TLD. Spurious TL signals are reduced by purging the sample compartment with a low flow of inert gas, such as dry nitrogen. Light detection is typically accomplished with a photomultiplier tube, using either a DC or photon counting mode of operation. The glow curve is collected using any of the heating methods described, and the TL signal can be reported as either a glow peak height or as the integrated area of a glow peak.

The conventional TLD technology described above requires bulk heating of the TLD to high temperatures (400°C to 600°C) in order to read the stored dose information. Once the TLD has been read, the dose information is permanently erased. If any malfunction in the equipment occurs during readout, the data cannot be recovered. Alternative TLD technologies have been developed that do not completely erase the dose information and permit additional, successive readouts of the absorbed dose. This characteristic can eliminate accidental loss of dose information and can also provide, if desired, an archival record of exposure. Two such dosimeters, utilizing laser readout methods, are commercially available. These dosimeters function based on optical phenomena known as phototransferred thermoluminescence (PTTL) [6] and radiophotoluminescence (RPL) [7]. A commercial dosimeter (Landauer, Inc.) based on the phenomenon of PTTL is also known as a cooled optically stimulated luminescence (COSL) dosimeter. In preparation for readout of the dose information, the dosimeter is first cooled to liquid nitrogen temperature. It is then irradiated with ultraviolet laser light to phototransfer electrons from deep traps to shallow traps. The thermoluminescence that results from the release of electrons from these very shallow traps, as the dosimeter is allowed to warm to room temperature, provides a very sensitive measure of the absorbed dose. Since it is not necessary to heat the dosimeter to high temperatures, the trapped charges are not fully annealed and the process can be repeated several times. A commercial RPL dosimeter, also known as the flat glass dosimeter (Toshiba Glass Co., Ltd.) uses a silver-activated phosphate glass that is read out by a pulsed ultraviolet laser. The manufacturer employs a special luminescence analysis protocol since the glass exhibits a prompt luminescence even in the absence of ionizing radiation exposure. RPL dosimeters are nevertheless capable of performing sensitive and reproducible dose measurements. New optical dosimetry technologies, based on the phenomenon of room-temperature optically stimulated luminescence (OSL), are being developed [8,9] and promise to provide both superior sensitivity and multiple readout capability.

Companies that provide TLD and other personal dosimetry products and services are listed in [Table 69.2](#). This list is not intended to be comprehensive, nor is it intended to represent an endorsement by the U.S. government.

69.3 Ionization Chamber Dosimeters

Ionization chamber-based radiation dosimeters are among the most widely used and the most accurate instruments available for determining radiation exposure and absorbed dose. The operational principle of the ionization chamber is based on the formation and the collection of ion pairs that result from the interaction of energetic charged particles that pass through gases contained in a well-defined volume and electric field. Several types of ionization chambers are available, including real-time radiation field monitors, and integrating devices that accumulate dose information for extended periods of time. Real-time devices monitor the radiation-induced currents while integrating devices record changes in a static electric field. A wide array of ionization chambers, intended for applications in medical physics, equipment calibration, and personal dosimetry, are available. Small volume (<1 mL), precision ionization chambers are used by medical physicists for radiotherapy applications. These chambers are generally tissue or air equivalent and while very accurate, have low sensitivity. Larger volume (<1000 mL) ionization chambers are used for applications such as field standardization and diagnostic X-ray machine calibration that require high sensitivity in addition to excellent accuracy. For personal dosimetry applications, compact integrating ionization chambers, about the size of a ballpoint pen, termed “pocket chambers” are used. Some pocket chamber dosimeters provide a method for direct visual readout based on the electrostatic deflection of a charged quartz fiber relative to a calibrated scale. Initially, the dosimeter is fully charged, representing the zero dose setting. Exposure to a radiation source causes a loss of charge on the fiber and spring tension causes the fiber to partially return to its uncharged position. A lens system incorporated into the dosimeter in conjunction with a scale can be used to determine the absorbed dose. A commercially available direct-reading dosimeter is illustrated schematically in [Figure 69.3](#). These instruments can measure gamma and X-ray doses from a fraction of a milligray up to several gray. Greater accuracy is possible using indirect readout, pocket chambers that utilize precision electrometers to measure the change in the potential between the cathode and anode following exposure to radiation. These dosimeters are particularly useful for measuring low-level (<mGy) exposures. Another type of ionization chamber, used primarily for radon detection, utilizes the voltage drop across an electret element to determine radiation dose (Rad-Elec, Inc.). An electret is an electrically poled insulator material, such as Teflon, that retains surface charges for long periods of time. Ion pairs produced by radiation exposure are separated and collected, resulting in a net decrease in the electret charge. Changes in the electret voltage can then be calibrated in terms of radiation exposure.

69.4 Film Dosimetry

Photographic films have been used for many years for radiography and personal dosimetry applications. However, due to the greater convenience, superior sensitivity, faster turnaround, and reusability of TLD personal dosimeters, film emulsion personal dosimeters have in many cases been displaced by TLD dosimeters. A notable example of this trend is the dosimetry program of the United States Navy, which has turned exclusively to TLD dosimeters. Despite this, film remains useful for specific applications that require analysis of an image or a charged particle track and they remain the most convenient dosimetry method available if a permanent record of the exposure is desired. Radiographic films are sensitive to a variety of radiation sources, including photons (X-ray and gamma ray), charged particles (electrons, protons, and alpha particles), and neutrons (slow and fast). A major problem associated with the use of radiographic films for dosimetry purposes is that the energy response is not at all flat. A number of approaches have been used to flatten the response, including, for example, the incorporation of a

scintillator dye such as *p*-terphenyl in the emulsion [10]. This approach has the effect of flattening the response curve dramatically between 0.1 MeV and 1.0 MeV, as well as increasing the sensitivity of the film. More commonly, in a manner similar to that used in multiple chip TLD badges, a series of metal filters, applied to different portions of the film, is used to provide energy discrimination. The film is then analyzed according to the sensitivity of each film segment for a particular radiation energy range. [Figure 69.4](#) is a photograph of a commercially available film dosimeter badge that incorporates six absorbing filters to discriminate beta-, gamma-, and X-radiation. The dose range that can be measured is 0.1 mGy to 5 Gy for gamma- and X-radiation and 0.4 mGy to 10 Gy for energetic beta particles. Radiographic films consist of a thin layer of gelatin, approximately 10 μm to 20 μm thick, containing silver halide microcrystals, coated onto a polymer or glass substrate. Exposure to a source of radiation sensitizes the microcrystallites, creating a latent image that darkens visibly following development of the film. The radiation dose is determined by measuring the extent of the darkening with a densitometer. The densitometer measures the optical density (OD) of the film by comparing the transmission, T , of light through the exposed film with the transmission, T_0 , of an identical film that has not been exposed to radiation. The optical density is a logarithmic function, $\text{OD} = \log(T_0/T)$, and can be measured accurately for values up to approximately 3. Developed film typically has a background OD of about 0.1 due to scattered light. Undeveloped film is quite sensitive to environmental factors such as light, temperature and, in particular, moisture and must be carefully protected while in use. Film dosimeters are available that can also perform thermal and fast neutron dosimetry. The response of film to thermal neutrons is enhanced by the use of a film-converter such as a 0.5 to 1 mm thick Cd foil. The foil absorbs thermal neutrons, yielding gamma rays that interact with the emulsion. Nuclear track emulsions are films that are used for dosimetry of fast neutrons in a manner quite similar to the track-etch detectors described in the next section. Nuclear track emulsions are generally much thicker than radiographic film emulsions and contain higher concentrations of silver halide microcrystals. Recoil protons transfer energy to the microcrystallites in the emulsion, creating latent images of the tracks of the protons. The range of charged particles in the emulsion is generally quite small, compared to photons, so that practically all of the energy is deposited in the film along the tracks. Nuclear track emulsions are no longer widely used due largely to the extremely high threshold, ~ 0.7 MeV, required for track visualization. Fast neutron dosimetry with film badges is most often accomplished by using a track-etch detector in conjunction with the radiographic film emulsion.

69.5 Track-Etch Dosimetry

Solid-state track detectors exploit the damage that occurs in dielectric materials upon exposure to ionizing charged particles. Energy is deposited in the material along a track defined by the trajectory of the ionizing particle. The damage is manifested as pits that develop on the surface of the material upon etching by chemical and electrochemical techniques. The pits are clearly evident using a simple optical microscope and the track density can be estimated using either manual or automated pit counting methods. The

FIGURE 69.3 Schematic of direct reading pocket ionization chamber. The radiation dose is determined by measuring the deflection of a movable quartz fiber electrode. The deflection of the fiber is determined optically by projecting the image of the fiber onto a reticle using a microscope objective. (Courtesy of Dosimeter Corp. of America.)

FIGURE 69.4 Film badge for personal dosimetry. (Courtesy of Landauer, Inc.)

track density is a direct measure of the radiation dose (for many particles, there is one track formed per particle), and track-etch detectors are very effective and sensitive dosimeters. At present the most important track-etch dosimetry applications utilize organic polymer films for alpha track detection (radon monitoring) and fast neutron personal dosimetry. The principal attractive features of track-etch detectors are their extreme simplicity and low cost, good sensitivity, near tissue equivalence, small size, passive operation, and insensitivity to fast electrons and gamma rays. Track-etch detection is a favorite dosimetry technique of graduate students worldwide because of its simplicity; however, commercially available track-etch detectors are manufactured with extreme care to provide users with uniform polymer films and reproducible dose response.

Alpha Track Dosimetry

Commonly used solid-state track detectors that possess sensitivity suitable for alpha particle dosimetry include plastics such as cellulose nitrate, polycarbonate, and polyallyl diglycol carbonate [11]. Since track-etch detection is a surface phenomenon, care must be exercised to avoid scratching the surface of the polymer film, as any surface imperfections can result in false positive signals. The surfaces of the polymer film should also be protected from soiling since dust, dirt, grease, water, or any other foreign material can attenuate the alpha particles and prevent track registration in the detector. Polymer track-etch detectors do not fade significantly at room temperature; however, if the temperature is elevated such that the polymer softens, then the track damage can be annealed and etching will not yield a pit. Typically, radon track dosimeters are allowed to accumulate the alpha dose due to radon and its daughters for

extended periods (up to a year) before being returned to the manufacturer for determination of the track density and the corresponding alpha particle activity. Dosimetry of other radioisotopes that emit alpha particles can also be performed; however, the response of the detector is dependent on the isotope detected. For example, alpha track detectors have been used for monitoring plutonium and americium contamination in soil and provide a convenient and cost-effective radiation survey method for decontamination and decommissioning activities [12].

Fast Neutron Track Dosimetry

The performance of polymer track-etch detectors used for personal dosimetry of fast neutrons is typically enhanced by the use of adjacent layers of a hydrogen-rich polymer, known as a proton radiator [13]. Fast neutron dosimetry is made possible by the neutron-proton elastic scattering process that occurs in the track-etch detector and the radiator. The recoil protons produced by this process are responsible for generating the damage tracks in the polymer film and thus provide an indirect measurement of the neutron flux. Although the polymers used for track-etch detection of neutrons, such as CR-39, contain hydrogen and provide for neutron-proton elastic scattering, the use of a proton radiator, such as polyethylene (having a much higher concentration of hydrogen), significantly improves the performance of the dosimeter [14]. The energy spectrum of the protons that leave the radiator and reach the detector depends on both the neutron energy and the thickness of the radiator. In addition, the total number of protons emitted depends on the neutron energy and the radiator thickness. When the thickness of the radiator equals the range of the most energetic proton emitted, then the condition of protonic equilibrium is met. Under this condition, the greatest number of protons are emitted and the detector has the greatest sensitivity. However, at protonic equilibrium, the sensitivity also displays the greatest variation in the energy response. A flatter energy response can be obtained using thinner radiators that avoid the condition of protonic equilibrium. This is obtained, however, at the expense of the sensitivity. Track-etch detection can be used for dosimetry of fast neutrons at nuclear power plants, particle accelerators and due to exposure from unmoderated isotope sources such as californium-252 and americium-241 beryllium.

69.6 Bubble Dosimetry

Another method for fast neutron personal dosimetry is bubble detection. Bubble dosimeters are manufactured using a clear, elastic polymer gel as a host matrix, supporting a dispersion of nanometer-scale superheated droplets of a liquid, such as Freon. Neutrons incident on the polymer gel generate recoil protons in an elastic scattering process, followed by deposition of the proton energy along a track, in a process similar to that described in the discussion of track-etch detectors. However, in the track-etch detectors, the tracks must be visualized by a separate etching procedure. The charged particles in a bubble dosimeter deposit their energy directly into the superheated droplets, causing the droplets to effectively explode into much larger gas bubbles. This process, which can be readily heard, is immediate, generating bubbles that can easily be seen by the naked eye, provided the bubble diameter exceeds a critical diameter required in order for the bubble to persist stably in the gel. The fast neutron dose is determined by counting the total number of bubbles generated. Bubble counting can be performed manually, by visual inspection of the dosimeter, or by automated means. Commercial bubble dosimeters are available that use either optical or acoustic automated counting techniques. Dosimeters have been developed using droplet materials that have differing energy thresholds, thereby providing the dosimeters with limited spectroscopic capabilities. Bubble dosimeters have been developed that are compensated to provide a temperature-independent response. Fast neutron bubble dosimeters have several advantages in common with track-etch detectors, including good sensitivity, near tissue equivalence, passive operation, small size, and insensitivity to thermal neutrons and gamma radiation. Additional advantages include immediate bubble visualization (no need for a separate track developing step), limited reusability, sensitivity adjustability, a flat dose response over a wide energy range, utilization of the entire volume of the dosimeter, and angular response superior to that of track-etch detectors. Bubble dosimeters are more

FIGURE 69.5 Bubble dosimeters for personal dosimetry of fast neutrons. The dosimeter on the left is shown before exposure to fast neutrons. For comparison, a dosimeter exposed to fast neutrons is shown on the right. Bubbles are clearly evident throughout the volume of the dosimeter. (Courtesy of Siemens Medical Systems, Inc.)

expensive than track-etch dosimeters and are best utilized when the energy of the neutron field is known. [Figure 69.5](#) is a photograph of commercially available bubble dosimeters, before and after exposure to neutrons. A comprehensive review of bubble dosimeters, including new developments, has been published recently [15].

69.7 Electronic Personal Dosimeters

All of the personal dosimeters discussed to this point are passive devices that require no external power source. The radiation dose is determined upon completion of the sampling period by subjecting the dosimeter to a separate processing step. The nature of the processing depends on the dosimeter, but examples include heating of a TLD, chemical etching of a foil, development of an emulsion, or simply

FIGURE 69.6 Electronic personal dosimeter. (Courtesy of Siemens Medical Systems, Inc.)

counting bubbles. The electronic personal dosimeter (EPD), by contrast, is an active device that uses silicon diode detector technology to provide real-time measurements of radiation dose. The EPD has gained popularity in recent years and has mounted a serious challenge to thermoluminescence dosimetry as the preferred official dosimeter of record. EPDs can provide extremely sensitive real-time measurements of both the total dose and the dose rate. In addition, the EPD can be designed to provide an audible alarm if the total dose or dose rate exceed user defined settings. While the quality and characteristics of EPDs from different manufacturers can vary significantly, some EPDs offer accurate dose measurements over a wide range of doses, dose rates and energies, and perform on a par with TLD dosimeters. A commercially available EPD is shown in [Figure 69.6](#). This unit uses three silicon diodes to provide deep and shallow dose information for a wide range of gamma, beta, and X-radiation energies. EPDs typically have a display for manual readout of dose data, but can be used with an automated reader for convenient archiving of data and for rezeroing the dosimeter for repeat use. Personal dosimeters are envisioned that would combine active and passive technologies, providing the accuracy and convenience of real time dose monitoring in addition to the reliability of passive, cumulative dose measurements.

Defining Terms

Radiation dosimetry: The quantitative measurement of the physical changes that occur in matter upon exposure to ionizing radiation.

Absorbed dose (D): The mean energy absorbed per unit mass.

Dose equivalent (H): The mean energy absorbed per unit mass, scaled with a quality factor, Q , that provides an estimate of the relative biological hazard of the radiation.

Equivalent dose (H_T): The mean absorbed dose in an organ, T , scaled by a radiation weighting factor, w_R .

Effective dose (E): The total mean absorbed dose for an exposed individual. Obtained by summing the equivalent doses for all tissues, each scaled by a tissue weighting factor, w_T .

Personal dose equivalent $H_p(d)$: The dose equivalent in soft tissue at a depth, d , below a specified point in the body. Commonly reported as shallow dose ($d = 3$ mm) and deep dose ($d = 10$ mm).

70.1 Electrochemical Composition Measurement

Michael J. Schöning, Olaf Glück, and Marion Thust

Electrochemical analysis in liquid solutions is concerned with the measurement of electrical quantities, such as potential, current, and charge, to gain information about the composition of the solution and the reaction kinetics of its components. The main techniques are based on the quantitative determination of reagents needed to complete a reaction or the reaction products themselves. Four traditional methods of electrochemistry are described here (Figure 70.1): potentiometry, voltammetry, coulometry, and conductometry. Potentiometry implies the measurement of an electrode potential in a system in which the electrode and the solution are in electrochemical equilibrium. Voltammetry is a technique in which the potential is controlled according to some prescribed function while the current is measured. Coulometry involves the measurement of charge needed to completely convert an analyte, and conductometry determines the electrical conductivity of the investigated test solution. The practical applications of these measurement techniques for analytical purposes range from industrial process control and environmental monitoring to food analysis and biomedical diagnostics. Both the analytical methods and their instrumentation as well as recent trends, such as electrochemical sensors are discussed.

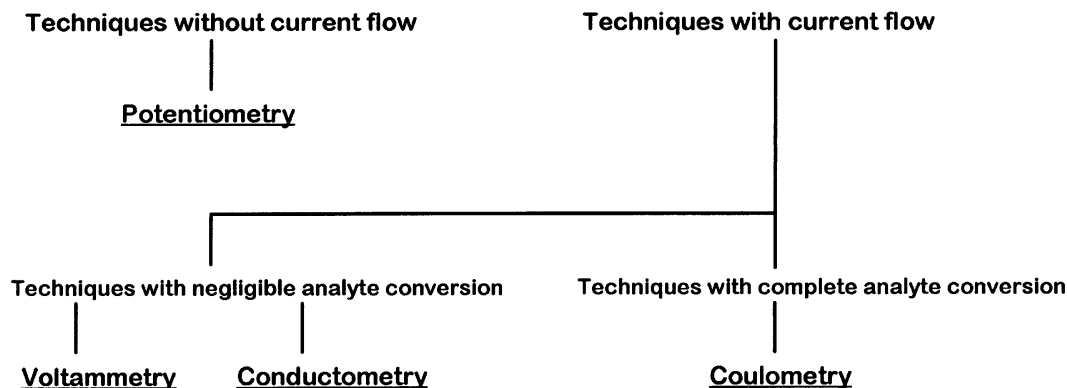

FIGURE 70.1 Electrochemical methods described in this section.

Basic Concepts and Definitions

Electrodes and the Electrical Double Layer

In electrochemistry, *electrodes* are devices for the detection of charge transfer and charge separation at phase boundaries or for the generation and variation of the charge transfer and separation with an impressed current across the phase boundary. One important feature of electrodes is a potential difference across the electrode/electrolyte phase boundary. At this interface, the conduction mechanism changes since electrode materials conduct the current via electrons whereas electrolytes conduct via ions. To understand the processes that lead to the formation of the potential difference, it is helpful to consider first an atomistic model, which was given by Helmholtz. It leads to the idea of an *electrical double layer*.

If an electrode is immersed in an electrolyte solution, the bulk regions of the two homogeneous phases — the electrode material and the electrolyte — are in equilibrium. This means that far away from the phase boundary ($>1 \mu\text{m}$), the sum of the forces on the particles is zero and charges are distributed homogeneously. Since the cohesion forces that bind the individual particles together in the bulk are significantly reduced at the surface of the electrode, particles in this region will have less neighbors or neighbors from the other phase. Thus, close to the phase boundary, the equilibrium conditions are drastically different from the equilibrium conditions in the bulk of the electrolyte. This change in the equilibrium of forces on particles at the interface can lead to an *interfacial tension*. In addition, the surface of a condensed phase usually has different electrical properties than the bulk phase, for example, due to the accumulation of free charge on the surface of an electrically charged solid. Besides, the orientation of dipoles in the surface region and adsorption of ions and dipoles from the electrolyte can lead to a change in the electrical properties. This excess charge from ions, electrons, and dipoles produces an electrical field that is accompanied by a potential difference across the phase boundary. The region in which these charges are present is termed the *electrical double layer*. The formation of an electrical double layer at interfaces is a general phenomenon but only the electrode/electrolyte interface will be considered here in more detail.

According to the hypothesis of Helmholtz, the electrical double layer has the character of a plate capacitor, whose plates consist of a homogeneously distributed charge in the metal electrode and ions of opposite charge lying in a parallel plane in the solution at a minimal distance from the surface of the electrode [1]. Modern conceptions are based on the assumption that the electron cloud in the metal extends to a certain degree into a thin layer of solvent molecules in the immediate vicinity of the electrode surface. In this layer, the dipoles of the solvent molecules (e.g., H_2O) are oriented to various degrees toward the electrode surface. Ions can accumulate in it due to electrostatic forces or be adsorbed specifically on the electrode through van der Waals and chemical forces. These substances are called *surface-active substances* or *surfactants*. The sum of oriented solvent molecules and surfactants in the immediate

FIGURE 70.2 Electrical double layer according to the Helmholtz model and equivalent circuit representation.

vicinity of the electrode is considered as one layer. The plane through the centers of these molecules and ions parallel to the electrode surface is termed *inner Helmholtz plane* (Figure 70.2). If only electrostatic attraction is taken into account, ions from the solution can approach the surface to a distance given by their primary solvation sheaths. This means that at least a monomolecular solvent layer remains between the electrode and the solvated ion. The plane through the centers of these ions is called *outer Helmholtz plane*, and the solution region between the electrode surface and this outer Helmholtz plane is called *Helmholtz or compact layer*. In reality, electrostatic forces cannot retain ions at a minimal distance from the electrode surface. Due to thermal motion, the excess charge is smeared out in the direction of the electrolyte bulk to form a *diffuse layer*, also termed the *Gouy-Chapman layer*. It describes the region between the outer Helmholtz plane and the bulk of the solution. In concentrated electrolyte solutions (approx. 1 mol/L), the diffuse layer is as thin as the inner Helmholtz plane and may be considered as rigid. In highly dilute solutions, its thickness can be as large as 100 nm. As in the early model of Helmholtz, the double layer acts as a capacitor [2]. Here, two different dielectric layers with permittivities ϵ_i and ϵ_o represent the region between the electrode surface and the inner Helmholtz plane and the region between the inner and the outer Helmholtz plane, respectively (Figure 70.2).

In addition to these ideal electrostatic processes that lead to the formation of the electrical double layer, one has also to consider the transition of charge, ions and/or electrons from the electrode phase into the electrolyte phase or vice versa. In the equivalent circuit representation, such a charge transport through the double layer is symbolized as a transfer resistance R_t connected in parallel with the capacitor. If any charge transport through the double layer is excluded, the transfer resistance is nearly infinite. According to Ohm's law, any current impressed across the electrode surface leads to a high polarization voltage determining the electrode as *ideally polarizable*. One example of a polarizable electrode is the dropping mercury electrode, which is frequently used in polarography. In the opposite case with a nearly vanishing transfer resistance, the electrode is termed *ideally unpolarizable*. In the equivalent circuit representation, this corresponds to a short-circuit of the capacitor. The current flow then does not influence the voltage drop across the phase boundary. *Reference electrodes*, whose voltage have to be constant when immersed in an electrolyte, are nearly unpolarizable electrodes. Since every voltage measurement is accompanied by a small current flow, the difference between polarizable and unpolarizable electrodes is very important in measurement technique.

The Nernst Equation

If the electrode phase and the electrolyte phase contain a common ion, the potential difference across the phase boundary is determined by the effective concentration (activity) of this ion in the solution. This fact is described quantitatively by the *Nernst equation* and will be derived in the following. If one mole of ions of a species i has to be transferred from a given reference state outside into the bulk of an electrically charged phase work must be expended to overcome the chemical bonding forces and the electrical forces. This work is given by the electrochemical potential $\tilde{\mu}_i$. Since the chemical interactions of a species with its environment always possess electric components, generally the electrochemical potential cannot be separated into chemical and electrical parts. Nonetheless, the electrochemical potential is frequently given formally as a sum of the chemical potential μ_i and an electrostatic work $zF\phi$:

$$\tilde{\mu}_i = \mu_i + zF\phi \quad (70.1)$$

The chemical potential μ_i of an uncharged component of a system is the amount of Gibbs energy G inherent in 1 mol of that component [3]:

$$\mu_i = \left(\frac{\partial G}{\partial n_i} \right)_{p,T} \quad (70.2)$$

Here, n_i is the number of moles of the given component. In the case of a dilute solution, the chemical potential of a component i is

$$\mu_i = \mu_i^0 + RT \ln c_i \quad (70.3)$$

μ_i^0 denotes the standard chemical potential and c_i the concentration of the species i , R is the gas constant, and T is the absolute temperature. The values of standard chemical potentials can be found in standard textbooks of thermodynamics and in tables of physicochemical constants under the name standard molar Gibbs energies. μ_i^0 is independent of the concentration c_i . In concentrated electrolytes, the concentration c_i has to be replaced by the respective activity a_i . The activity a_i is given by the relationship $a_i = \gamma c_i$, where γ is the activity coefficient which is a correction factor for non-ideal behavior. In the second term of Equation 70.1, z denotes the charge number of the ion i , F is the Faraday constant, and ϕ is the *inner electric potential*, which is, in general, the electric work necessary for the transfer of a unit charge: for example, 1 coulomb, from infinity to a given site.

The inner electric potential may consist of two components, an *outer electric potential* ψ and a *surface electrical potential* χ . Whereas the outer electrical potential of a phase is produced by excess electric charge supplied from outside, the surface electric potential is an effect of electric forces at the interface which leads to the electrical double layer introduced above. The difference of the outer potentials of the electrode (e) and the solution (s):

$$\psi_e - \psi_s = \Delta\psi \quad (70.4)$$

is termed *Volta potential difference* and is the only measurable quantity. Neither the difference of the surface potentials of the appropriate phases $\Delta\chi$ nor the difference of the inner electric potentials:

$$\Delta\phi = \Delta\psi + \Delta\chi \quad (70.5)$$

defined as *Galvani potential difference*, can be measured directly. Strictly speaking, even the Volta potential difference between the solution and the electrode is a not measurable quantity since only the Volta potential difference between two electrodes can be measured. To determine the potential of the solution phase, one has to dip an electrode in the solution. This, however, creates a new electrode/solution interphase and, consequently, one measures the sum of two potential differences. This is the reason for the lack of absolute potentials in electrochemistry. Therefore, one uses a reference electrode that has a known potential relative to a standard electrode.

In thermodynamic equilibrium, the electrochemical potentials of the considered species are equal in both phases. For a charged particle i that may cross the phase boundary solution/electrode, this means

$$\mu_{i,s}^0 + RT \ln a_{i,s} + z_i F \phi_s = \mu_{i,e}^0 + RT \ln a_{i,e} + z_i F \phi_e \quad (70.6)$$

and therefore in equilibrium the Galvani potential difference is given by:

$$\Delta\phi = \phi_e - \phi_s = \frac{\mu_{i,s}^0 - \mu_{i,e}^0}{z_i F} + \frac{RT}{z_i F} \ln \frac{a_{i,s}}{a_{i,e}} \quad (70.7)$$

Since the chemical standard potential of the respective phases are constants, the first term in Equation 70.7 can be expressed as a standard Galvani potential difference $\Delta\phi^0$:

$$\Delta\phi = \Delta\phi^0 + \frac{RT}{z_i F} \ln \frac{a_{i,s}}{a_{i,e}} \quad (70.8)$$

For metal electrodes, the activity of the metal atoms M and that of the electrons in the electrode phase equal unity per definition. Thus, for an electrode reaction of type:

Equation 70.8 becomes the *Nernst equation*

$$\Delta\phi = \Delta\phi^0 + \frac{RT}{zF} \ln a_s \quad (70.10)$$

which gives the relation between the activity of the potential determining ion a_s and the Galvani potential difference $\Delta\phi$. Using base 10 logarithm, the Nernst equation is given as:

FIGURE 70.3 Schematic of an electrochemical cell with a working electrode and a reference electrode immersed in the test solution (electrolyte).

$$\Delta\phi = \Delta\phi^0 + \frac{RT \cdot 2.3}{zF} \log a_s = \Delta\phi^0 + k \cdot \log a_s \quad (70.11)$$

where k is called *Nernst constant*.

The classical form of the Nernst equation (Equation 70.10) can be formulated more generally for a redox reaction. If a_{ox} and a_{red} are the activities of the oxidized and reduced form of the considered ion, the Galvani potential difference is given as:

$$\Delta\phi = \Delta\phi^0 + \frac{RT}{zF} \ln \frac{a_{\text{ox}}}{a_{\text{red}}} \quad (70.12)$$

In *potentiometry*, the activity of a certain ion can be determined directly by the measurement of the equilibrium Galvani potential difference of a suitable electrode (*direct potentiometry*). On the other hand, changes of the activity of the detected ion and equivalence points can be detected in titration reactions (*potentiometric endpoint titration*).

After this rather theoretical definition of the Galvani potential difference, the question arises how to *measure* this potential difference between the bulk of the electrode and the solution. Since a potential difference cannot be measured with only one electrode, a second one must be immersed in the solution. Both are connected to a voltmeter, to complete the *electrochemical cell* (Figure 70.3). An electrochemical cell generally consists of two (or more) electrodes immersed in an analyte. Thus, in some of the old literature, a single electrode is often referred to as a *half-cell* and its potential is called *half-cell potential*. In modern electrochemistry, usually the term *electrode potential* is used. An electrochemical cell is in a current-free state during potentiometric measurements (e.g., with an *ion-selective electrode* (ISE)), but may also supply electric energy (a galvanic cell) or accept electric energy from an external source (an electrolytic cell). Since a second electrode potential arises at the phase boundary second electrode/electrolyte, only the sum of at least two Galvani potential differences can be measured. A separation into the two individual parts is impossible. Hence, the function of the second electrode, named reference electrode, is to act as an electrode of constant potential against which variations in the potential of the measuring electrode in various samples can be measured. In the Nernst equation, the Galvani potential ϕ is then replaced by E , the symbol for measurable voltages.

Classification of Electrodes

Electrodes are termed *reversible electrodes* if they transfer electrons and ions with negligible impedance. Therefore, under current, the electrochemical potential of electrons, ions, and neutral species do not change across the different interfaces that may exist in an electrode. Otherwise, the electrode is not suitable to measure thermodynamic (equilibrium) quantities such as ion activity. Since a distribution equilibrium of charged species is considered here, the electrode and the solution phase must have at least one charged species in common. Depending on the number of equilibria being involved in the forming of the electrode potential, reversible electrodes can be divided into different groups:

1. *Electrodes of the first kind.* These may be cationic or anionic electrodes at which equilibrium is established between the atoms or molecules in the electrode material and the respective cations or anions in the solution. According to the Nernst equation, the equilibrium Galvani potential difference is here determined by the activity of the considered ion in the solution. Examples for electrodes of the first kind are ISEs including metal and amalgam electrodes and the hydrogen electrode.
2. *Electrodes of the second kind.* These electrodes consist of three phases. A metal wire is covered by a layer of its sparingly soluble salt which usually has the character of a solid electrolyte (e.g., Ag and AgCl). This wire is immersed in a solution containing a soluble salt of the anions of this solid electrolyte (e.g., KCl). Here, the equilibrium between the Ag atoms in the metal and the anions in the solution is established through two equilibria: The first one is given between the metal and the cation in its sparingly soluble salt; for example,

and the second one between the anion in the sparingly soluble salt and the anion in the solution; for example,

The electrode potential of electrodes of the second kind is rather insensitive to small current flows. Thus, they are often used as reference electrodes.

3. *Electrodes of the third kind.* In this electrode, the sparingly soluble salt contains a second cation that also forms a sparingly soluble compound with the common anion but with a higher solubility product than the electrode metal compound (e.g., Ag₂S and PbS). Here, the electrode potential depends on the activity of this cation in the solution.
4. *Oxidation-reduction (redox) electrodes.* They consist of an inert metal such as Pt, Au, or Hg that is immersed in a solution of two soluble oxidation forms of a single substance (e.g., Fe³⁺ and Fe²⁺). Thus, for the electrode reaction:

the Nernst equation is:

$$E_{\text{Fe}^{3+}/\text{Fe}^{2+}} = E_{\text{Fe}^{3+}/\text{Fe}^{2+}}^0 + \frac{RT}{F} \ln \frac{a_{\text{Fe}^{3+}}}{a_{\text{Fe}^{2+}}} \quad (70.16)$$

according to Equation 70.10. Here, E is termed the *electrode potential* and E^0 is designated the *standard electrode (or redox) potential* of the electrode reaction if it is measured versus the *standard hydrogen electrode* (SHE). The subscripts of E and E^0 denote the redox couple of the considered

electrode reaction. The standard redox potential is a measure of the reducing or oxidizing ability of a substance. If one considers, for example, two systems 1 and 2 with their respective standard redox potentials E_1^0 and E_2^0 , system 1 is a stronger oxidant than system 2 if $E_1^0 > E_2^0$. This means that in a mixture of the solutions of these two systems where originally the activities of the reduced forms equal that of the oxidized forms ($a_{\text{red}}^1 = a_{\text{ox}}^1$ and $a_{\text{red}}^2 = a_{\text{ox}}^2$), an equilibrium will be established with $a_{\text{ox}}^2 > a_{\text{red}}^2$ and $a_{\text{red}}^1 > a_{\text{ox}}^1$. The experimentally determined standard potentials of well-known redox systems are listed in Reference 4. Table 70.1 gives some examples. In redox electrodes, the metal acts as a medium for the electron transfer between the two forms. In contrast to electrodes of the first kind, the solution should not contain ions of the electrode metal in order to avoid an additional Galvani potential difference at the electrode determined by the activity of the electrode metal ions in the solution. This disturbing ion activity is negligible if the standard potential of the electrode metal is a few 100 mV higher than the redox potential to be measured. Thus, mainly platinum electrodes ($E_{\text{Pt}^{2+}/\text{Pt}}^0 = 1.20$ V) and gold electrodes ($E_{\text{Au}^+/\text{Au}}^0 = 1.42$ V) are used as redox electrodes.

Reference Electrodes

The potential of an ion-selective electrode (ISE) is always measured with respect to a reference electrode. Ideally, the reference electrode should not cause chemical changes in the sample solution, or vice versa. It should maintain a constant potential relative to the sample solution, regardless of its composition. In practice, any changes of its potential with composition should be at least as small as possible and reproducible. Reference electrodes with liquid junctions, strictly speaking reference electrode *assemblies*, consist of a reference element immersed in a filling solution (often called bridge solution) contained within the electrode. This reference element should possess a fixed activity of the ion defining the potential of the element with respect to the filling solution. The electric contact between the electrode and the sample solution is made by the liquid junction consisting of a porous plug or a flow restriction which permits the filling solution to flow very slowly into the sample.

At the junction between the two electrolyte solutions, ions from both solutions diffuse into each other. Since different ions have different mobilities, they will diffuse at different rates. Thus, a charge separation will occur related in size to the difference in mobilities of the anions and cations in the two solutions. This charge separation produces a potential difference across the junction called the *liquid junction potential* [5]. In reference electrodes, usually the bridge solution is given a slightly higher pressure than the sample so that the solution, often concentrated potassium chloride, flows out relatively rapidly into

the sample, and diffusion of the sample back into the salt bridge is impeded. If the bridge solution is concentrated enough, it is assumed that variations in the liquid junction potential due to the varying composition of the sample are suppressed. This is the basis on which the reference electrode assembly is used. Since the potential of the whole assembly E_{ref} is the sum of the potential of the reference element E_r in the bridge solution and the liquid junction potential E_j :

$$E_{\text{ref}} = E_r + E_j \quad (70.17)$$

any change in the liquid junction potential appears as a change in the potential of the assembly. An extra liquid junction potential must be included if a *double junction* reference electrode is considered. When an analysis using a cell with an ion-selective electrode is carried out, standard solutions are used to calibrate the ISE. A change in the liquid junction potential that occurs when the standard solutions are replaced by the sample is termed the *residual liquid junction potential* and constitutes an error in the analytical measurement. The needed constancy of the potential can be approached by a suitable choice of standards and/or sample pretreatment, and by the use of a proper bridge solution and the best physical form of the liquid junction.

Several types of liquid junctions exist from which the best ones with regard to stability and reproducibility are complicated to realize in practice, and the worst ones are easy to use but much less stable and reproducible. Most of the commercial reference electrodes with adequate properties possess *restrained diffusion junctions* where the most common junctions available are the ceramic plug, the asbestos wick or fiber, two types of ground sleeve junction, and the palladium annulus junction (Figure 70.4). For a very large majority of applications with ion-selective electrodes, a ceramic plug will perform adequately. The flow rate of the bridge solution into the sample solution is sometimes called leak rate and is given

FIGURE 70.4 Different types of liquid junctions: (a) ceramic plug, (b) ground glass sleeve (type 1), (c) ground glass sleeve (type 2), (d) asbestos wick, (e) palladium annulus.

in mL per 5 cm head of bridge solution per day. The head of bridge solution is measured as the height of the surface of the bridge solution above the surface of the sample. In order to work satisfactorily, the surface of the bridge solution of all these restricted junction devices has to be at least 1 cm above the sample solution. Otherwise, if the bridge solution falls too low, the junction and the bridge will become contaminated by species diffusing from the sample. The bridge solution has then to be replaced. For the same reason, reference electrodes should be stored, when not in use, with the junction immersed in bridge solution.

Whereas the ceramic plug and the asbestos wick and fiber (Figure 70.4(a) and (d)) have relatively slow flow rates of about 0.01 to 0.1 mL per 5 cm head of bridge solution per day, ground sleeve junctions of type (b) have a flow rate of 1 to 2 mL. On the other hand, the flow rates of different asbestos wick junctions may vary by a factor up to 100 and the liquid junction potential may have a day-to-day (in)stability of ± 2 mV under the favorable conditions of a junction between strong potassium chloride solution and an intermediate pH buffer. Under the same conditions, ground glass sleeve junctions of type (b) and the little-used palladium annulus junction show stabilities of ± 0.06 mV and ± 0.2 mV, respectively. It is worth mentioning that palladium annulus junctions may partly respond as a redox electrode in strong oxidants (e.g., 0.2 M KMnO_4 in 0.05 M H_2SO_4) and mild or strong reductants (e.g., 0.5 M SnCl_2 in 1 M HCl). In such samples, reference electrodes with palladium or platinum annulus junctions should not be used. Although ground glass sleeve junctions have inconveniently high flow rates and the bridge solution needs to be replenished frequently, these junction types have found particular use in applications where the junction has the tendency to clog, such as measurements in protein solutions. However, the stability of the liquid junction potential appears to be relatively poor in fast-flowing sample solutions and may be very sensitive to sample flow rate. Asbestos wick junctions are particularly liable to blockage and should consequently be used in clear solutions only.

In *double-junction reference electrodes*, the filling solution in which the reference element is immersed (reference solution) makes contact with another solution, the bridge solution, by means of a liquid junction. A second liquid junction enables contact to be made between the bridge solution and the sample. Such electrodes are useful when it is essential that contamination of the sample by the inner filling solution must be kept at a very low level. The outer bridge solution can be selected to be compatible with the sample. In order to minimize the liquid junction potentials that can drift and cause instability, the bridge solution should be equitransferent; that is, the transport numbers of its anion and cation should be nearly equal. However, the complication of a second liquid junction in the cell should be avoided if possible.

The Standard Hydrogen Electrode.

Aqueous solutions are of major concern in electrochemistry because of their hydrogen ion content. Thus, it is advantageous to use a reference electrode where a reaction occurs that involves the participation of hydrogen ions. One of this reactions is:

Figure 70.5 shows a hydrogen electrode. A hydrogen electrode usually consists of a platinum sheet covered by a thin layer of sponge-like structured platinum, so-called platinum black, that has a high specific surface area. This electrode is rinsed with pure gaseous hydrogen in order to form a complete layer of adsorbed H_2 molecules at the surface. If this electrode is immersed in an electrolyte, it acts as an electrode consisting of hydrogen at which the gaseous hydrogen is oxidized to hydronium ions or the hydronium ions are reduced to hydrogen, respectively, according to Equation 70.18. The real mechanism of this electrode process is rather complicated because the platinum electrode is in contact with the hydronium ions in the solution as well as with the gaseous hydrogen that is bubbled through it. Thus, the final equilibrium between the gaseous hydrogen, the dissolved hydronium ions, and the electrode phase consists of several successive equilibrium steps which can be found in Reference 6. To calculate the

FIGURE 70.5 Schematic of a hydrogen electrode.

potential of a hydrogen electrode, which is strictly speaking the difference between the potential of the electrode and that of the solution, one has to consider the electrochemical potentials of the respective phases. The chemical potential of gases is usually expressed in terms of the pressure p instead of the molar concentration c . Due to the elementary relationship $pV = nRT$ for ideal gases, where V is the volume of the gas and n is the amount of moles the pressure, p is proportional to the molar concentration $c = n/V$. Thus, according to Equation 70.3:

$$\mu_{\text{H}_2} = \mu_{\text{H}_2}^0 + RT \ln \frac{p_{\text{H}_2}}{p_{\text{H}_2}^0} \quad (70.19)$$

where μ_{H_2} and $\mu_{\text{H}_2}^0$ are the pressure and standard pressure of hydrogen, respectively. In the case of moderate ion concentrations, the chemical potential of the solvent water is equal to its standard chemical potential. Hence, the potential difference between the electrode and the solution is, according to Equation 70.7:

$$\Delta\phi = \frac{\mu_{\text{H}_3\text{O}^+}^0 - \frac{1}{2}\mu_{\text{H}_2}^0 - \mu_{\text{H}_2\text{O}}^0}{F} + \frac{RT}{F} \ln c_{\text{H}_3\text{O}^+} - \frac{RT}{2F} \ln \frac{p_{\text{H}_2}}{p_{\text{H}_2}^0} \quad (70.20)$$

This equation is generally valid for hydrogen electrodes. The electrode is called *standard hydrogen electrode* (SHE) if the molar concentration is such that the activity of the hydronium ions is unity ($a_{\text{H}_3\text{O}^+} = 1$) and the pressure of hydrogen is equal to its standard pressure. Hence, for an SHE, the second and third term in Equation 70.20 vanish. The combination of standard chemical potentials in the first term of Equation 70.20 is defined as zero. Consequently, the total potential difference across the interface SHE/electrolyte is equal to zero *by definition* at any temperature. Since standard hydrogen electrodes are very difficult to prepare, they are not used as reference electrodes in practice. However, electrode potentials are usually standardized with respect to the SHE and their values are thus called “on the hydrogen scale.”

FIGURE 70.6 Schematic of a calomel reference electrode.

The Calomel Electrode.

The calomel electrode is the most common of all reference electrodes. It consists of a pool of mercury that is covered by a layer of mercurous chloride (calomel, Hg_2Cl_2). The calomel is in contact with a reference solution that is nearly always a solution of potassium chloride, saturated with mercurous chloride. Thus, the calomel electrode is a typical electrode of the second kind. Figure 70.6 shows a typical arrangement of a commercial calomel electrode assembly where the electrode is inverted, with the mercury uppermost, and packed into a narrow tube. Depending on the strength of the potassium chloride solution used, the electrode is called saturated calomel electrode (SCE), 3.8 *M* or 3.5 *M* calomel electrode, respectively. Potassium chloride is used as reference solution because it gives rise to a small liquid junction potential at the outer liquid junction of the electrode, i.e., the liquid junction with the sample. Hence, potassium chloride is a suitable reference solution as well as a good bridge solution. Furthermore, mercurous chloride has a very low solubility in potassium chloride solutions, regardless of concentration. The electrode reaction of a calomel electrode is:

Its standard potential, including the liquid junction, is 0.2444 V vs. SHE at 25°C for the SCE, and 0.2501 V for the 3.5 *M* calomel electrode according to Reference 7. Further data are given, for example, in Reference 8.

The components of a calomel electrode are chemically stable except for the mercurous chloride, which significantly disproportionates at temperatures above 70°C according to the equation:

Hence, potential drift occurs and life time decreases with increasing working temperature. On the other hand, calomel electrodes can be used at temperatures down to -30°C if 50% glycerol is added to the potassium chloride solution.

FIGURE 70.7 Schematic of a Ag/AgCl reference electrode.

Impurities in the potassium chloride solution, such as bromide and sulfide ions as well as redox agents and complexants, cause a small shift in the electrode potential. Nevertheless, the measurement of potential differences is not affected. However, the most unsatisfactory feature of the performance of the calomel electrode is its thermal hysteresis that occurs if the electrode filling material is not in thermal equilibrium or if the electrode and the sample have different temperatures. Thus, temperature stability during the storage and measurements is very important. In any cases where the temperature of the reference electrode or the sample has to be varied, it is thus usually better to use a silver/silver chloride electrode instead of a calomel electrode.

The Silver/Silver Chloride Electrode.

The silver/silver chloride electrode consists of a silver wire or plate that is coated with silver chloride. For the same reasons as with the calomel electrode, this phase is in contact with a strong potassium chloride solution, here saturated with silver chloride. Figure 70.7 shows the diagram of a typical Ag/AgCl reference electrode. Since this kind of reference electrode is the simplest and for many applications the most satisfactory one, it is commonly used as internal reference electrode of pH electrodes and other ion-selective electrodes. Besides, Ag/AgCl electrodes can be easily prepared in the laboratory. In contrast to mercury-based electrodes, the Ag/AgCl electrode does not contain toxic chemicals and is therefore recommendable for measurements in food.

The major problem with the Ag/AgCl electrode is the considerably high solubility of AgCl in concentrated potassium chloride solution. Thus, especially for the use at high temperatures, a sufficient excess of solid silver chloride must be present in the reference solution. This can be achieved, for example, through the addition of a few drops of diluted silver nitrate solution. Otherwise, silver chloride will dissolve off the electrode until saturation is reached. As a consequence, the electrode potential will drift and the lifetime of the electrode will be shortened. However, in contrast to the calomel electrode, the Ag/AgCl electrode can be used successfully up to 125°C. Its electrode potential is very stable in the long term in pure potassium chloride solutions, but is affected by impurities like redox reagents and species that react with the silver chloride, as with the calomel electrode. Unlike the calomel electrode, in the Ag/AgCl electrode, the concentration of the electrode coating in the bridge solution is rather high. Thus, a greater amount of reaction products (e.g., solid silver sulfide) may arise in the reference solution and

FIGURE 70.8 For voltammetric measurements a three electrode arrangement is usually employed.

block the liquid junction causing drift and instability of the electrode potential. In contrast to the calomel electrode, the silver/silver chloride electrode shows only very small thermal hysteresis effects that are usually negligible. Hence, this kind of electrode is suitable for measurements in samples with varying temperatures. Ag/AgCl electrodes are relatively insensitive to polarization. The standard potentials, including the liquid junction potentials of saturated and 3.5 M silver/silver chloride electrodes, at 25°C are 0.1989 V and 0.2046 V, respectively according to Reference 9. As with the calomel electrode, the nomenclature of the electrodes is derived from the potassium chloride concentration of the respective reference solution.

Voltammetry

The basic concept of *voltammetry* is the measurement of the current i at a redox electrode as a function of the electrode potential E . During the experiment, the electrode is immersed in a solution that contains an electroactive species; that is, a species that can undergo an electrode reaction (standard redox potential E^0). The electrode potential is changed from a value $E_1 < E^0$ to a value $E_2 > E^0$ or vice versa in a manner that is predetermined by the operator. Thus, during the measurement, the electrochemical equilibrium shifts from the oxidized (reduced) form of the analyte to the reduced (oxidized) form. The resulting charge transfer across the interface electrode/solution can be observed as a current flow, which is termed *faradaic*.

Instrumentation

Voltammetric measurements are usually performed with a cell arrangement of three electrodes (Figure 70.8). The redox electrode at which the electrode processes occurs is called *working electrode*. Its potential is measured against a suitable reference electrode, often Ag/AgCl or calomel. To adjust the potential difference between the working and the reference electrode to a certain value, a current is forced through the working electrode. Because the current and the electrode potential are related functionally, this current is unique. However, the current through the reference electrode must be kept as small as possible. Therefore, a third electrode called *auxiliary electrode* or *counter electrode* is usually employed to close the current circuit. It should be emphasized that there are two circuits: one in which the current flows and which contains the working and the auxiliary electrode and another, and a current-free one in which the potential difference between the working and the reference electrode is measured. Since almost no current flows through the reference electrode, its potential can be regarded as constant and the measured change in potential equals the potential change of the working electrode. The current

through the working electrode, and thus its potential, can be adjusted by controlling the voltage between the working and the auxiliary electrode. This task is performed by an instrument called a *potentiostat*, which basically consists of a voltage source and a high-impedance feedback loop. With a function generator, that may be integrated into the potentiostat, the potential–time course can be predetermined. Modern potentiostats are controlled by a PC and offer the possibility to program many different potential–time courses. Thus, they allow the performance of several voltammetric techniques, as are discussed below. The measured current can be displayed as a function of the electrode potential or of time using a strip-chart or *xy*-recorder or a PC.

There are two possibilities to operate an electrochemical cell. In so-called *batch cells*, the electrolyte solution rests stationary during the measurement, whereas in *flow-through cells*, it flows across the electrode. Between two measurements with different solutions the cell must be cleaned in order to remove residues of the preceding measurement's solution that could disturb the new measurement. The electrochemical cell is usually built of glass or teflon because of these materials' chemical inertness.

The chemical inertness is also important for the choice of the working electrode because the electrode must not change during the measurement. Common materials are gold, platinum, and mercury. Several kinds of carbon electrodes (e.g., glassy carbon) are also used but are often covered with gold or mercury. An advantage of the solid-state electrodes is their easy handling. They can be employed as planar or as wire electrodes. Further, with the noble metal electrodes, substances having a more positive redox potential than mercury can be investigated [10]. However, the use of mercury electrodes offers distinct advantages and the voltammetric techniques using mercury electrodes are extremely well developed. These techniques play a major role in electroanalytical methods and are summarized under the term *polarography*.

In polarography, mercury is either used as a *thin mercury film electrode* (TMFE) or as a *hanging mercury drop electrode* (HMDE). The HMDE can be a *stationary mercury drop electrode* (SMDE) or a *dropping mercury electrode* (DME). The drop is produced from a thin capillary with an inner diameter that can range from several ten to a few hundred micrometers. The size of an SMDE is held constant during the measurement, whereas a DME constantly grows during its lifetime until it falls from the capillary due to its weight.

The main advantages of mercury drop electrodes are their good reproducibility and their high *overpotential* for the hydrogen evolution; that is, the fact that hydrogen evolution is inhibited and thus occurs at much higher potentials than would be expected from the standard potential. The good reproducibility is achieved because a new drop can easily and rapidly be produced from the capillary for each measurement. Hence, the contamination of the electrode with substances from a preceding measurement and from impurities in the solution is near zero. However, a drawback of HMDEs is their relative mechanical instability, which can be a problem in flow-through cells, in field measurements, and if the solution is stirred.

Stirring of the solution is often applied during the measurement if the supply of reactive species at the electrode should be enhanced. However, this forced convection affects the electrode current. Moreover, the electrolyte is often stirred and bubbled with an inert gas like nitrogen or argon before voltammetric measurements are carried out to remove dissolved oxygen. This is usually necessary to reduce background currents from oxygen reduction and to prevent undesirable oxidation or precipitation of solution components. Because the electrode currents, especially in trace and ultra-trace analysis, can be quite small, it is common to place the cell in a Faradaic cage to shield it from electromagnetic stray fields. Coaxial cables are then used for the electric connections from the cell to the instruments.

Principles of Voltammetry

Actually, the electrode current measured in voltammetry is a sum of two currents that arise due to different processes. Besides the faradaic current i_f , a capacitive current i_c results from changes in the *double layer charging*. Although the faradaic current is a direct measure for the rate of the electrode reaction, several effects usually occur that have to be considered.

Diffusion Limitation of the Faradaic Current.

The decrease of the analyte concentration at the electrode surface due to an electrode reaction must be balanced by the diffusion of species from the bulk solution. In most measurements, the consumption of reactive species is faster than the supply by diffusion and the effect of *diffusion limitation* of the faradaic electrode current is observed. To understand this important point, the time-dependent concentration profile of the analyte has to be calculated using *Fick's laws*. The electrode current can then be derived as a function of time. According to Fick's first law, the flux j of the analyte at the point \mathbf{r} and at the time t is proportional to the gradient of the analyte concentration c :

$$j(\mathbf{r}, t) = -D\nabla c(\mathbf{r}, t) \quad (70.23)$$

The proportionality factor D is called the *diffusion coefficient*. At the electrode surface, the flux must be equal to the number of moles N converted per unit of time and surface area by the electrode reaction:

$$j(0, t) = dN/dt \quad (70.24)$$

The faradaic current i_f is related to dN/dt according to:

$$i_f = nFAdN/dt \quad (70.25)$$

where n is the number of electrons involved in the reaction of a single analyte particle, F is the Faraday constant, and A is the surface area of the working electrode. The *Nernst diffusion layer* model assumes that within a layer of thickness δ , the analyte concentration depends linearly on the distance from the electrode surface until it reaches the bulk concentration c_0 . For simplicity, the diffusion problem is often considered to be one-dimensional as it is the case for a planar working electrode in a cylindrical cell. The combination of Equations 70.23 to 70.25 then gives:

$$i_f = nFAD\left((c_0 - c_e)/\delta\right) \quad (70.26)$$

where c_e is the concentration at the electrode surface. For a sufficiently large difference between the applied potential and the standard potential of the analyte's redox couple, all species reaching the electrode surface by diffusion are immediately converted and the faradaic current reaches a maximum. In this case, the analyte concentration c_e at the electrode surface can be regarded as zero.

The diffusion profile and thus the dependence of δ from time can be obtained by solving the differential equation that is known as Fick's second law:

$$\frac{\partial c(\mathbf{r}, t)}{\partial t} = D\nabla^2 c(\mathbf{r}, t) \quad (70.27)$$

where ∇^2 is the Laplacian operator. For *linear diffusion* — that is, one-dimensional diffusion as it was considered in Equation 70.26 — the solution of Equation 70.27 with the appropriate boundary conditions ($c_e(t=0) = c_0$; $c_e(t > 0) = 0$; $c(x > \delta) = c_0$) yields:

$$\delta = \text{sqrt}(\pi Dt) \quad (70.28)$$

Combination with Equation 70.26 leads to the *Cottrell equation*:

$$i_f(t) = nFAc_0\text{sqrt}(D/\pi t) \quad (70.29)$$

FIGURE 70.9 At a planar electrode, the diffusion-layer thickness increases with $t^{1/2}$ (a) whereas the diffusion-limited current decreases with $t^{-1/2}$ (b).

After reaching a maximum value, the current decreases with $t^{-1/2}$ and is proportional to c_0 , whereas the diffusion layer thickness increases with $t^{1/2}$ (Figure 70.9).

For a spherical electrode of radius r_0 , as it is the case for HMDEs, one has to change to spherical coordinates and Fick's second law becomes:

$$dc(r,t)/dt = D \left[d^2c(r,t)/dr^2 + 2/r dc(r,t)/dr \right] \quad (70.30)$$

where $r > r_0$ is the radial distance from the electrode center. The solution of Equation 70.30 with the appropriate boundary conditions $c(r,0) = c_0$, $\lim(r \rightarrow \infty) c(r,t) = c_0$, $c(r_0,t > 0) = 0$ yields the current-time relation

$$i_f(t) = nFADc_0 \left[1/\left(\pi Dt\right)^{1/2} + 1/r_0 \right] \quad (70.31)$$

FIGURE 70.10 At a DME the measurement is performed during a time interval Δt_m at the end of the drop's lifetime when the ratio i_r/i_c is very large.

The first term in brackets equals that for the linear case; the second, constant term reflects the fact that the surface of the spherical diffusion layer grows and thus can draw an increasing number of reactive species.

The situation is even more complicated for DMEs because in addition to the surface of the diffusion layer, the surface and the radius of the drop are growing during the drop's lifetime. At any time, the growing electrode surface forces the depletion layer to stretch over a still larger sphere, which makes the layer thinner than it otherwise would be. A rigorous mathematical approach to this is rather difficult [11] because the relative convective movement between the solution and the electrode during drop growth must be considered. However, a simplified approach that is valid when the second term in Equation 70.31 is negligible, and the diffusion problem can be regarded as linear, yields the *Ilkovic equation*

$$i_r(t) = 708nDcm^{2/3}t^{1/6} \quad (70.32)$$

where m is the mercury flow rate (mass/time) from the capillary. Consequently, the current increases during the lifetime t_d of the drop (*drop time*), whereas it decreases with time in the other arrangements that have been described. **Figure 70.10** depicts this current–time relation of a DME with the characteristic current plateau at the end of the drop's lifetime.

In the considerations that have been made above, analyte transport by convection and migration in the electric field have been neglected. Convection can be regarded as absent if the solution is unstirred and if the working electrode rests motionless. However, in longer-lasting measurements, convective mass transport can play a role due to arising inhomogeneities in the density of the solution. Furthermore, if a DME is employed, the growth of the drop may cause a considerable convection of the solution. When the drop falls off, it stirs the surrounding solution and the depletion effect almost vanishes. Consequently, every drop is born in an almost homogeneous environment. The migration of electrically charged analyte particles due to the electric field in the solution can easily be suppressed using an inert supporting electrolyte with a concentration that is much larger than the analyte concentration. Since all charged species contribute to the migration current, the migration of the analyte species can then be neglected.

Double-Layer Charging Current.

A process that affects all kinds of voltammetric measurements is the flow of *capacitive current*. The accumulation of charge on one side of the electrode/solution interface causes the necessity of a mirror charge on the other side. Hence, a change of the electrode potential (i.e., in the electrode charging) causes a corresponding flux of charged particles between the double layer and the bulk solution. Therefore, the interface has a certain capacitance that is called the double-layer capacitance. The resulting *double-layer charging current* i_c is superimposed on the faradaic current and often perturbs its measurement. In analytical techniques, one is often concerned with the reduction of the capacitive/faradaic current ratio. However, the actual measurement of the double-layer capacitance is demanding and requires the technique of *impedance spectroscopy*, as described, for example, in References 12 and 13.

Irreversible Electrode Processes.

Another assumption that has been made implicitly is that the rate of the electrode reaction is very fast in comparison to the supply of analyte by diffusion (*reversible electrode process*). Under this condition, all analyte species reaching the electrode are immediately converted. However, if the reaction rate is too slow, the consumption of reactive species is compensated by the diffusion of the analyte (*irreversible electrode process*) and thus, the concentration at the electrode surface never drops to zero. The electrode current is then determined by the reaction rate and the calculations above do not hold. In practice, the situation is sometimes complicated if so-called *quasi-reversible* electrode processes with intermediate reaction rates occur. Although this concept of electrochemical *reversibility* is a simplification, it is a suitable working basis and can be summarized in the following statement: In a given electrochemical experiment, an electrode process that follows the *Nernst equation at any time* is called *reversible*.

Influence of Adsorption, Catalysts, and Chemical Reactions.

Besides the diffusion and reaction rate, some other processes can influence the electrode current. *Adsorption* of the analyte or its reaction product on the electrode changes the double-layer capacitance or can passivate the electrode surface and thus lower the current. Moreover, if a species serves as a *catalyst*, it may shift the equilibrium potential. In the case that the catalyst returns the product of the electrode reaction back into the initial form of the analyte, the analyte concentration at the electrode surface will always be large and thus increases the limiting current and shifts the equilibrium. All these *catalytic currents* are subject to analytical studies. Besides adsorption and catalysis, complicated scenarios occur if the electrode reaction is followed by a chemical reaction whose product itself undergoes an electrode reaction within the observed potential range.

Techniques

The several voltammetric (i.e., *potential-controlled*) techniques differ just in the manner in which the electrode potential is varied with time. The potential can be changed in distinct steps, in a continuous sweep, or it can be pulsed or superimposed with an ac signal. In addition, the rate of potential change can be varied. The characteristics, advantages, and drawbacks of the most important techniques will be discussed in the following sections. Special attention will be given to polarography due to its practical importance in electroanalysis. Besides, the emphasis will be on reversible electrode processes because only they allow the realization of *analytical investigations*, on which this chapter is focused.

Amperometry.

If in a *potential step* experiment the working electrode potential is abruptly changed from a constant value E_1 where faradaic processes do not occur to another constant value E_2 where the electrochemical equilibrium is on the side of the oxidized or reduced form of the analyte, then a faradaic current begins to flow (Figure 70.11(a)). In the case that the difference between the applied potential and the standard potential E^0 of the analyte's redox couple is sufficiently large, the effect of *diffusion limitation* sets in and a further increase of the potential difference yields no increase in the electrode current. The current is then called *limiting current*. The current–time relationship follows the Cottrell equation (Equation 70.29), with the current decreasing while the diffusion layer thickness increases.

FIGURE 70.11 In potential step techniques, the current is measured a fixed time τ after the potential step (a). The measurement of $i(\tau)$ for different potential steps ΔE yields a wave-shaped current–potential relation with a half-wave-potential $E_{1/2} \approx E^0$ (b). The maximum current is proportional to the analyte’s bulk concentration c_0 .

If the diffusion layer thickness could be held constant, then from Equation 70.26, it follows that the current would not decrease with time but remain at a constant value. This can be accomplished if the solution is stirred or flows across the electrode in a proper way. According to Equation 70.26 (with $c_e = 0$), the current then is proportional to the analyte concentration in the solution.

The described method corresponds to the electroanalytical technique called *amperometry* [14], with the exception that in this the potential step is omitted and the electrode current is measured at a fixed potential E at which the analyte undergoes an electrode reaction and the faradaic current is in the limited region. The solution usually crosses the electrode in a laminar flow, keeping the diffusion layer thickness constant.

Because the electrode current is proportional to the concentration of the analyte, only two measurements are needed for calibration. The base current is measured in an analyte-free solution and a second measurement is performed at a known analyte concentration. It should be mentioned that amperometry cannot only be used to determine liquid and ionic components of a solution but also to measure the amount of dissolved gas in a liquid. Moreover, with modified electrochemical cells, even gas analysis can be accomplished.

The main disadvantage of amperometry is its poor selectivity. Given a certain analyte and operating at a higher potential than the corresponding standard potential E^0 , all components of the solution with a standard potential smaller than E also contribute to the faradaic current. Operating at a potential $E < E^0$, the same problem occurs if substances with a standard potential larger than E are present in the solution. For this reason, amperometry is preferably carried out in solutions containing only one electroactive substance or, if possible, at a potential at which only one substance is involved in an electrode reaction. If this is impossible, the selectivity can often be enhanced by covering the working electrode with a membrane which, in comparison to the diffusion rate of the analyte through the membrane, is virtually impermeable for the interfering substances.

In addition to analytical purposes, amperometric methods can also be used to investigate reaction constants of chemical reactions. In *reversed potential step techniques*, the first potential step is followed by a second one in the opposite direction, often back to the initial value. The reaction product B of the first step is then reconverted into the original analyte A . However, if the first electrode reaction is followed by an additional chemical reaction, a certain part of B is converted into a product C before the reversed step is applied. Therefore, the current during the reversed step is reduced. The ratio of the electrode currents during the forward and reversed steps depends on the reaction constant of the chemical reaction. Because the reversion of B into A is required, batch arrangements without convection of the electrolyte are used for reversed step methods. Otherwise, a large part of B would be flushed away from the electrode surface and could not be reconverted.

Amperometric Titration.

In *amperometric titration techniques* [15], a titrant that reacts with the analyte is added to the analyte solution. During the titration, the limiting current is measured as a function of the volume of titrant added. The titrant has to be chosen such that the reaction product is not reducible or oxidizable at the applied potential and, hence, does not contribute to the current.

If the analyte as well as the titrant are electroactive at the applied potential, then the current flow will be large at the beginning of the measurement and decreases linearly with the volume of the titrant added, because both, the analyte and the titrant, are consumed by the reaction. The concentration of electroactive species then diminishes until the analyte is totally consumed. Further addition of titrant leads to a linearly increasing current because the titrant is no longer consumed. In the plot of the current versus the volume of titrant added, the point where the slope changes is called *endpoint* of the titration. From the corresponding amount of titrant added and the stoichiometry of the reaction the original volume of analyte can be computed. If only the analyte is electroactive, then from the endpoint the current will not increase but remain zero. If only the titrant undergoes an electrode reaction, the current will be zero until all analyte is consumed and then will linearly increase from the endpoint. In practical operation, the slope of the current does not change abruptly due to background currents and the endpoint has to be determined by extrapolation of the two linear regions.

In contrast to the majority of other electrochemical techniques, amperometric titration offers the advantage that even analytes which are not reducible or oxidizable can be determined using the oxidation-reduction characteristics of the titrant. Moreover, it is possible to analyze systems that have no measurable standard potential but can be electrolyzed.

Sampled-Current Voltammetry.

Consider a *potential step* experiment like the one in the section next to previous one. If the potential difference between E_2 and E^0 is too small, the electrode reaction is not so efficient that the analyte concentration at the electrode surface becomes zero (i.e., $c_c > 0$ in Equation 70.26). Within this region,

the current depends on the applied potential. However, even in this situation, a depletion effect occurs so that the current always decreases with time. Recording the current i for different values of E_2 at a fixed time τ after switching the potential (*sampled-current voltammetry*), a sigmoidal (wave-shaped) curve is obtained (Figure 70.11(b)).

The shape of this curve can also be calculated by exactly solving the diffusion problem. A wave rising from a baseline to the diffusion-limited current i_d is obtained. In the common case, the diffusion coefficients of the analyte and its redox partner are nearly equal the *half-wave potential* $E_{1/2}$, where $i = i_d/2$ is almost identical with the standard potential E^0 . Therefore, $E_{1/2}$ is often used in qualitative analysis to determine the analyte. Quantitative information about the analyte concentration is obtained from the maximum current (Cottrell current), which according to Equation 70.29 is proportional to c_0 .

The influence of the double-layer charging current has been neglected thus far, but is worth considering. It obeys the equation:

$$i_c = \Delta E / R_s \exp\left(-t / (R_s C_{dl})\right) \quad (70.33)$$

where ΔE is the potential step width, R_s the solution resistance, and C_{dl} is the double-layer capacitance. Although the measurement of R_s and C_{dl} is not trivial, one can obtain qualitative information from this formula. Comparison of Equations 70.33 and 70.29 yields that the capacitive current decreases exponentially while the faradaic current decreases according to $t^{-1/2}$. Consequently, the electrode current is measured a sufficiently long time after the potential step when the capacitive current has largely decayed, whereas the faradaic current is still significant. In polarography with DMEs, the growth of the electrode surface alters the temporal decrease of the double-layer charging current according to:

$$i_c \sim m^{2/3} t^{-1/3} \quad (70.34)$$

whereas the faradaic current increases according to $t^{1/6}$ (Equation 70.32). The current is measured shortly before the drop falls off (Figure 70.10).

The lower detection limit amounts to 10^{-5} to 10^{-6} mol/L for the determination of organic and inorganic analytes. The half-wave potential of different substances should be at least 100 mV apart for a simultaneous determination.

Linear Sweep and Cyclic Voltammetry.

In *linear sweep voltammetry* (LSV), the electrode potential is changed *continuously* from an initial to a final value at a constant rate $v = dE/dt$, such that $E(t) = E_1 \pm vt$. Starting at a potential E_1 where no faradaic process occurs, a current begins to flow when the electrode potential comes into the vicinity of E^0 . The current rises to a maximum and then decreases due to the depletion effect (Figure 70.12). The solution of the diffusion equations, which yields the shape of the i - E wave, can only be found numerically. For the electrode process to always follow the Nernst equation and thus be reversible, the sweep rate must not be too high (e.g., $v < 100$ mV s⁻¹). The peak potential E_p can then be calculated to be:

$$E_p = E_{1/2} \pm 1.1 \cdot (RT/nF) = E_{1/2} \pm (28.0/n) \text{ mV (at } 25^\circ\text{C)} \quad (70.35)$$

The positive sign in Equation 70.35 applies to an anodic sweep (from negative to positive potential with $v > 0$) and the negative sign to a cathodic one (from positive to negative potentials with $v < 0$). The peak current is given by:

$$i_p = 0.446 n F A \left(n F / RT \right)^{1/2} D^{1/2} c_0 v^{1/2} \quad (70.36)$$

Thus, the peak current is proportional to the bulk concentration c_0 of the analyte and depends on the sweep rate according to $v^{1/2}$.

FIGURE 70.12 In LSV the potential varies linearly with time (a). The current–potential relation yields a peak-shaped curve with a half-wave potential $E_{1/2} \approx E^0$ (b). The peak current is proportional to the analyte's bulk concentration c_0 .

Another contribution to the measured current is the capacitive double-layer-charging current i_c , which always flows in LSV due to the continuous change of potential. It can be calculated using the equation:

$$i_c = C(dE/dt) = C\nu \quad (70.37)$$

which yields a proportionality to ν while the faradaic peak current is proportional to $\nu^{1/2}$. Thus, for the faradaic current to dominate the measurement, the sweep rate should not be chosen too large. A sweep rate of 100 mV s^{-1} can be regarded as an upper limit. Moreover, the surface area of the working electrode must be taken into consideration. Rough electrodes have a much larger active than geometric surface area and thus a very large capacitance. Therefore, small, very smooth electrodes should be chosen.

FIGURE 70.13 In CV, the potential is swept forth and back between two fixed values (a). The current–potential relation yields a peak-shaped curve with a half-wave potential $E_{1/2} \approx E^0$ (b). The peak current is proportional to the analyte’s bulk concentration c_0 . For totally reversible systems, the peak currents of the forward and the backward sweep are equal in magnitude but of opposite sign.

A variation of LSV is a technique called *cyclic voltammetry* (CV). Here, the electrode potential is swept forth and back between two potentials E_1 and E_2 (Figure 70.13(a)). Although the bulk concentration of the reaction product is essentially zero, its concentration at the electrode surface after the first sweep is quite large. In the backward sweep, the reaction product of the analyte is converted into the analyte again. The current flows in the opposite direction and using an xy -recorder, an i – E curve is obtained (Figure 70.13(b)). From Equation 70.35, it follows that for reversible processes, the peak potentials of the forward and backward sweep have a distance of $(56/n)$ mV at room temperature. Therefore, cyclic voltammetry is a favorable method for the investigation of the reversibility of a system. If the electrode current totally decays in the forward sweep, the analyte concentration has dropped to zero and the product

concentration at the electrode surface is about c_0 . Ideally, the peak current during the reverse scan should be equal (with reversed sign) to the peak current of the forward sweep.

Although the theory of LSV and CV measurements is very promising, the methods have several practical limitations. One is the frequently insufficient stability of the i - E characteristic during the first cycles in CV. However, after 5 to 10 cycles, it tends to become highly reproducible. Yet, one must be careful deriving quantitative information from these later cycles because the initial and boundary conditions of the diffusion problem have changed and convective mass transport may already play a role. Thus, the equations developed for LSV cannot be used. Another problem that concerns both LSV and CV is the potential drop that occurs in the solution between the working and the reference electrode and which leads to a distortion of the shape of the i - E wave. This error increases with increasing current flow. Thus, the rate of change ν of the electrode potential is not really constant, as has been assumed in the boundary conditions for solving the diffusion equations. Furthermore, the quantitative information is usually obtained from the position E_p and the height i_p of the current peak where the error is maximum. Finally, the determination of the peak height itself is sometimes problematic due to difficulties in the extrapolation of the baseline. For all these reasons, it may be advisable to verify the results of quantitative analysis with additional methods. Nevertheless, on easy terms, the lower detection limit of LSV and CV in quantitative analysis can amount to 10^{-7} mol/L with a resolution of about 50 mV.

Besides the analysis of faradaic processes, LSV and CV are favorable techniques for the investigation of the adsorption of species on the electrode surface [16]. In such adsorption processes, the current is called *pseudocapacitive current*. Although it is a charge transfer across the interface, it exhibits many of the properties of a pure capacitive current. The current-potential wave has a very similar shape as for faradaic processes. If Θ denotes the coverage ($0 \leq \Theta \leq 1$) and q_1 the charge that is required to form a monolayer of a species, the pseudocapacitive current i_a can be expressed as:

$$i_a = q_1 \left(\frac{d\Theta}{dt} \right) = q_1 \left(\frac{d\Theta}{dE} \right) \left(\frac{dE}{dt} \right) = C_a \nu \quad (70.38)$$

where C_a is called the *adsorption pseudocapacitance*. The calculation of C_a yields that the pseudocapacitance does not depend on ν . Therefore, at any potential the current is proportional to the sweep rate ($i \sim \nu$). The peak potential gives information about the adsorption kinetics. In contrast to faradaic CV, it has the same value for the forward and the backward sweep.

Pulse Techniques.

Voltammetric pulse techniques are derived from potential step experiments to suppress the capacitive currents during the measurement. A potential step that can vary in amplitude and sign is periodically repeated and superimposed with a potential ramp. The current is measured at the end of the step when the double-layer charging current has largely decayed.

Normal Pulse Voltammetry. In *normal pulse techniques*, periodic voltage pulses with an increasing amplitude from pulse to pulse are superimposed on a constant potential. A typical pulse duration is about 50 ms and the current is measured during a time interval Δt_m of about 10 to 15 ms at the end of each pulse. Between two pulses there is a waiting period of a few seconds (Figure 70.14). In polarography with a DME, each drop is dislodged directly after the pulse and thus used for just one measurement.

Because normal pulse voltammetry equals a series of potential-step measurements with increasing step widths, the current obeys to Equation 70.29 and the evaluation of the measured current values can be carried out using the sampled-current method. In comparison with the step technique, the lower detection limit is enhanced for one to two orders of magnitude up to 10^{-6} and 10^{-7} mol/L [17]. The peak resolution is about 100 mV.

Square-Wave Voltammetry. In *square-wave techniques*, a periodic rectangular voltage is superimposed on a linearly rising potential ramp. The measuring interval lies at the end of a pulse when the capacitive current can be neglected (Figure 70.15(a)). Typical pulses have frequencies between 200 Hz and 250 Hz and an amplitude of $\Delta E_p = 5$ to 30 mV [17]. The capacitive current is suppressed even more effectively if the pulse is tilted to decrease during the pulse period. No pulse tilt is required if the potential ramp is

FIGURE 70.14 Normal pulse voltammetry equals a series of potential-step measurements with increasing step widths. The current is measured during a time interval t_m near the end of the pulse. In polarography with a DME, the drop is dislodged after each measurement. The drop's lifetime is denoted by t_d .

stepped (staircase ramp) instead of a linear ramp. The voltage pulse is then applied on the plateau of the stepped ramp (Figure 70.15(b)).

After rectification of the measured current values, one obtains peak-shaped i - E -curves. The peak potential corresponds to the half-wave potential of LSV and, thus, to the standard potential of the analyte's redox couple. The peak current i_p depends on the frequency and amplitude ΔE of the voltage pulses and obeys:

$$i_p \sim n^2 D \Delta E c_0 \quad (70.39)$$

where the frequency dependence is included in the proportionality constant. The lower detection limit is in the range of 10^{-8} mol/L and the peak resolution amounts to 40 to 50 mV.

Shorter analysis times are achieved if very short and relatively large rectangular pulses with a duration $t_p = 5$ to 10 ms and an amplitude of $\Delta E = 50$ mV are superimposed on a stepped potential ramp with the same duration but smaller potential steps of about 10 mV. The potential can then be scanned at extremely high rates of up to 1200 mV s^{-1} . However, the sensitivity decreases because the ratio of faradaic to capacitive currents is lowered by the short pulse times.

Differential Pulse Voltammetry. *Differential pulse methods* are the most important ones in analytical voltammetry. Periodically repeated rectangular voltage pulses with a constant amplitude ΔE of several 10 mV are superimposed on a stepped potential ramp (Figure 70.16). The pulse duration Δt_p is about 5 to 100 ms [17]. Between two pulses, the potential is held constant for a few seconds. The current is measured in a short time interval ($\Delta t_m \approx 1$ to 20 ms) directly before a pulse is applied and for the same duration near the pulse end. If a DME is used, the drop is knocked off mechanically between two pulses and each drop serves for just one measurement.

For the evaluation, the difference between the two measured current values Δi that corresponds to one pulse is recorded as a function of the base potential. A peak-shaped curve is obtained with a maximum very close to the half-wave potential $E_{1/2}$. The peak height is proportional to the analyte concentration in the bulk:

$$\Delta i_p \sim nFA \left(D / \pi t_p \right)^{1/2} c_0 \quad (70.40)$$

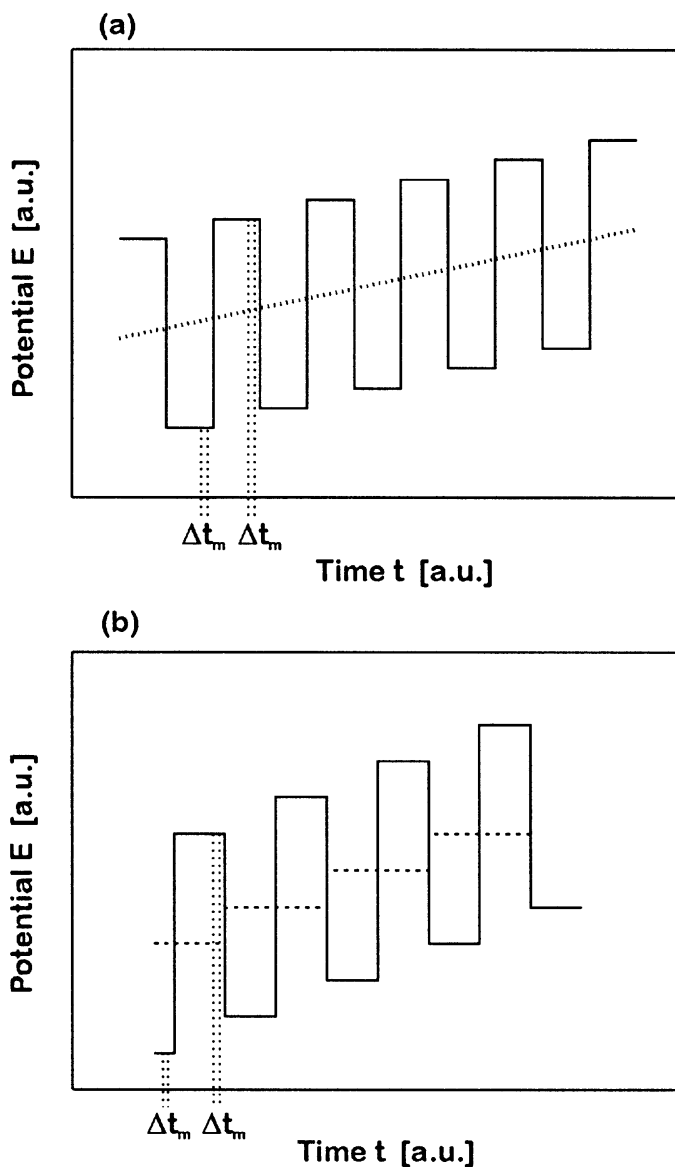

FIGURE 70.15 In square-wave voltammetry, a periodic rectangular voltage pulse is superimposed on (a) a linearly changing potential ramp (dotted line) or (b) on a stepped ramp (dashed curve). The current is measured during a time interval Δt_m at the end of each pulse.

With differential pulse measurements, a lower detection limit of 10^{-8} mol/L and a resolution of 50 to 100 mV can be achieved.

Alternating Current Voltammetry.

Alternating current techniques are similar to differential pulse methods. A linear potential ramp is modulated with a low frequency ($f \sim 50$ Hz) sinusoidal alternating voltage of small amplitude ($\Delta E \sim 50$ mV) [17]. The amplitude of the resulting alternating current is plotted against the base potential. A peak-shaped curve is obtained with a maximum that is proportional to the bulk concentration of the analyte:

$$i_p \sim \Delta E f^{1/2} c_0 \quad (70.41)$$

FIGURE 70.16 In differential pulse voltammetry, periodic rectangular pulses are superimposed on a stepped potential ramp. The difference between the current measured in a time interval Δt_m^1 directly before each pulse and during a time interval Δt_m^2 at the end of each pulse is plotted against the base potential. In polarography with a DME, the drop is dislodged after each pulse. The drop's lifetime is denoted by t_d .

The lower detection limit is 10^{-5} mol/L due to the large capacitive currents. It can be enhanced by phase-selective rectification because the capacitive and the faradaic currents have a phase shift of 90° and 45° , respectively. The peak resolution amounts to 50 to 100 mV.

Stripping Voltammetry.

Stripping techniques can be performed with analytes whose reaction products adsorb on the electrode surface. For accumulation, the electrode potential is held at a value at which the electrochemical equilibrium is on the product's side. Accumulation times usually amount up to several minutes. During this period, the solution is stirred to prevent the depletion of the analyte at the electrode surface. The accumulation is followed by a rest period of 2 to 30 s, during which the solution remains unstirred and the current falls to a small residual value. In the subsequent *stripping step*, the electrode potential is shifted to a value at which the adsorbed product is reconverted into the analyte by oxidation or reduction. Depending on whether an oxidation or reduction process occurs, the method is called *anodic stripping voltammetry* (ASV) or *cathodic stripping voltammetry* (CSV), respectively. The stripping step can be performed in various manners [18] of which the linear sweep method shall be exemplarily discussed here. It yields a peak-shaped i - E curve with a maximum at:

$$E_p = E_{1/2} - 1.1 RT/nF \quad (70.42)$$

and a peak height that is proportional to the bulk analyte concentration according to:

$$i_p \sim n^{3/2} v^{1/2} c_0 \quad (70.43)$$

Different substances can be determined in successive experiments with an adequate choice of the accumulation potentials. For the first measurement, the accumulation potential is chosen to allow adsorption of only one species; in the next experiment, the first and one further analyte adsorb, and so on. For the simultaneous determination of two or more substances their peak potentials should be at least 150 mV apart.

A special case of the stripping techniques is *adsorptive stripping voltammetry* (AdSV). Here, the analyte is deposited in the form of metal chelates or organic molecules. For the formation of metal chelates, a complexing agent is added to the electrolyte or the surface of a solid-state electrode is modified with it. The stripping current is then due to the oxidation or reduction of the central atom or the ligand of the metal chelate complex. With this method, organic and organometallic compounds can be determined in the ultratrace range.

A crucial point in stripping analysis is the reproducibility. All experimental parameters have to be selected very carefully. In particular, the electrode surface must not be changed significantly by the adsorption and dissolution processes. Therefore, HMDEs are frequently employed for stripping analysis. A new drop is produced for each measurement. Another advantage of mercury electrodes is the fact that not only their surface but rather the hole bulk is used for the accumulation of analyte species. Consequently, more material can be collected. This leads to an enhanced lower determination limit which can be below 10^{-8} mol/L. Comprehensive monographs about stripping techniques are given in References 18 and 19.

Applications

Analytical applications of voltammetry concern the determination of (heavy) metal cations, typical anions (halides, pseudohalides), organometallic, and organic compounds in the 10^{-4} to 10^{-9} mol/L concentration range. Therefore, they are established in several fields like environmental, medical, food, and water analysis. A disadvantage is the usually labor-intensive sample preparation necessary, for example, to disintegrate ions from complexes, to adjust the pH of the solution, or to remove interfering species like oxygen and organic molecules. Principally, the preparation of the electrode (surface) is also crucial. However, commercially available equipment is well developed not only to enhance determination limits, sensitivity, selectivity, and reproducibility, but also to reduce the expense for electrode and cell preparation. Moreover, sample and electrode preparation can be automated to a certain degree by devices which pump different solutions for cleaning, conditioning and analysis through the cell setup. A further improvement of the instrumentation is the use of *microelectrodes* with dimensions of 1 to 100 μm . Because their dimensions are small in comparison with the diffusion length of the analyte, even for planar microelectrodes the diffusion is rather hemispherical than linear. Therefore, the depletion effect is less strong and the faradaic current is increased. Moreover, planar microelectrodes can be rotated (*rotating disk electrode*, RDE) to intensify convection and the solution can be stirred with ultrasound. Another advantage of microelectrodes is the possibility to realize several electrodes in a close neighborhood, so-called *electrode arrays*. They serve as *one* electrode if they are held at *one* potential and exhibit an improved signal-to-noise ratio due to the better diffusion conditions. In contrast, if different potentials are applied at different electrodes, the simultaneous determination of different species is possible. These techniques have just become commercially available as electrochemical detectors, for example, for high performance liquid chromatography (HPLC). In this arrangement, the different species in the solution are separated by the HPLC and flow through the detector cell one after the other. Thus, interference between different analytes is minimized. The selectivity can often be further improved by the use of membrane-covered microelectrodes. The well-known *Clark oxygen sensor* and different biochemical sensors represent promising examples of this application in amperometry. Moreover, it opens up new possibilities for the creation of microelectrode arrays.

Due to the high analytical potential and the relatively low costs of voltammetric methods in comparison with spectroscopic techniques, all aspects of voltammetry are still subject of intense research. Current efforts concern the *miniaturization* of the whole cell, including microchannels, microvalves, micropumps, and microelectrodes by means of precision mechanics and *micromachining techniques* [20]. They employ fabrication methods of silicon planar technology and LIGA technique (Lithographie, Galvanoformung, Abformung). Thin-film techniques like physical and chemical vapor deposition (PVD, CVD) allow the fabrication of electrodes with a thickness in the submicrometer range and with lateral dimensions from the micrometer to the nanometer range. One goal is the realization of a *microsystem* with the sensitive components (i.e., the electrodes) and microelectronics integrated on a single chip. The electronics could

serve as a first stage of signal amplification and information processing. Although first demonstrator devices have already been presented [21] it is still quite a long way to commercially available systems.

Potentiometry

Potentiometry implies the measurement of an electrode potential in a system in which the electrode and the solution are in electrochemical equilibrium. Thus, the potential becomes the dependent variable, for example, as a function of time. In potentiometry, the current is attempted to be kept as small as possible; ideally, it should be zero. Potentiometry implies known fluxes (i.e., concentration gradients at the electrode surface) and thus information on the composition of the sample. In this section, potentiometry is related to the measurement of potentials, where the voltage source is a form of a galvanic cell, consisting of a measuring electrode and a reference electrode (in general, electrodes of the second kind). The principles of *direct potentiometric measurements* as well as *potentiometric titrations* will be described.

Ion-Selective Electrodes

The equipment required for potentiometric analysis includes a measuring electrode, also called an *ion-selective electrode* (ISE) or *indicator electrode*, and a reference electrode. In addition to the sensitivity, the most important characteristic of the ISE is given by its *selectivity*. Depending on the type of membrane, ISEs can be classified into four different groups: *glass electrodes*, *solid-state electrodes*, *liquid-membrane electrodes*, and miscellaneous *combined electrodes*. For all ISEs, the validity of the Nernst equation could be proved.

Glass Electrodes.

The most common *glass electrode* is the *pH electrode*, widely used for hydrogen ion determination. The pH glass electrode consists of a thin, pH-sensitive *glass membrane* sealed to the bottom of an ordinary glass tube. The tube is filled with a solution of hydrochloric acid (e.g., 0.1 M HCl) that is saturated with silver chloride. A silver wire, connected to an external potential-measuring device, is immersed in this solution. Note that the internal HCl concentration is constant and, thus, the internal potential (inner surface of glass membrane) of the pH electrode is fixed. Only the potential that occurs between the outer surface of the glass bulb and the test solution responds to pH changes. To measure the hydrogen ion concentration of the test solution, the glass electrode (indicator electrode) must be combined with an external reference electrode, which is required for all kinds of ISE determination. Often, pH glass electrodes are available as a combination of the indicator electrode and an internal reference electrode (e.g., Ag/AgCl in saturated KCl solution) as schematically shown in [Figure 70.17](#).

The composition of the glass membrane clearly influences the sensitivity of the pH electrode. Usually, three-component systems of, for example, SiO₂/Na₂O/CaO are employed [22]. The pH dependence can be expressed by the Nernst equation (Equation 70.11). At room temperature (T = 25°C), Equation 70.11 can be simplified by:

$$E = E^0 + 59.1 \text{ mV pH} \quad (70.44)$$

where E^0 is the standard Galvani potential with respect to the SHE. Thus, the measured potential is a linear function of pH within an extremely wide range (10 to 14 decades). The selective pH response of the pH ISE is due to the ion exchange process, in particular, due to the replacement of sodium ions in the glass membrane (m) by protons in the solution (s), and vice versa:

The sodium ion exchange is also responsible for the *alkaline error* of pH electrodes in solution with pH greater than 10. In spite of the high resistance of the glass membrane against chemical attack, one

FIGURE 70.17 Combination pH glass electrode with an integrated Ag/AgCl reference electrode.

has to deal with deviations (alkaline error) from the linear pH dependence. This error (i.e., the sensitivity toward alkali-metal ions) can be greatly reduced if Na_2O is replaced by Li_2O . Because pH glass electrodes can be used in the presence of substances that interfere with other electrodes (e.g., proteins, oxidants, reductants, and viscous media), they have a wide range of applications. Typical fields are the clinical and food analysis, environmental monitoring (e.g., industrial waste, acidity of rain), and process control (e.g., fermentation, boiler water, galvanization and precipitation).

The employment of glass membranes prepared with different glass compositions allows an electrode response sensitive to cations. For example, sodium-, potassium-, and ammonium-selective glasses consist of a mixture of Na_2O , Al_2O_3 , and SiO_2 in various proportions (aluminosilicate glasses). Using specific compositions and mixtures of chalcogenides, ion-selective *chalcogenide glass electrodes* with sensitivities toward monovalent ions (e.g., Ag^+ , Tl^+ , F^- , Cl^- , Br^- , I^-) and double-charged species (e.g., Cu^{2+} , Pb^{2+} , Cd^{2+} , Hg^{2+} , S^{2-}) can be prepared [23]. However, in all cases, some sensitivity to charged species (e.g., H^+ ions) remains. The electrode potential under these conditions is described by the *Nikolsky-Eisenmann* equation

$$E = E^0 \pm \frac{RT}{zF} \ln \left(a_i + K_{ij} a_j^{z_i/z_j} \right) \quad (70.46)$$

where z_i , z_j , and a_i , a_j are the ionic charge and activity of the primary or determined (i) and the interfering (j) ion. K_{ij} is the *selectivity coefficient*. It is a measure of the ISE ability to discriminate against the interfering ion. A small value of K_{ij} indicates an ISE with a poor selectivity.

Solid-State Electrodes.

The glass membrane of an ISE can be replaced by a single or a mixed crystal, or a polycrystalline (pressed) pellet (Figure 70.18(a)). With respect to their membrane composition, *solid-state electrodes* are divided into *homogeneous* and *heterogeneous membrane electrodes*.

FIGURE 70.18 Typical membrane electrode types: solid-state electrode (a), liquid-membrane electrode (b), gas-sensing electrode (c), and enzyme-based electrode (d).

A typical single-crystal electrode (homogeneous membrane electrode) is the fluoride-sensitive ISE, which contains a LaF_3 crystal doped with Eu^{2+} . The crystal with a thickness of about 2 mm is sealed into the bottom of a plastic tube. The internal solution (0.1 M of NaF and NaCl) controls the potential at the crystal inner side by means of an Ag/AgCl wire as reference electrode. In contact with the test solution at the crystal outer side, an electrochemical equilibrium is established, proportional to the fluoride ion activity. This is due to an ion exchange process at the phase boundary membrane/electrolyte. In particular, fluoride ions from the membrane are replaced by fluoride ions from the solution and vice versa, where the fluoride ions can migrate from one lattice defect to another inside the crystalline membrane. Further homogeneous membrane electrodes are silver halide electrodes, where the respective silver halide (AgCl , AgI , AgBr , Ag_2S) is pressed into a pellet, placed in a tube, and contacted via a silver wire. In these substances, silver ions are accordingly able to migrate. Such electrodes have been successfully used for the selective determination of chloride, bromide, iodide, silver, and sulfide ions. Likewise, if the pellets contain Ag_2S together with the silver halides or mixtures of PbS , CdS , and CuS , solid-state electrodes sensitive toward Pb^{2+} , Cd^{2+} , Cu^{2+} , and SCN^- can be realized. Moreover, the general problem of light sensitivity and high membrane resistance can be reduced by the additional use of Ag_2S .

Instead of the pressed pellets, the ion-selective material can be incorporated into an organic polymer matrix, like silicon rubber, carbon paste, or paraffin. In heterogeneous membrane electrode preparation, a mixture of the precipitate (e.g., $\text{AgI}/\text{Ag}_2\text{S}$) and polysiloxane is homogenized, and the polymerization is carried out. The resulting disks are fixed on the end of a tube and the internal solution (e.g., 0.1 M KI) is contacted via a Ag/AgCl wire. *Coated-wire electrodes* represent another possibility. They can be manufactured by coating an appropriate polymeric membrane onto a conducting wire. Often, the conductor (Pt, Ag, Cu, or graphite) is dipped in a solution of polymer (e.g., polyvinylbenzylchloride (PVC) or polyacrylic acid) and the active substance. These electrodes allow the determination of K^+ , Na^+ , amino acids, and some drugs (e.g., cocaine). In addition to their simple miniaturization, the preparation is easy and inexpensive. However, further work is necessary to improve their analytical performance with regard to reproducibility and long-term stability.

Liquid-Membrane Electrodes.

Liquid-membrane electrodes base on two different membrane-active components, *solid ion-exchanger* and *complex-forming neutral-charged carriers*. They permit the determination of several polyvalent cations as well as certain anions. The sensor membrane (10 to 100 μm thickness) is usually prepared of a plasticized PVC containing the organic sensor-active component that is insoluble in water. A Ag/AgCl wire is immersed into the internal reference solution. The liquid-membrane electrode differs from the glass electrode only in that the test solution is separated from the solution with the known target ion activity by a hydrophobic membrane, instead of the glass layer (Figure 70.18(b)). As membrane materials besides PVC, teflon, sintered glass, filtering textile, or disks can be employed to hold the organic layer.

Liquid-membrane electrodes with ion-exchangers have been realized for the determination of, for example, Ca^{2+} , K^+ , BF_4^- , ClO_4^- , IO_4^- , SCN^- , I^- , Br^- , Cl^- , HCO_3^- , H_2PO_4^- , and NO_3^- . On the other hand, the synthesis of compounds containing individual cavities of molecule-sized dimensions results in complex-forming neutral-charged carriers. These *ionophores* (e.g., crown ethers like cyclic polyether, depsipeptides like valinomycin, and macrotetrolides like nonactin and monactin) are capable of enveloping various target ions reversibly in their pockets. For example, valinomycin membranes show a high K^+ selectivity. Many cyclic and monocyclic carriers with remarkable ion selectivities have been successfully developed for the determination of Li^+ , Cs^{2+} , Ca^{2+} , Na^+ , NH_3^+ , Mg^{2+} , Ag^+ , Hg^{2+} , SCN^- , and H_2PO_4^- [24]. For all kind of membranes, a high molecular weight (i.e., a slight overpressure) prevents the quick intrusion of the test solution inside. Hence, the electrode's lifetime is limited as a consequence of diffusion of the sensor-active component into the analyte (*leaching out*).

Combined Electrodes.

Two different types of *combined electrodes* will be presented here: *gas-sensing electrodes* and *enzyme-based electrodes*. Gas-sensing electrodes can be used to determine solutions of gases. They consist of an inner sensing element, normally a suitable ISE with an electrolyte solution (0.1 M), surrounded by a gas-permeable membrane (Figure 70.18(c)). On immersion of this ISE, the gas-permeable membrane contacts the liquid of the gas which diffuses through it, and the resultant internal solution will be examined with the ISE. The partial pressure of the gas attains an equilibrium between the test solution/membrane and the membrane/ISE phase boundary. For example, the determination of carbon dioxide, which diffuses through the semipermeable membrane, lowers the pH values of the inner solution:

Such pH changes are detected by the ISE, in this case by a pH-sensitive glass electrode. Semipermeable membrane materials are polytetrafluorethylene, polypropylene, or silicone rubber. The internal solution contains sodium chloride and an electrolyte with the corresponding ion that is determined. Gas-sensing electrodes have been realized for gases dissolved in solution, such as NH_3 , NH_4Cl , CO_2 , H_2CO_3 , NaHCO_3 , NO_2 , NaNO_2 , SO_2 , H_2SO_3 , $\text{K}_2\text{S}_2\text{O}_5$, CN , SCN , Cl_2 , Br_2 , I_2 , and H_2S .

Enzyme electrodes are based on the coupling of an enzymatic membrane with any type of appropriate ISE. The enzyme converts (*catalyzes*) the analyte (*substrate*) to be determined extremely selective into an ionic product. The latter can be detected by the known ISE (Figure 70.18(d)). The coupling of the enzyme can be carried out by several *immobilization procedures*, such as entrapping in a gauze or gel, adsorptive or covalent binding, and cross-linking. A typical example for the operation of an enzyme electrode is given by the urea electrode. The enzyme urease hydrolyzes urea in order to liberate ammonium ions:

Either the alteration of the pH by a pH ISE or the variation of the NH_4^+ concentration by an ammonium-sensitive gas electrode can be detected. Likewise, penicillin, glucose, lactate, phenol, creatinine, cholesterol, salicylate, or ethanol will be catalyzed by means of the respective enzyme. Using different biological

FIGURE 70.19 Schematic calibration curves for anions and cations (LDL: lower detection limit).

components (enzymes, cells, tissues, antibodies, receptors, or nucleic acids), a wide variety of analytically important substances for clinical, environmental, and food analysis can be determined. However, disadvantages of this type of electrode are its slow response time (several minutes) and the insufficient stability in the long term.

Instrumentation and Measurement.

For potentiometric measurements, one uses an indicator electrode (ISE) versus a reference electrode and a *potentiometer*, also called *pH meter* or *ion meter*. Owing to the high resistance of the ISE membranes (e.g., 5 to 500 M Ω for the glass membrane), a potentiometer with a high input resistance is required. Modern potentiometers consist of an electronic digital voltmeter with a suitable operational amplifier, scaled directly to pH units or mV, with a resolution of better than ± 0.002 pH and ± 0.1 mV. They may range from simple hand-held instruments for field applications to more convenient laboratory models. Frequently, potentiometers include a bias control that can be adjusted to correspond to the temperature of the test solution (*automatic temperature compensation*).

Direct Potentiometry. *Direct potentiometric* measurements can be performed for the determination of ionic species for which an appropriate ISE is available. A schematic measuring set up for direct potentiometry is shown in Figure 70.3. The measuring technique is quite simple: comparing the potential of the ISE in the test solution with its potential in a known *standard solution*. That means, before the determination, the ISE must be calibrated in solutions of known concentration of the chosen ionic species. Thus, for the ion determination to be made, at least two to three reference solutions are necessary which differ by two to five concentration decades. Typical resulting *calibration curves* for anions and cations are plotted in Figure 70.19. The curves can be separated into three distinct regions: (1) the straight part corresponding to the Nernstian slope (i.e., the sensitivity of the ISE), (2) the curve portion, and (3) the horizontal part below the lower detection limit, where almost no sensitivity exists. The *lower detection limit* (LDL) of the ISE is defined as the concentration at which the extrapolated horizontal portion of the graph intersects the extrapolated Nernstian portion of the graph.

For practical applications, there are two aspects to be dealt with: often a *total ionic strength adjuster buffer* (TISAB) is added to both the standard solutions and the test solution (same temperature) to achieve comparable ionic strengths. Then, the potential difference can be assigned to the equivalent concentration of the calibration curve. Various methods for calibration calculations are described by, for

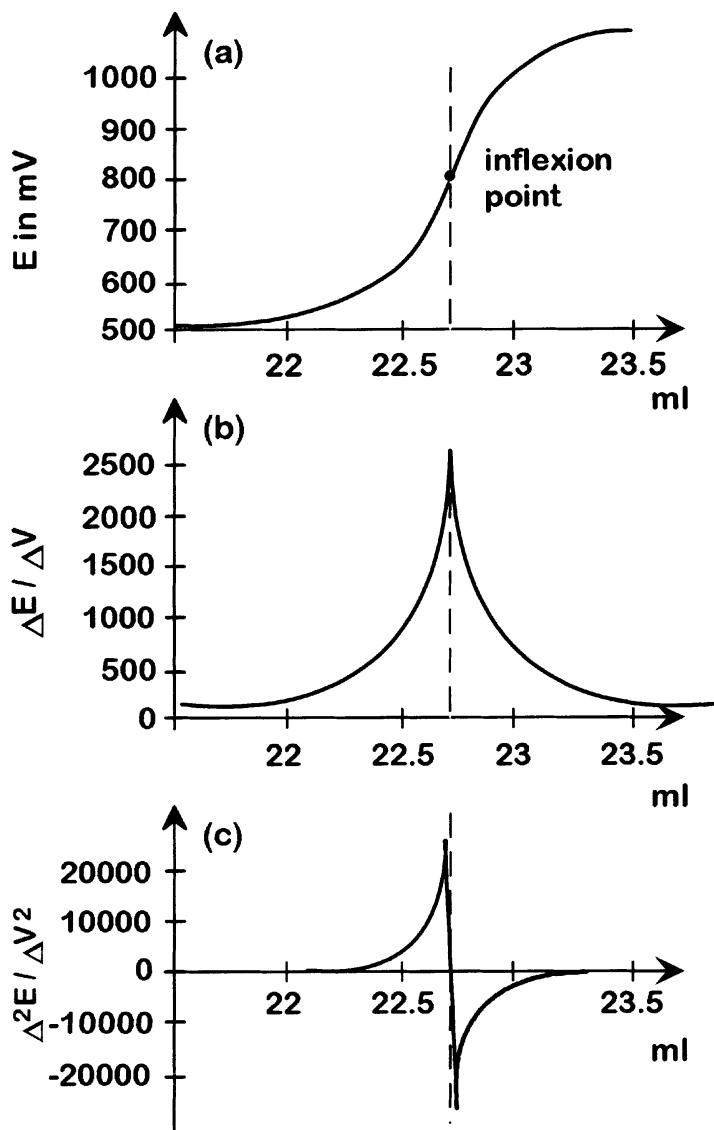

FIGURE 70.20 Characteristic potentiometric titration curve (a), first-derivative curve (b), and second-derivative curve (c).

example, Gran's plot or the standard addition method [25]. Because all measurements take place in dilute solutions ($\leq 0.1 M$), ion concentrations can be used in the Nernst equation instead of ion activities.

Potentiometric Titrations. *Potentiometric titrations* can be applied in the fields of *acid-base*, *precipitation*, *complex-formation*, and *redox reactions*. Therefore, the ISE is used in combination with a reference electrode in order to establish the *equivalence point* in a titration curve. A typical S-shaped potentiometric titration curve, where the electrode potential is plotted versus the reagent volume (*titrant*) is given in Figure 70.20(a). The titrant is added to the initial solution which is stirred, and the ISE records the potential value at equilibrium. The equivalence point (*endpoint*) of the reaction is reached when a sudden change in the potential of the ISE occurs. The midpoint in the curve (i.e., the steeply rising portion) is termed *endpoint* or *inflexion point*. It can be evaluated by analytical methods, namely the first- and second-derivative curve (Figure 70.20(b) and (c)). The first-derivative curve gives the potential change per unit change in volume of reagent and depicts the endpoint at the maximum of the inflexion point.

The second-derivative curve is zero where $\Delta E/\Delta V$ reaches its maximum. The greater the slope at the endpoint, the smaller should be the volume increment in order to reduce titration errors.

For practical applications, modern microprocessor-controlled titrators are commercially available (*auto-titrator*), coupled to a chart recorder to produce the titration curve directly. Such instruments also allow to evaluate the first- and second-derivative curves, and provide Gran's plot. Acid-base (neutralization) titrations are performed with a glass/calomel electrode system and can be used to titrate a mixture of acids that differ greatly in their strengths (e.g., acetic (ethanoic) and hydrochloric acids). For precipitation titrations, the ISE consists of an electrode (e.g., a silver or a platinum wire) that quickly reaches equilibrium with the ions to be precipitated. A typical precipitate reagent represents silver nitrate for the determination of halogens, halogenides, mercaptans, sulfides, arsenates, phosphates, and oxalates. For complex formation titrations, membrane electrodes can be used that involve the formation of soluble complexes, like EDTA (ethylene-diaminetetraacetic acid) or silver cyanide ($\text{Ag}(\text{CN})_2^-$). Oxidation-reduction titrations are performed by a platinum indicator electrode to any redox couples where the potential depends on the concentration ratio of the reactants. Some experimental details for potentiometric titration are described in Reference 26.

As an alternative principle, *chronopotentiometry* is based on the observation of the change in potential of a working electrode as a function of time during electrolysis. Usually, this electrolysis is performed with a constant current, whereas the time is measured that is necessary for the potential to go from one level to another. Since chronopotentiometry is disappointing at concentrations below 10^{-4} mol/L, it is only a powerful tool for studying electrode processes at higher concentrations. Consequently, this method is not very important for practical applications.

Ion-Sensitive Field-Effect Sensors

The integration of thin ion-selective membranes with solid-state electronics leads to miniaturized *chemically sensitive solid-state devices* (CSSDs). They can be distinguished into two different types: *chemically sensitive field-effect transistors* and *chemically sensitive capacitors*. These field-effect devices are based on the technology used for manufacturing microelectronic chips and thus offer the possibility of mass production. However, the techniques and miniaturized sensors presented in this section are in the most cases still in the state of research and development.

Chemically Sensitive Field-Effect Transistors.

Chemically sensitive field-effect transistors (ChemFET) can react sensitive to some ions (*ISFET: ion-sensitive FET*), biomolecules (*BioFET: biologically sensitive FET*), or gases (*GasFET: gas-sensitive FET*) in aqueous media, or they can be insensitive (*ReFET: reference FET*). They incorporate the sensor membrane directly on the gate area of a field-effect transistor (FET). A schematic of an ISFET with an SiO_2 gate insulator (about 100-nm thickness), mounted in a measuring cell and contacted via a reference electrode, is given in [Figure 70.21\(a\)](#). When the sensor membrane is placed into contact with the test solution of the ion to be detected, a potential shift (ΔV) occurs. The charge density at the interface solution/membrane changes because of the chemical interaction with the ions, and this potential affects the drain current (I_D) flowing between source (S) and drain (D) of the transistor. After calibration of the ISFET with standard solutions of known ion activity, the variation of I_D can be used to determine the ion concentration in the test solution ([Figure 70.21\(b\)](#)). Often, the ISFET is operated in a feedback loop (e.g., the *constant charge mode*, [Figure 70.21\(c\)](#)) and the voltage V_M needed to maintain I_D at a fixed value represents the sensor response. The sensor response can be described by the same Nernst and Nikolsky equations that characterize conventional ion-selective electrodes.

The operation principle of ChemFETs can be derived from the essential electronic behavior of *MOSFET* (*metal-oxide-semiconductor FET*) devices [27], where the drain current I_D is expressed by:

$$I_D = K_d \left((V_G - V_T) V_D - \frac{V_D^2}{2} \right) \quad (70.49)$$

FIGURE 70.21 ISFET configuration (a), input characteristic (b), and schematic circuit of CCM (c). The metallic gate from a MOSFET (metal-oxide-semiconductor FET) is replaced by the arrangement sensitive membrane/test solution/reference electrode (V_G : gate-source voltage, V_D : drain-source voltage).

for the *nonsaturated “triode” region* ($V_D < V_G - V_T$), and

$$I_D = K_d \frac{(V_G - V_T)^2}{2} \quad (70.50)$$

for the *saturated region* ($V_D > V_G - V_T$), with:

$$K_d = \mu \frac{\epsilon_i}{d_i} \frac{b}{L} = \mu C_i \frac{b}{L} \quad (70.51)$$

The proportionality constant K_d includes the geometric factors that influence the signal characteristic of the MOSFET. μ is the mobility of the electrons in the channel between source and drain, b is the width, and L is the length of the channel. C_i represents the gate capacitance of the insulator per unit area. The *threshold voltage* V_T is the gate voltage to create a conductive channel between source and drain (i.e., when an inversion layer at the surface of the semiconductor is formed). For example, a positive gate voltage V_G is applied in Figure 70.21(a) that causes an n -inversion layer between the two n^+ -regions (highly n -doped silicon) S and D. The additional positive drain-source voltage V_D controls the measured current in a kind that the FET is operated in the saturated region. Thus, a small change in V_G results in a significant change in I_D .

Like with the ISEs, the most attention is gained to pH-sensitive ISFETs, built up of SiO_2 and an additional layer of Si_3N_4 , Al_2O_3 , IrO_2 , or Ta_2O_5 . The additional layer is necessary because the pH response of SiO_2 , initially used as pH-sensitive dielectric, is poor (20 to 40 mV/pH) and the material was indeed found to be unstable and to suffer from considerable drift of the sensor signal. Therefore, different insulating materials have been investigated with respect to their stability and sensitivity. For example, a double layer of $\text{SiO}_2/\text{Si}_3\text{N}_4$ shows a sensitivity of about 45 to 55 mV/pH. The sensitivity can be improved by using $\text{SiO}_2/\text{Al}_2\text{O}_3$ or $\text{SiO}_2/\text{Ta}_2\text{O}_5$ with 53 to 57 mV/pH and 55 to 59 mV/pH, respectively. Also, the reported drift values are less than 1 mV per hour. Usually, after thermal oxidation of the silicon to realize the SiO_2 layer, the pH-sensitive Al_2O_3 and Ta_2O_5 layers (about 30 to 100 nm) are deposited by means of chemical vapor deposition or sputtering. The chemical sensitivity of these gate insulating materials can be explained by the site-binding theory, which is exemplary discussed for SiO_2 in Reference 28.

Several methods and membrane types were developed to realize ISFETs sensitive toward various ions. By implantation of high doses of B, Al, Ga, In, Ti, Li, or Na, potassium- and sodium-sensitive ISFETs were achieved. Also, the deposition of thin layers of modified chalcogenide glasses offers the determination of heavy metal ions for biological investigations and industrial applications [23]. By means of vacuum evaporation, ion-sensitive films of LaF_3 , Ag_2S , or AgX ($X = \text{Cl}, \text{Br}, \text{I}$) for the determination of F^- , Cl^- , Br^- , I^- , Ag^+ , and S^{2-} can be prepared. A chemical surface modification of the original gate insulator (e.g., the covalent linking of hydrophilic layers that contain the sensing molecule), leads to organic gate materials for the determination of different ions, such as Ca^{2+} , NH_4^+ , K^+ , Cl^- , NO_3^- , Na^+ , Ag^+ , etc. [29]. Similar results were obtained for homogeneous polymeric membranes, containing solid ion-exchanger or neutral-charged carriers (see section on ISE). In order to achieve well-defined and highly ordered sensor membranes, the gate can be coated with ultrathin Langmuir-Blodgett films [30].

BioFETs (biologically sensitive FET) have been mainly realized as ISFET-based enzyme sensors, so-called *EnFETs* (*enzyme FET*). The EnFET directly corresponds to the enzyme ISE and detects the potentiometric response to either the concentration change in one of the products or reactants catalyzed by the enzyme. Frequently, EnFETs consist of a pH ISFET with the individual enzyme layer for the determination of, for example, glucose, penicillin, urea, creatinine, adenosin, acetylcholine, etc. Dual pH-sensitive FETs on the same chip can be formed as an ISFET and an EnFET, where the latter one is loaded with the active enzyme. The ISFET serves as reference and the differential output signal is insensitive to pH changes. The demand of compatibility with integrated circuit technology provides enzymatic membranes that can be photolithographically patterned (e.g., photocrosslinkable materials). A review of

FIGURE 70.22 Schematic of a suspended gate FET (SGFET).

different categories of sensitive films and coatings and basic concepts of chemically sensitive field-effect transistors are given in Reference 31.

ReFETs (reference FETs) consist of a sensor surface that is as insensitive as possible to all kinds of substances in the test solution. Thus, a differential pair of an ISFET and a ReFET eliminates perturbations, like temperature and potential of the analyte. Appropriate materials to cover the ISFET surface with an insensitive layer are blocking materials, such as teflon or different polymers (e.g., parylene, polyacrylate, PVC). However, not well-defined potential processes as well as some ion exchange will result in nonideal behavior. Alternative concepts use nonblocking polymer membranes with a fixed membrane potential or quasi-ReFETs with a delayed pH response. The most promising approaches are the application of an inert metallic layer or wire in a differential ISFET setup as a *quasi-reference electrode*, and the miniaturization of conventional reference electrodes. For example, by means of physical vapor deposition methods, Ag/AgCl electrodes were miniaturized on silicon chips inside anisotropically etched cavities [31].

The basic mechanism of gas-sensitive FETs (GasFETs) is due to the chemical modification of the *electron work function* of a metal-insulator-semiconductor field-effect structure, for example, of a *suspended gate FET (SGFET)* as schematically shown in Figure 70.22. The SGFET contains an additional insulator, the “*gap*” within the gate structure, which consists of a vacuum, a gas or a nonconducting liquid. As gate metal, usually a platinum layer or mesh is used. The chemically sensitive layer on top of this structure, for example palladium, exhibits sensitivity toward hydrogen. The hydrogen molecules adsorb and dissociate atoms (H_a) on the metal surface (Pd), depending on their partial pressure, as well as desorb from the metal surface by recombination into H_2 and reacting with oxygen to form water:

The adsorbed atoms diffuse rapidly to the inner surface gap/insulator where they become polarized and form an interface dipole layer, resulting in a potential drop. For example, SGFETs with Pd, operated at 100 to 140°C, are sensitive to H_2 , CO, and H_2S in the ppm range, whereas an increased operating temperature up to 240°C allows the detection of alcohols (methanol, ethanol, propanol, buthanol). To achieve selectivity, the surface of the suspended gate can be modified by inorganic or organic layers. Ammonia sensitivity can be achieved by catalytic metals such as Pt, Ir, Ru, or Rh. By the deposition of organic layers like polypyrrole, sensitivities to alcohols and aromatic hydrocarbons are achieved. Several related devices based on SGFETs are explained in Reference 32.

Chemically Sensitive Capacitors.

Sensors on the basis of capacitive field-effect structures are much simpler to fabricate than chemically sensitive FETs, and consequently they are favorable for laboratory use. Such *EIS (electrolyte-insulator-semiconductor) structures* correspond to *MIS (metal-insulator-semiconductor) capacitors* and their operation

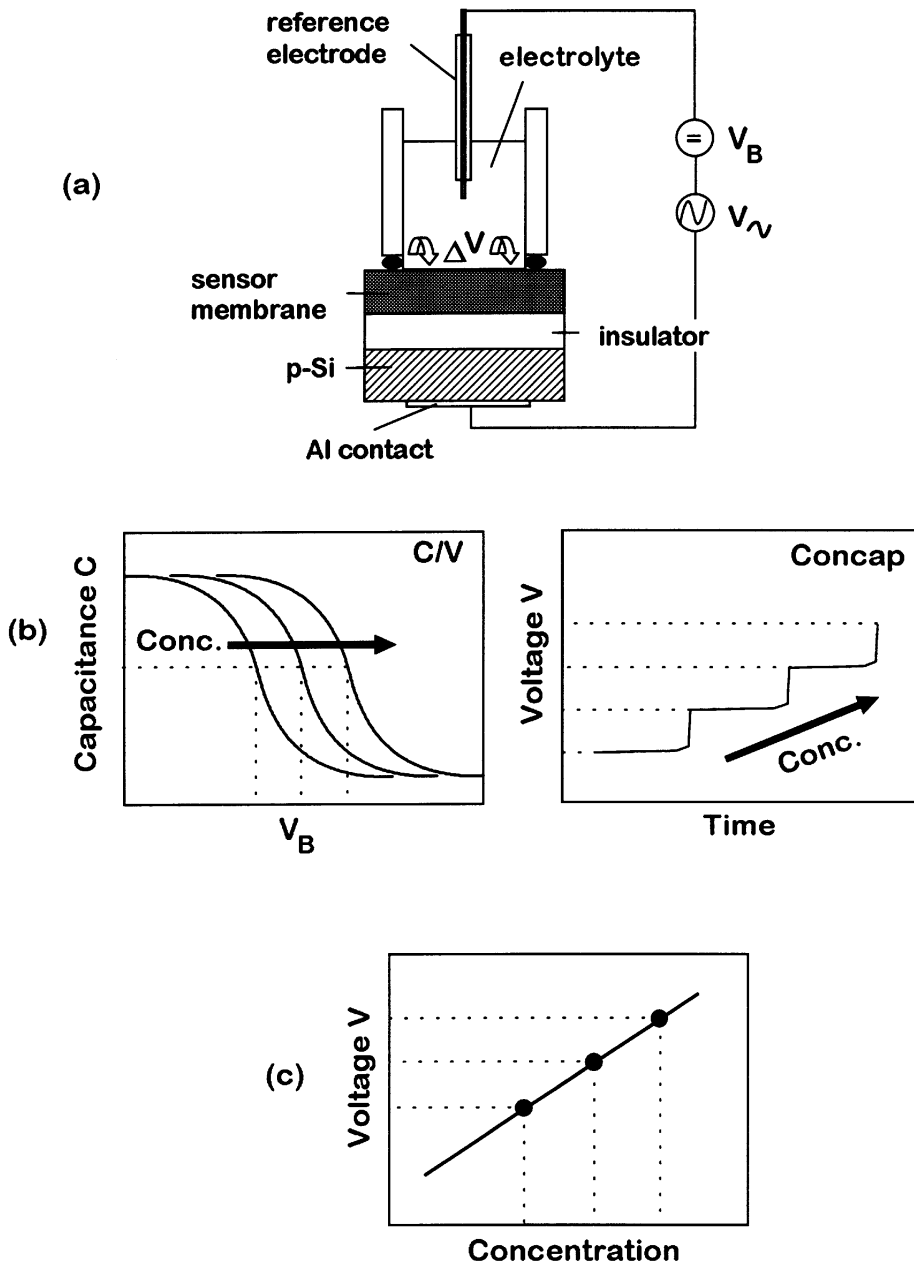

FIGURE 70.23 Schematic of an EIS (electrolyte-insulator-semiconductor) structure (a). Measurement of the EIS sensor in the C/V (capacitance/voltage) and the Concap (constant capacitance) mode (b), and resulting calibration curve (c).

principle can be derived from the fundamental MIS devices [33]. A schematic build-up of an EIS structure and the measuring principle is given in Figure 70.23(a). The sensor consists of a *p*- or *n*-type semiconductor (silicon) covered by a thermally grown SiO_2 insulating layer (<100 nm) and the sensor membrane that is directly immersed into the test solution. Usually, the sensor is contacted via a reference electrode.

Its physical properties can be explained by the charge carrier distribution at the insulator/semiconductor interface, which is controlled by both an external dc voltage (V_B) and an electrochemical interaction between the test solution and the sensor membrane (ΔV). For a *p*-Si substrate, a negative V_B ($V_B < 0$)

on the reference electrode accumulates mobile charge carriers (i.e., positive holes) at the Si/SiO₂ interface (*accumulation*). When V_B becomes positive ($V_B > 0$), the holes are displaced from the interface, forming a space charge region (*depletion*) at the semiconductor surface. If the potential gets more positive ($V_B \gg 0$), an inversion layer of accumulated electrons at the interface is created (*inversion*). The electrical behavior is given by the small-signal capacitance of the EIS structure. Depending on the applied V_B and a superimposed ac voltage (e.g., 1 kHz, 20 mV), a characteristic C/V (*capacitance/voltage*) curve results (Figure 70.23(b), left). The integral capacitance C , corresponding to V_B , is given by:

$$\frac{1}{C} = \frac{1}{C_M} + \frac{1}{C_I} + \frac{1}{C_S} \quad (70.53)$$

where C_M , C_I , and C_S are the capacitance values of the sensor membrane, the insulator, and the space charge region, respectively, with:

$$C = \frac{\epsilon_0 \epsilon_r A}{d} \quad (70.54)$$

where A is the area, d the thickness, ϵ_r the dielectric permittivity, and ϵ_0 the dielectric constant. Due to the electrochemical interaction (ΔV), a horizontal shift of the C/V curve is provided, depending on the change of the ion concentration in the test solution. As resulting measuring signal (calibration curve), the shift can be evaluated at a fixed capacitance value within the linear region of the C/V curves (e.g., 60% of the maximum capacitance, Figure 70.23(c)). Using a feedback circuit, the measured capacitance can be adjusted at a fixed value in the *Concap* (*constant capacitance*) mode (Figure 70.23(b), right). Thus, potential shifts can be recorded directly.

Chemical and biological sensing EIS structures with different organic and inorganic sensor membranes have been developed within the last few years. They consist of nearly identical sensor membrane materials and compositions as ISFETs, ranging from inorganic pH-sensitive layers (e.g., Si₃N₄, Al₂O₃, Ta₂O₅) or crystalline films (e.g., LaF₃, silver halides) over organic Langmuir-Blodgett films to enzymatic layers (e.g., urease, penicillinase). Much effort has been done in order to improve the limiting long-term stability that is often disclosed by FET devices in permanent contact with the analyte. Novel approaches pursue a further optimization with regard to the preparation (e.g., due to specific immobilization procedures) or the deposition of the sensor membrane in order to raise the sensor performance. For example, an extremely long-term stable pH sensor was developed by the suggestion of the pulsed laser deposition (PLD) process as the thin-film preparation method. The EIS structure consists of a layer sequence of Al/*p*-Si/SiO₂/Al₂O₃, where no degradation of the pH sensitivity during a measurement period of 2 years was found [34].

Like GasFETs, MIS (metal-insulator-silicon) capacitors and *MIS Schottky diodes* are also available as gas-sensitive devices. For the MIS capacitor, a concentration-dependent dipole layer is detected as a shift of the C/V curve. To reduce the drift of these devices, additional insulating layers, such as Al₂O₃, Si₃N₄, or Ta₂O₅ can be deposited between the metal layer and the SiO₂ insulator. Experimental results of Pd/Al₂O₃/SiO₂/Si structures show sensitivities of 25 mV ppm⁻¹ around 1 ppm [35]. Schottky barrier diodes consist of a thin insulating layer (e.g., 2 nm SiO₂) between the metallic gate (e.g., Pd) and the semiconductor, in order to allow the current to pass through it. By variation of the metallic gate films, different sensitivities can be achieved, comparable to those of the SGFETs.

Practical Applications and Limitations.

ChemFETs possess significant advantages over classical ISEs, such as a high-input impedance that consequently eliminates the need of shielding wires and the need for voltmeters. The small sensor area includes the possibility of multiple sensor applications (*sensor arrays*) on a single chip. Moreover, temperature compensation is possible. However, most of these sensors are exposed to a chemically very reactive environment and therefore, a highly long-term stable protection (encapsulation) of the electronics

from the analyte is required. The instability of the materials used induces sensor drifts of several millivolts per day. In some cases, attachment and fixation of the sensor membranes must be improved. To take the advantage of miniaturized FET devices, there is also the necessity of a small reference electrode. For ChemFETs, there exist two approaches for successful commercialization: dealing with small sample volumes for biomedical use (e.g., intracellular measurements) and the high-volume fabrication for a low-price market (e.g., environmental and process monitoring, agriculture and food analysis, leak detectors). The employment of capacitive EIS and MIS sensors offers besides the more easier manufacturing technique distinct advantages concerning the improved mechanical and electrochemical stability and sensor lifetime.

Conductometry

In addition to potentiometry, *conductometric analysis* represents the most important nonfaradaic method. *Conductometry* is based on the measurement of the electrical conductance of an electrolyte solution, which directly depends on the number of positively and negatively charged species in the solution. This analysis method is limited due to its nonselective nature, because all ions in the solution will contribute to the total conductance. Nevertheless, *direct conductance measurements* play an important role in the analysis of binary water/electrolyte mixtures, for example, in chemical water monitoring. The technique can also be applied to ascertain the endpoint detection in *conductometric titrations* for the determination of numerous substances.

Measurement of Conductance and Instrumentation

The *conductance* G of a solution is the reciprocal of the electrical resistance R and has the units of siemens (S) that correspond to ohm^{-1} (Ω^{-1}). The conductance of a uniform sample with the length l and cross-sectional area A is given by:

$$G = \kappa \frac{A}{l} \quad (70.55)$$

where the proportionality constant $\kappa = 1/\rho$ (ρ : resistivity) describes the *conductivity* (*specific conductance*) of the solution, expressed in units of S cm^{-1} . The *equivalent conductivity* Λ (*molar conductivity*) of a solution is defined as the conductivity due to one mole, measured between two electrodes which are spaced 1 cm apart, and is:

$$\Lambda = \frac{1000 \kappa}{c} \quad (70.56)$$

where c corresponds to the concentration of the solution in mol L^{-1} . The units of Λ are $\text{S cm}^{-1}\text{mol}^{-1}$. Equation 70.55 permits the calculation of the molar conductivity for a solution of known concentration by considering the experimental values of κ . The molar conductivity Λ , i.e., the mobility of ions in solution, is mainly influenced by interionic effects for strong electrolytes and the degree of dissociation for weak solutions. For strong electrolytes, the molar conductivity increases as the dilution is increased. By linear graphical extrapolation for diluted solutions of strong electrolytes, a limiting value is defined as *molar conductivity at infinite dilution* Λ_0 . At infinite dilution, the interionic attraction is nil, the ions are independent of each other, and the total conductivity is:

$$\Lambda_0 = \lambda_+^0 + \lambda_-^0 \quad (70.57)$$

where λ_+^0 and λ_-^0 are the ionic molar conductivities of the cations and anions, respectively, at infinite dilution. For weak electrolytes, due to the nonlinear relationship between Λ and c , a graphical extrapolation cannot be made. Typical values for the limiting molar conductivities for various species in water are listed in [Table 70.2](#).

TABLE 70.2 Molar Conductivity at Infinite Dilution Λ_0 ($\Omega^{-1} \text{ cm}^2 \text{ mol}^{-1}$)

Cations λ_+^0		Anions λ_-^0	
H ⁺	349.8	OH ⁻	198.3
Na ⁺	50.1	F ⁻	55.4
K ⁺	73.5	Cl ⁻	76.3
Li ⁺	38.7	Br ⁻	78.1
NH ₄ ⁺	73.4	I ⁻	76.8
Ag ⁺	61.9	NO ₃ ⁻	71.5
N(CH ₃) ₄ ⁺	44.9	ClO ₄ ⁻	67.3
Ca ²⁺	119.0	C ₂ H ₃ O ₂ ⁻	40.9
Mg ²⁺	106.2	HCO ₃ ⁻	44.5
Cu ²⁺	107.2	AcO ⁻	40.9
Zn ²⁺	105.6	SO ₄ ²⁻	160.0
Ba ²⁺	127.7	CO ₃ ²⁻	138.6
Pb ²⁺	139.0	C ₂ O ₄ ²⁻	148.4
Fe ³⁺	204.0	PO ₄ ³⁻	240.0
La ³⁺	208.8	Fe(CN) ₆ ⁴⁻	442.0

The equipment needed for measuring the conductivity includes an electric power source, a cell containing the solution, and a suitable measuring bridge. The electric power source consists of an alternating current source that produces signals of about 1 kHz in order to eliminate effects of faradaic current. The measurement is performed by a Wheatstone bridge arrangement. Modern *conductivity meters* supply the alternating current and allow the measurement in a wide range of conductivities (0,001 $\mu\text{S cm}^{-1}$ to 1300 mS cm^{-1}). Additional electronics eliminate disturbing capacitance effects and offer automatic range switching. An integrated temperature sensor corrects automatically conductivities to their value at 25°C. The conductivity cell consists of a pair of electrodes placed in a defined geometry to each other. Usually, the electrodes are platinized to increase their effective surface (high capacitance). Thus, disturbing faradaic currents are minimized. For accurate conductivity determination, the precise area of the electrodes A and their distance apart d , the *cell constant* K , must be known exactly. Therefore, the cell constant ($K = A/d$) must be evaluated by calibration with a solution of accurately known conductivity (e.g., a standard KCl solution). Details of calibration standards and concepts of conductivity cells are given in Reference 36.

Applications of Conductometry

Direct Conductometric Measurement.

In spite of the insufficient selectivity of *direct conductometric measurements*, the high sensitivity of this procedure makes it an important analytical tool for certain applications. The specific conductivity of pure water (distilled or deionized) is about $5 \times 10^{-8} \text{ S cm}^{-1}$, and the smallest trace of ionic impurity leads to a large increase in conductivity by an order of magnitude and more. Therefore, conductometric monitoring is employed where a high purity of water is required (e.g., laboratories, semiconductor processing, steam-generating power plants, ion exchanger). Conductometric measurements are widely used to control pollution of rivers and lakes, and in oceanography to control the salinity of sea water.

Conductometric Titrations.

In *conductometric titrations*, the reaction is followed by means of conductometry and is used for locating endpoints (i.e., the equivalence point (EP) in acid-base titrations (neutralization titration)). To define the titration curve, at least three or four measurements before and after the EP are required. The obtained data of the conductivity are plotted as a function of the titrant volume, and the EP is given as the intersection of the two linear extrapolated fractions. A characteristic titration curve of a strong acid (hydrochloric acid) with a strong base (sodium hydroxide) is depicted in [Figure 70.24](#). The solid line represents the resulting titration curve, whereas the broken lines indicate the contribution of the individual species. By adding NaOH to the solution, the hydrogen ions are replaced by the equivalent number

FIGURE 70.24 Conductometric titration of a strong acid (HCl) with a strong base (NaOH). The equivalence point is represented by EP.

of less mobile sodium ions (and $\text{H}^+ + \text{OH}^- \rightarrow \text{H}_2\text{O}$). As a result, the conductivity decreases to lower values. The solution exhibits its lowest conductivity at the equivalence point, where the concentrations of hydrogen and hydroxide ions are at the minimum. Further addition of NaOH reverses the slope of the titration curve, since both the sodium ion concentration and hydroxide ion concentration increase.

Due to the high linearity between the conductance and the volume of the added species, this method possesses a high accuracy and can be employed in dilute as well as in more concentrated solutions. In contrast to potentiometric titration methods, the immediate equivalence point region has no strong significance. Thus, very weak acids, such as basic acid and phenol can be titrated. Moreover, mixtures of hydrochloric acid or another strong acid and acetic (ethanoic) acid or any other weak acid can be titrated with a weak base (e.g., aqueous ammonia, acetate) or with a strong base (e.g., sodium hydroxide). Moreover, precipitation and complex-formation titrations of, for example, sodium chloride with silver nitrate are possible. For practical applications, the volume of the solution should not change appreciably during the titration. Therefore, the titrating reagent may be 20 to 100 times more concentrated than the solution being titrated, whereas the latter should be as diluted as practicable. For additional examples of analytical procedures and results of conductometric titrations, see Reference 37.

Oscillometry.

In order to investigate electrolyte solutions with high resistivities and dielectric constants, *high-frequency titration (oscillometry)* can be performed at 10^5 Hz to 10^7 Hz. For that, a specific measuring cell is required, where the metal electrodes encircle the outside of a glass container. In this arrangement, the electrodes are not in contact with the test solution, which is advantageous for dealing with corrosive materials. Oscillometric measurements can be employed for the determination of binary mixtures of nonionic species, where the dielectric behavior predominates (e.g., ethanol/nitrobenzene, benzene/chlorobenzene, and alcohol/water). Further practical examples are EDTA titrations and the determination of thorium (Th^{4+}) with sodium carbonate, beryllium (Be^{2+}) with sodium hydroxide, and hydrocarbons (e.g., benzene). However, the instrumentation as well as the interrelations are more complicated than for the classical conductivity method. Thus, oscillometry gets only significance for specific applications, where the presence of the electrodes interferes.

Conductometric Sensors.

Depending on the demanded size and geometry, miniaturized cells with two or more electrodes (e.g., a four-electrode conductivity meter) as well as contactless cells are commercially available as *conductometric*

sensors. The contactless methods use *capacitive* and *inductive conductivity cells*, which are advantageous to circumvent electrochemically caused electrode reactions. Conductivity cells can be coupled as detectors to ion chromatographic systems for measuring ionic concentration in the eluate. For this, special *micro-conductivity cells* with a volume of about 1.5 μL have been developed.

Within the last 10 years, two aspects of conductometric applications became important: *conductometric gas sensors* and the use of *conductometric chemiresistors* as sensors. In the former, a phase change that transfers the gaseous component into a solution is necessary (e.g., by a bubbler nebulizer). All methods deal with acidic gases, such as HCl, SO₂, or CO₃, or with alkaline gases like NH₃. Also, organic halogens can be detected after their conversion into HCl or HF. By means of integrated circuit technology, thin metal films can be photolithographically patterned as interdigital electrodes onto semiconductor substrates with insulating dielectric layers of SiO₂ or Si₃N₄. Both the thin metal films and additionally deposited organic layers on top of the metallic films can lead to a change of the total resistance by variation of the ionic composition of the reacting solution. For chemiresistors, the organic layer usually consists of an ion-selective polymer layer or a Langmuir-Blodgett membrane, for biosensors enzymatic layers are used (see the ISE section). Such sensors allow the determination of different gaseous components, such as CO, NO₂, H₂S, SO₂, or NH₃, as well as the detection of biologically relevant species like urea, glucose, penicillin, and choline chlorides. Although several companies offer such gas analyzer systems, conductometric sensors and chemiresistors are still in the state of research and development.

Coulometry

Coulometry represents an electroanalytical method, where the analyte is specifically and completely converted due to direct or indirect electrolysis. The quantity of electricity (in coulombs) consumed by this reaction, the charge, is measured. A fundamental requirement of coulometry is that the species in the solution interact with 100% current efficiency; that is, the reaction corresponds to Faraday's law. According to this condition, there exist two alternatives: the analyte participates in the electrode reaction (*primary* or *direct coulometric analysis*), and the analyte reacts with a reagent, generated by an electrode reaction (*secondary* or *indirect coulometric analysis*). Two general techniques — *controlled-potential coulometry* and *coulometric titration (controlled-current coulometry)* — are used for coulometric analysis.

Controlled-Potential Coulometry

In this method, the potential of the working electrode is held at a constant value compared to a reference electrode. The resulting current is adjusted continuously to maintain the desired potential. The substance being determined reacts without involvement of other components in the sample. The reaction is completed when the current has practically decreased to zero. To measure the charge, a potentiostat, an instrument for measuring the time-dependent current, and a current-time integrating device are used. Modern potentiostats have a built-in electronic coulometer and allow extremely accurate determinations. Otherwise, one can use free-standing coulometers.

Controlled-potential coulometry has been widely employed for the determination of various metal ions, such as Cu, Bi, Cd, Zn, Ni, Co, Pu, and U. To apply this method, current–voltage diagrams must be available for the oxidation reduction system to be measured as well as for any reaction system at the working electrode. Current–voltage diagrams can be obtained by plotting the measured current versus the cathode-reference electrode potential. To fulfill the requirement of the 100% current efficiency in generation, it is necessary to control the potential of the working electrode. With regard to their determination, the metals are deposited at controlled potentials with a mercury cathode as working electrode and a silver wire or a platinum cylinder as anode. Typical applications are the electrolytic determination and synthesis of organic compounds like acetic acid and picric acid. Further, controlled-potential coulometry is frequently used for monitoring the concentration of constituents in gas or liquid streams, typically small oxygen contents. Here, the reduction of oxygen takes place within the pores of a porous silver cathode:

Using a cadmium sheet (m) as anode, the electrode reaction in solution (s) is:

The quantity of the electricity (current) is passed through a standard resistor and converted to a voltage signal. Hence, the oxygen concentration is proportional to the recorded potential drop. Controlled-potential coulometry needs relatively long electrolysis times, although it proceeds virtually unattended with automatic coulometers. With a multimeter, changes in the range from 1 ppm to 1% can be dissolved. Thus, controlled-potential coulometry permits analysis with an accuracy of a few tenths of a percent.

Coulometric Titration (Controlled-Current Coulometry)

Controlled-current coulometry maintains a constant current throughout the reaction period. Here, an excess of a redox buffer substance must be added in such a way that the potential does not cause any undesirable reaction. That means the product of the electrolysis of the redox buffer must react quantitatively with the unknown substance to be determined. *Coulometric titrations* need an electrolytically generated titrant that reacts stoichiometrically with the analyte to be determined. As in controlled-potential coulometry, 100% current efficiency is required. The current is accurately fixed at a constant value and the quantity of electricity can be calculated by the product of the current (in amperes) and the time (in seconds) using endpoint detection. In principle, any endpoint detection system that fits chemically can be used; for example, chemical indicators (color change), and potentiometric, amperometric or conductometric procedures. For coulometric titrations the instrumentation consists of a titrator (constant-current source, integrator) and a cell. As the constant-current source, an electronically controlled amperostat is preferably used. The integrator measures the product of current and time (i.e., the number of coulombs). The electrolysis cell, filled with the solution from which the titrant will be generated electrolytically and the solution to be titrated, is schematically shown in [Figure 70.25](#). The generator electrode, at which the reagent is formed, possesses a large surface area (e.g., a rectangular strip of platinum). The auxiliary electrode (e.g., a platinum wire) is in contact with an appropriate electrolyte of higher concentration than the solution to be titrated. It is isolated from the analyte by a sintered disk or some other porous media. This is required to avoid the interference of additional products generated at the second electrode. To circumvent these limitations of internal generation, an external generator cell is often used.

Typical applications of coulometric titrations are neutralization titrations, precipitation and complex-formation titrations, and oxidation-reduction titrations. Neutralization titrations can be employed for both weak and strong acids and bases. The former can be performed with hydroxide ions generated at a platinum anode by the reaction:

the latter one with hydrogen ions by the reaction:

A working (*generator*) electrode of silver as anode offers the determination of Cl^- , Br^- , I^- , and mercaptans in solution(s). For bromide, the reaction becomes:

Similar precipitation and complex-formation titrations as well as oxidation-reduction titrations are described in Reference 38.

FIGURE 70.25 Coulometric titration cell with working electrode and auxiliary electrode, and equivalent circuit diagram (schematically).

Coulometric titrations possess some practical advantages: no standard solutions are required and unstable reagents can be generated or consumed immediately, small amounts of titrants can be electrically quantified with high accuracy, pretitration is possible, and the method can be readily adapted to automatic remote control. Thus, with respect to controlled-potential coulometry a wider field of practical applications exists. Often, automatic titrators for multipurpose and single analysis employ potentiometric endpoint detection. Examples are sulfur dioxide monitors and water titrators (*Karl Fischer*). For more detailed information concerning applications of coulometry, see Reference 39.

70.2 Thermal Composition Measurement

Mushtaq Ali, Behrooz Pahlavanpour, and Maria Eklund

Thermal analysis is the measurement of a physical parameter as a function of temperature. The area comprises several techniques where thermogravimetry, thermometric titrimetry, thermomechanical analysis, differential thermal analysis, differential scanning calorimetry, and some specialized techniques are among those described in this section. Applications are found in the characterization of organic materials, both solids and liquids. Materials of interest can be polymers, mineral and synthetic oils, lubricants, greases, paper (cellulose), and pharmaceuticals. The material to be analyzed (typically 10 mg) must be isolated and subjected to thermal treatment, hence the technique is destructive. The obvious advantage is that the thermal profile, or structure of a large specimen can be investigated. The disadvantage is that the small sample size can give rise to excessive statistical errors. However, recent advances in microcalorimetry techniques to look at slow degradation of pharmaceuticals allow thermal analysis to be performed at room temperature on samples up to a few grams without destruction of the sample. A general schematic of thermal analysis apparatus is shown in [Figure 70.26](#).

The history of the development of thermal analysis methods from the sixteenth century is the subject of a number of excellent papers by Mackenzie [1–3], Wendlandt [4], and Keatch [5]. Lavoisier and Laplace [6] were pioneers in the development of thermal analysis by their practical approach.

The International Confederation for Thermal Analysis and Calorimetry (ICTAC) has produced definitive guidelines regarding nomenclature and calibration [7–10].

Factors Affecting Results

The five factors affecting thermal analysis can be remembered by the acronym S.C.R.A.M. [11]. This refers to the **S**ample, **C**rucible, **R**ate of heating, **A**tmosphere, and **M**ass. See [Table 70.3](#).

Thermogravimetry

Thermogravimetry (TG) or TGA (thermogravimetric analysis) [8] is a technique in which the mass of the sample is monitored against time or temperature while the temperature of the sample, in a specified atmosphere, is programmed.

FIGURE 70.26 Schematic thermal analysis apparatus. The figure shows the essential components of a generalized thermal analysis apparatus.

TABLE 70.3 Factors Affecting Thermal-Analysis

Factor	Details
Sample	History of sample and preparative technique used can affect the curve and the presence of trace impurities (in some cases) may catalyze decompositions. Particle size can alter shape of curve (e.g., by surface reaction).
Crucible	The crucible (or sample holder) material should be such that it does not react with the sample or catalyze a reaction. The geometry of the sample holder may affect the results [12].
Rate of heating	Thermal lag; rate of heat transfer between furnace and all parts of the sample are not instantaneous. Therefore, care should be taken when working at different heating. Corrections can be applied [12].
Atmosphere	Various effects [12], including dissociation of sample.
Mass of sample	Size and packing density.

Note: Details the five main areas which would affect analysis of a sample via thermal experiments. The effects can be marked and would certainly affect repeatability also.

Derivative Thermogravimetry (DTG) shows the change in mass per unit time as a function of temperature.

Apparatus

The apparatus is referred to as a thermobalance or thermogravimetric analyzer. There are a number of configurations: horizontal, simultaneous (TGA-DTA), and vertical. The vertical design provides better sensitivity and weight capacity. The thermobalance consists of five essential components: furnace, temperature regulator, weighing mechanism, atmosphere controller, and recording system.

Calibration

Small furnaces can be calibrated by a method [8] using Curie points of a range of metals and alloys. The Curie point is the temperature at which a ferromagnetic material loses its ferromagnetism. At the Curie point, the magnetic force is reduced to zero and an apparent mass change is observed.

The study of the reactions can be divided into the stages: (1) intermediates and (2) products of reaction, (3) energetics of reaction, and (4) the reaction kinetics. Stages (1) and (2) can be readily studied by TG and DSC.

For example, the decomposition of calcium oxalate monohydrate shows three distinct steps. The first around 200°C with a loss of 12.4% corresponds to dehydration, while those at 500°C and 800°C match with a loss of CO and CO₂. These are confirmed by analysis of residues.

Kinetics of Reaction Including Measurement of α and $d\alpha/dt$.

The use of thermogravimetry as a means for the elucidation of the reaction kinetics is attractive. The nature of solid-solid interactions is quite complex [14] and will not be discussed in this section.

Consider an endothermic solid-state reaction:

During the course of the reaction, there is a mass loss, combined with the loss of gas. Heat absorption also occurs. This process can be modeled. However, it should be noted that the equation (although generally applicable) are not valid for all cases. Methods and mathematical treatment of results are given in the papers by Šatava, Šesták, and Škvára [15-18].

Static (isothermal) and dynamic methods can be used in a kinetic study of the weight change. The former is based on the determination of the degree of transformation at constant temperature as a function of time. The latter is the determination of the degree of transformation as a function of time during a linear increase of temperature. The static method is probably better suited for obtaining information about the slowest process, the reaction order, and reaction mechanism. The dynamic method is better if data on the kinetics of the reaction from a single curve for the whole temperature range is required. Comparisons between both methods have shown comparable results with respect to precision [19].

The extent of a reaction ξ may be defined [20] by Equation 70.64.

$$n_B = n_{B,0} + \nu_B \xi \quad (70.64)$$

where n_B = Amount of substance B

$n_{B,0}$ = Amount of substance B at $t = 0$

ν_B = Stoichiometric number of B (positive number if B is a product and negative if B is a reactant)

For solid-state reactions, the changes in the portion reacted α are followed with respect to time. Therefore, the rate of reaction can be defined by Equation 70.65.

$$\text{Rate} = d\alpha/dt \quad (70.65)$$

For solution reactions (referring to Equation 70.63), the change in concentration C_B of B is followed.

Since the rate of reaction varies with time (even at constant temperature) at a value of α Equation 70.66 is derived.

$$\text{Rate} = d\alpha/dt = k_T, f(\alpha) \quad (70.66)$$

where k_T = the rate constant at temperature T

$f(\alpha)$ = mathematical expression in α

It should be noted that the form of $f(\alpha)$ sometimes alters part way through a reaction.

If hyphenated group-specific techniques are employed to study a reaction simultaneously (e.g., as is the case in TGA and FTIR), the IR-active species may not contribute the greatest mass loss and therefore the values of α will not be the same.

There are many equations relating the rate of solid-state reactions to α and they have been summarized by Sestak and Berggren [21].

A general *integrated* kinetic equation is given in Equation 70.67.

$$g(\alpha) = k_T t \quad (70.67)$$

where $g(\alpha) = \int d\alpha/f(\alpha)$.

The rate constant k_T can be calculated from the Arrhenius equation given in Equation 70.68.

$$k_T = A \exp(-E_A/RT) \quad (70.68)$$

where E_A = Activation energy (J mol⁻¹)

A = Pre-exponential factor

R = Molar gas constant, 8.314 J (K mol)⁻¹

Measurement of α and $d\alpha/dt$

Consider a thermogravimetric curve consisting of one step. α at a particular time can be found using:

$$\alpha = m_i / (m_i - m_f) - m_t / (m_i - m_f) \quad (70.69)$$

The differential is hence:

$$d\alpha/dt = - \left[dm_t/dt / (m_i - m_f) \right] \quad (70.70)$$

This states that the rate of reaction can be measured from the slope of the mass–time curve. Since dm_t/dt is already measured by the DTG curve, $d\alpha/dt$ can be found directly from the curve.

Combination of a number of the equations discussed [13] gives:

$$\ln d\alpha/dt - \ln(f(\alpha)) = \ln(A/\beta) - E_A/RT \quad (70.71)$$

where $\beta = dT/dt$.

Thermometric Titrimetry

Thermometric titration is the measurement of the temperature change in a system as a function of time or volume of titrant. The technique consists of the measurement of the change in temperature as the titrant is added to it, under near adiabatic or more commonly referred to as isoperibol conditions. The experiments are typically carried out in a small dewar flask submerged in a well-controlled constant-temperature bath. The method can be used to study oxidation-reduction, complexation, precipitation, and neutralization reactions in aqueous solvents. Publications by Zenchelsky [22] and Jordan [23] review the technique in detail.

The basic principle is that a free energy change occurs in the system [24], and is based on the measurement of the free energy-dependent term:

$$\Delta G^\ominus = -RT \ln K \quad (70.72)$$

where ΔG^\ominus = Change in free energy under standard conditions

R = Molar gas constant

T = Temperature in kelvin

K = Equilibrium constant for the system at the temperature T

A calorimetric method (entropy titration) for the determination of ΔG , ΔH , and ΔS from one thermometric titration has been described by Christensen et al. [24].

Thermomechanical Analysis

Thermomechanical analysis relates to techniques where deformation is measured as a change in either volume or length. The deformation is plotted against temperature when a sample is heated under a controlled temperature program. Thermodilatometry measures the dimensional changes as a function of time under negligible loads. Thermomechanical analysis (TMA) is similar to thermodilatometry, but also provides information regarding penetration, extension, and flexure using various types of loads on the test specimen. In dynamic mechanical analysis (DMA), the test specimen is subjected to a sinusoidally modulated stress under specified temperature. The viscoelastic response of a material is then monitored under tensile, compressive, shear, or torsional load [25].

Apparatus

A typical instrument for thermal mechanical analysis is called a dilatometer and is equipped with a linear variable differential transformer (LVDT). The displacement of the sample is transferred to the LVDT via a rod (probe) that is unaffected by heat and dimensional changes. A zero weight is accomplished for thermodilatometry by a float system so that a minimum of a load is subjected to the sample. The sample is placed on a sample holder in an oven. A force is applied through the probe in TMA and DMA. The sample cylinder and the probe are independently connected to the measuring device. The top of the probe is also connected to a balance arm. Probe movement and sample length changes are detected. The recorded signals are time, temperature, dimensional changes, and load. Various probes are available, depending on the analysis needs. Expansion, compression, and penetration probes are standard. Tension, three-point bending, and cubical expansion probes are available. Measuring temperature from -150°C to 600°C or even up to 1500°C is possible, depending on the instrument.

Calibration of Probe

The temperature is usually the measured quantity in thermomechanical analysis. Therefore, calibrating the temperature axis is important. Thermomechanical analyzers can be temperature calibrated according to ASTM standard test method E 1363 [26]. An equation is developed for a linear correlation of the experimentally obtained program temperature and the actual melting temperature for known melting standards (i.e., mercury, water, tin, benzoic acid). A penetration probe is used to obtain the onset temperatures for two melting standards. The two-point calibration assumes the relationship Equation 70.73 between the actual specimen temperature (T_i) and the observed extrapolated onset temperature (T_0). S and I are the slopes and intercept, respectively, in the TMA thermal curve (Figure 70.27).

$$T_i = (T_0 \times S) + I \quad (70.73)$$

Thermomechanical methods are generally applied on solid, shaped samples like polymeric products. Special clamps are used for testing of soft samples made of rubbers, adhesives, fats, etc. Films and fibers can be tested using clamps. Liquid polymers are tested on support. DMA is used for detecting α , β , and γ transitions in cured epoxy systems [25]. Thermomechanical analysis, TMA, is used for measuring the volume change of bitumen. Scratching and crack propagation at low temperatures is simulated. This is useful when investigating asphalt paving materials [27]. The thermal expansion coefficient of linear expansion is calculated from the slope of the expansion-temperature curve. This is obtained under zero load in thermodilatometry mode. Thermodilatometry can also provide information on phase changes, sintering, and chemical reactions. Softening temperatures are measured using small-diameter tips on the probe under a load (TMA). This sensitive technique is also used for the measurement of heat distortion temperatures and glass transition temperatures of polymers [28].

FIGURE 70.27 The calibration of a TMA instrument is a two-point method. There is an assumption that there is a relationship $T_i = (T_o \times S) + I$ between the actual specimen temperature and the onset temperature (Equation 70.73).

Differential Thermal Analysis and Differential Scanning Calorimetry

DTA is the detection of the temperature difference between the sample holder and the reference holder using the electromotive force of the thermocouples, which are attached to the holders. The sample and reference are subjected to a controlled temperature program. The **differential** is output as the DTA signal. DSC is similar to a DTA in construction, but the DSC measures the difference in heat flow rate to the sample and the reference. Consequently, more information is received on the thermodynamic behavior of the material using DSC. Quantitative DTA is also addressed as a DSC. This definition results in that the major part of all differential thermal analyses performed today uses DSC. An application is found for combined TGA/DTA analysis for kinetic evaluation of petroleum products [29].

Apparatus

The DTA apparatus has a sample and a reference cell subjected to the same temperature program. The measuring device consisting of a thermocouple or any temperature measurement device placed in each cell, measuring the difference in temperature. Operating temperature range is ambient to 1000°C or higher depending on the construction of the instrument and sample pan material. Differential scanning calorimetry is originally defined as individually heated cells. Equal temperature is maintained in the cells, giving an electrical signal proportional to the power needed. The DSC curves represent the rate of energy absorption. Today, most DTA units that can be calibrated to give calorimetric response are called DSC [25]. For qualitative applications, both classical DTA and DSC are equally good. In quantitative work, the DSC is claimed to be better at low heating rates [30].

Calibration and Reference Materials

The dynamic nature of thermal analysis requires a calibration and standard compound to be able to relate results obtained by different instruments. Temperature calibrations can be done using a range of selected materials. Different materials are chosen depending on the temperature range. Common standards are 1,2-dichloroethane, indium, silver sulfate, and quartz. Other organic compounds, metals, inorganic nitrates, sulfates, or chromates are also used [25].

Theory of DTA and DSC

The measured quantity is ΔT , the difference between the temperature of the sample and the reference material. In Equation 70.74, T_S is the temperature of the sample and T_R is the temperature of the reference material.

$$T_S - T_R \equiv \Delta T \quad (70.74)$$

The result is presented as a plot of ΔT against T under a stated temperature program, the differential thermal curve. An endothermic process is then shown as a negative signal. A quantity of material decomposition or the enthalpy of the process is obtained from the area of the peak. It is then, in fact, a calorimetric analysis and the technique is referred to as differential scanning calorimetry.

In DTA, heat transfer to a sample and reference causes a difference in temperature ΔT , which can be related to the energy of any transition of the sample.

$$\Delta H = K (\text{peak area}) \quad (70.75)$$

For heat flux DSC, a similar process occurs, whereas in power compensated DSC, electric heating is supplied to the sample and reference to keep their temperatures as close as possible. For best calorimetric accuracy, the constant K should vary little with T .

Specialized Techniques

Thermoelectrometry

Electrical properties such as resistance/conductance and capacitance can be measured as a function of temperature. A variation that can measure the generated EMF is called thermovoltic detection [8].

Modulated DSC

In MDSC, the heating rate is modulated. This is performed using a small alternating power supply in combination with the standard programmed heating. The heating program is given by the equation:

$$T = T_0 + \beta t + B \sin(\omega t) \quad (70.76)$$

and the heat flow is given by:

$$dq/dt = C_p [\beta \omega \cos(\omega t) + f(t, T) + C \sin(\omega t)] \quad (70.77)$$

- where T_0 = Initiation temperature
 B = Amplitude of temperature modulation
 ω = Angular frequency = $(2\pi f)$
 C_p = Heat capacity
 $f(t, T)$ = Kinetic response (average)
 C = Amplitude of response to sine-wave modulation

Simultaneous Techniques

Each of the techniques discussed above provides information about the sample. However, a synergistic effect exists, in that, the total amount of information obtained (by using techniques simultaneously) regarding the sample is greater than the sum of the information from the individual techniques.

Evolved Gas Analysis.

This allows the identification of gases evolved during thermal analysis and is performed by replacing the detector with a mass spectrometer or FTIR. An alternative technique is to precede the detector by passing gases evolved during the thermal analysis through a gas chromatograph.

Thermomicroscopy.

This can be incorporated under thermooptometry (a family of techniques that measure changes of an optical property with temperature change). Thermomicroscopy uses observations under a microscope.

Applications (Including the Analysis of Electrical Insulating Materials)

Oxidative Stability of Oils and Greases and Polymers.

Oxidative degradation of oils upon heating can be monitored using a DSC apparatus. The detected onset *time* or *temperature* of the exotherm can be taken as a measure of the thermal/oxidative stability of the oil. The detected onsets are a strong function of the sample size, instrument sensitivity, kinetics, and scan rate. This enables DSC to be used in an oxidation test. Isothermal high-pressure DSC (PDSC) has been used to characterize the oxidative stability and the oxidation mechanisms of lubricants [34,35]. A PDSC works at pressures up to 3.5 MPa of a selected gas, using a wide temperature range. The technique is useful in the development of new lubricants with improved thermal and oxidative properties. The influence of metal catalysis on oil oxidation can be determined using PDSC. The volatile degradation products have been determined using combined PDSC–GC/MS (gas chromatography–mass spectrometry) [36]. PDSC gives information about relative oxidation stability used for comparing the lifetime of oils [37,38]. It has been a good technique for evaluating the thermal and oxidative stability of lubricating oils [34,39]. PDSC has also been used for evaluating deposit-forming tendencies of liquid lubricants [39].

Volatilization occurs when a low-boiling oil is heated, especially at high temperatures. This leads to uncontrolled changes in composition. It also affects the size and shape of the DSC exotherm, causing imprecise determination of the oxidation onset [34]. Use of high pressure in the DSC cell reduces volatility and evaporation interference with it. Added to this, the onset value is shifted to lower temperatures [34]. The onset becomes better defined and the peak size increases [40].

DSC is a fast technique for oxidation stability testing. This is a great advantage in the quality control of electrical insulating oils. Experimental evaluations of transformer insulating oils have shown ranking to be possible. The remaining lifetime of inhibited oils may correlate to the oxidation induction time [41]. Important parameters in PDSC are sample weight, pressure, and temperature program and have to be carefully considered before applying the technique. The sample pans must not be overlooked. Results are significantly influenced by variations in metallurgy, due to the catalytic and inhibiting effects of various metals. Oxidation induction time of lubricating greases can be determined by ASTM method D5483-93.

Predicting the Lifetime of a Product.

Estimating the lifetime of a product typically uses some form of accelerated testing. TGA decomposition kinetics can be used to arrive at aging stability information and lifetime predictions in relatively short timescales (hours compared months in conventional oven aging). The sample (e.g., insulating paper, etc.) can be heated through its decomposition at several heating rates and the weight loss as a function of temperature recorded. The activation energy is calculated from a plot of log heating rate versus the reciprocal of the temperature for a constant decomposition level. The activation energy is subsequently used to calculate kinetic parameters such as specific rate constant (k) or half-life times, as well as to estimate the lifetime of the material at a given temperature. DTA and DSC have been employed in the

electric industry to study polymeric insulation and for the determination of dielectric stability and lifetime prediction.

Thermal Analysis and Stability of Materials.

TGA is widely employed in the determination of thermal stability of materials and analysis of their composition. The thermal history of electric cable insulation has been determined using DSC [42]. Thermal analysis techniques have greatly improved the quality control and inspection of electric cables. Hyphenated techniques have been employed in the analysis of trace components in electrical insulation [42-44]. ASTM method D3386-84 standardizes measurement of coefficient of linear thermal expansion of electrical insulating materials, while D3850-84 refers to the rapid determination of thermal degradation of solid electrical insulating materials by thermogravimetric methods.

Mechanical Stress Determinations.

Longitudinal mechanical stresses, frozen into electric cable insulation during the fabrication process, can produce "shrink back." This causes the insulation to shrink away from freshly cut cable ends, to varying degrees. TMA can be used to determine these stresses and has been found more versatile than the traditional BS6469 shrinkage measurement [45,46].

Evolved Gas Detection and Evolved Gas Analysis.

The main use of EGD is to distinguish between phase transitions and endothermic decompositions (e.g., coordination chemistry). It has been used for the analysis of effluents [47]. Thermogravimetric analysis coupled with FTIR has been used to establish the failure mechanisms of electrical insulating materials [48]. EGA is also used for assessing the thermal endurance of polymeric materials and is of particular value in thermosetting polymers used in the electric industry [49].

Investigation of Polymeric Systems.

Thermogravimetry can be applied to the study of polymer processes (pyrolysis, oxidative degradation, volatilization, absorption, adsorption, and polymerization) in which a change in weight occurs. The degree of crystallinity provides information regarding the thermal history of a polymer and can be measured by DSC. Physical and mechanical properties of polymers are related to the degree of crystallinity [50]. Thermophysical property measurements and analysis of additives in polymers can also be performed using thermal analysis techniques [51]. ASTM method D4000-89 can be used for the identification of plastic materials.

Pharmaceutical Applications.

Calorimetric purity determinations are used in the pharmaceutical industry. The concentration of the impurity is regarded as inversely proportional to its melting point. Therefore, an increase in the sample's impurity content decreases the melting point and broadens the melting range. DTA can also be used but DSC is preferred since it also gives the ΔH_f (heat of fusion) of the melt [52]. The DSC method is based on the van't Hoff equation. A compound may exist in various crystal forms DSC and TG are used to characterize polymorphs and assess the stability of the compounds. DSC has been used for investigating the effect of inhibitors with model membranes [53]. Drug incompatibility is defined as "an interaction between two or more components to produce changes in the chemical, physical, microbiological, or therapeutic properties of the preparation" [54]. DTA and DSC are used to record reactions as a function of temperature and investigate drug compatibility [55]. Recent advances in microcalorimetry have allowed nondestructive analysis at room temperature [56,57]. The technique is gaining popularity in the pharmaceutical industry and also in the study of ballistics.

Characterization of Greases and Lubricants.

Greases and lubricants are, in application, exposed to high temperatures in both inert and in oxidizing atmosphere. Material losses due to evaporation and loss or alteration due to thermal cracking or oxidation of the molecular structure are possible. The various aging reactions are usually inhibited by additives. Thermogravimetry, differential thermoanalysis, and differential scanning calorimetry are used as test

instruments, but the overall difficulty is to find methods that correlate with real thermal aging of the greases and lubricants.

The peak onset and peak maximum temperatures from DTG, DTA, and DSC curves are used or the peak onset from TGA curve. The evaporation behavior of greases is the most used parameter, but wax content, glass temperature, and cloud point are other characteristics of greases that are studied using thermoanalytical techniques [27].

In the Noack test of evaporative loss (DIN 51 581), the sample is held at 250°C for 60 min in an air flow. The sample is weighed before and after treatment. The cause of the weight loss is not clear, whether it is evaporation of parts of the original sample or evaporation of oxidative degradation products. The question has arisen whether isothermal thermogravimetry could replace the Noack test. This would provide continuous loss information during the thermal exposure. It has been shown that there is a higher weight loss in the thermobalance than in the Noack test at equal test conditions. The deviation is caused by the difference in surface:volume ratio between the two methods [27].

Oxidation studies of low boiling lubricant or lubricating oils do not give representative results. This is due to the evaporation of the oil and low boiling oxidative degradation products. A TGA curve of a lubricant produced in an air atmosphere does not always represent the oxidation reaction. The use of an elevated oxygen or air pressure in DSC has been shown to reduce sample evaporation due to an increased evaporation temperature and increase the rate of the oxidation. Several papers deal with this technique, which has found application in the characterization of lubricants [27,34-41,58].

Insulation Paper/Cellulose.

The rate of weight loss on pyrolysis of cellulosic materials has applications to engineering problems in many industries. On heating, cellulose undergoes a number of linked physical and chemical changes [59]. Properties such as weight, strength, crystallinity, and enthalpy are affected.

Thermogravimetric analysis can be used to perform a collective measurement of the weight loss due to the production of H₂O, CO, and CO₂ during degradation. Of course, the measurement will include evaporation of other pyrolysis products. The enthalpy changes can also be measured by DSC. These methods are very useful in determining the temperature range at which physical and chemical processes occur. The rate of these processes can be determined by using DTG (derivative thermogravimetry).

Acknowledgments

The authors would like to thank P. Haines, Chapman and Hall, and TA Instruments for their advice and permission.

Defining Terms

Thermal analysis: A group of techniques in which a property of the sample is monitored against time or programmed temperature (in a specified atmosphere).

Derivative: Techniques where a measurement or calculation of the first derivative is performed.

Differential: Techniques where a difference in a property is measured.

70.3 Kinetic Methods

E.E. Uzgiris and J.Y. Gui

Kinetic methods involve the measurement of chemical reactions or processes in a time-dependent manner. Rates of dynamic processes are measured rather than the properties of a system at equilibrium. Of course, this approach is a central one for the study of chemical reactions and reaction mechanisms; however, it has much value in analytic chemistry; that is, in the determination of the composition of materials. This fact has been recognized for some time, but in recent years there has been a resurgence in interest in the use of kinetic methods in analytic chemistry. There have been several world congresses on this subject, numerous monographs [1,2], and the number of papers on kinetic methods has dramatically increased in the last decade [3].

Why is there such an interest? After all, there are many analytic procedures that are quite general and sensitive. As a specific example, consider the analysis for various metals in environmental samples. Metal ions can be detected by numerous means such as by ion selective electrodes, atomic flame spectroscopy, or ion coupled plasma spectroscopy, yet there is abundant literature on metal detection by catalyzed reactions in a kinetic manner [1-3]. In this case, the method of choice is dictated by cost of analysis, speed, sensitivity, and convenience. Furthermore, certain molecular species may be difficult to discriminate from others in conventional analysis. In this case, with a proper reaction, the kinetic approach is a powerful tool in detecting such constituents. Finally, the kinetic approach is the only method capable of elucidating the nature of binding sites in molecular binding because the determination of an equilibrium association constant alone is insufficient to elucidate mixed binding sites [4]. It is also the principal means of identifying short-lived intermediate species in a reaction [5].

Thus, kinetic methods comprise an important group of methods available for the analysis of substances. In some cases, kinetic methods offer unique advantages as in the study of mixed binding sites, in the delineation of competing species, and in the determination of short-lived intermediates. In other cases, kinetic methods offer speed and convenience, and low cost, as for example in such applications as clinical analysis and environmental field analysis.

In a broader sense, time-dependent changes in chemical, physical, and biological processes are universal. Because equilibrium may not be achieved in certain processes, time-dependent effects must be considered and accounted for in a satisfactory manner for analytic determinations to be accurate and reproducible. In some instances, for reasons of speed of analysis, kinetic rates are measured rather than equilibrium values. The range of time dependencies can range from picoseconds, studied with mode-locked lasers, to seconds or minutes, studied with batch mixing procedures. Kinetic methods encompass a broad range of processes and time domains. The methods of simple chemical reactions can often be applied to complicated biological processes. This is possible because often one reaction in a group of coupled reactions controls the overall rate of the process.

Kinetic methods have been classified according to different criteria. The most common classification is based on whether the method involves a catalyst. This is so because reactions are frequently quite slow. In such cases, a catalyst must be added to speed up the reactions and make rate determinations practical. In other instances, the catalyst is the analyte itself. There are two major groups of catalysts: enzymatic and nonenzymatic. Another common classification of kinetic methods is based on whether the reaction proceeds in a homogeneous or heterogeneous system. Most of the discussion will be focused on homogeneous liquid and heterogeneous liquid–solid systems because these comprise the majority of kinetic analytical methods that have been developed. Presented in [Table 70.4](#) are classifications based on the above criteria along with example reactions.

Theoretical Aspects

A reaction involving species A and B proceeds to a product with a rate constant, k' , such that the rate of change of species A is given by

TABLE 70.4 Classification of Kinetic Methods Based on System and Catalyst

System	Catalyst	Reaction examples
Homogeneous	Enzymatic	Hydrolysis
	Nonenzymatic	Electron transfer
		Redox
		Complexation
Heterogeneous	No catalyst	Chemiluminescence
	Enzymatic	Redox
		Chemiluminescence
		Immunoenzymatic
Heterogeneous	Nonenzymatic	Electrode reactions
		Electrocatalysis
		Fluorescence
	No catalyst	Electrode reactions
		Electrocatalysis
		Fluorescence
		Fluorescence
		Radioimmunoassay

$$-dA/dt = k' [A] [B] \quad (70.78)$$

where the brackets denote concentration. If the species A is of interest, then the reactant B can be in excess, in which case changes in [B] can be ignored. A pseudo-first-order reaction can be written:

$$-d[A]/dt = k [A] \quad (70.79)$$

where $k = k' [B]$ and the time evolution of [A] is just:

$$[A] = [A]_0 e^{-kt} \quad (70.80)$$

The product, P, which is the species that is usually detected, evolves as:

$$[P] = [A]_0 (1 - e^{-kt}) \quad (70.81)$$

The species A can be expressed in terms of product by:

$$[A] = [P]_{\infty} - [P] \quad (70.82)$$

where $[P]_{\infty} = [A]_0$. By measuring [P] as a function of time, the initial concentration of A can be deduced from a plot of:

$$\ln [A] = \ln [A]_0 - kt \quad (70.83)$$

In this way, a calibration curve can be generated against which an unknown sample can be measured for the content of species A.

In case the reaction is of a different order, the time-dependent plots for determining $[A]_0$ take on a different form. For example, in a second-order reaction, the rate of change of $[A]$ is given by:

$$-d[A]/dt = k[A][A] \quad (70.84)$$

where, as before, the reactant $[B]$ is considered in excess and its time dependence can be assumed to be negligible. The calibration curve is now:

$$1/[A] = 1/[A]_0 + kt \quad (70.85)$$

Clearly, the order of the reaction under study must be known for a correct analysis. There are straightforward ways to determine the order by varying the initial concentration of $[A]$ and noting the initial velocity of the reaction. A plot of the initial velocities versus initial $[A]$ will reveal the order of the reaction [1].

One of the strong points of kinetic methods is that closely related species that may be difficult to resolve by other means can be resolved by kinetic measurements. This is particularly true when enzyme reactions are employed. Enzymatic reactions are extremely sensitive to molecular structure and closely related structural analogs may have significantly different kinetics. For example, consider species A and B going through a reaction to a product but each having a different rate constant, k_a and k_b . The detected product is given as a sum of the two components by:

$$[P]_{\infty} - [P] = [A]_0 \exp(-k_a t) + [B]_0 \exp(-k_b t) \quad (70.86)$$

Then, by computer fitting or graphical analysis of a semilog plot of

$$\ln \{ [P]_{\infty} - [P] \} = \ln [A]_0 - k_a t + \ln [B]_0 - k_b t \quad (70.87)$$

one can extrapolate to $t = 0$ and determine, $[A]_0$ and $[B]_0$.

The important case of catalyzed reactions must be considered separately as there are important differences from the case of uncatalyzed reactions considered above. The catalyst is usually the species to be determined as it often is a metal ion or nonorganic ion of interest. Usually the catalyst combines with the reactant species $[B]$ in a very fast reaction with a given equilibrium constant to give:

Here, CB , the reactant B bound to C, reacts with A with a much faster rate than if B is unbound. This develops because of the reduction of the activation energy provided by the catalyst C in combination with B as discussed below. Thus,

This more complex kinetics simplifies to pseudo-first-order if one considers only the initial rates of the reaction. The initial velocity of the indicator product, P, takes the simple form:

$$V_0 = d[P]/dt = K'[C]_0 + K'' \quad (70.90)$$

where K' and K'' are constants. A calibration curve for C can thereby be generated through initial velocity measurements.

Enzyme Reactions

Enzymes are a class of proteins that catalyze reactions with exquisite specificity. The activity of certain enzymes is in itself of great importance in clinical diagnosis, but enzymes can be useful in determining **substrate** concentration — also very important for clinical applications and for environmental analysis. The rates of enzyme reactions are directly proportional to enzyme concentration; however, there is a saturation of reaction rates with increasing substrate concentration. This saturation effect must be considered when analyzing such reactions. The essential feature of enzyme reactions involves the enzyme, the substrate, the enzyme–substrate complex, and the product. It is the formation of the enzyme–substrate complex that leads to the saturation kinetics [5]. The reaction can be represented as follows:

where the reaction to form the enzyme–substrate complex is reversible as indicated by the arrows and k_1 is the forward rate and k_2 is the backward, dissociation, rate, and there is no reversion of product to substrate in the initial stages of reaction.

With the condition that initially $P \sim 0$, and setting $d[ES]/dt = 0$, it is easy to show that:

$$[ES]/[E][S] = 1/K_M \quad (70.92)$$

where K_M is the Michaelis–Menton constant. Now, since the velocity of the reaction (and here one considers the initial velocity only) is given by:

$$V_i = k_3 [ES] \quad (70.93)$$

and one can define a maximum velocity such that:

$$V_{\text{imax}} = k_3 [E]_{\text{tot}} \quad (70.94)$$

The velocity is maximum when all of the enzyme binding sites are filled with substrate. Solving for $[ES]$ and using $[E] = [E]_{\text{tot}} - [ES]$, one obtains:

$$V_i = k_3 [E]_0 [S] / (K_M + [S]) \quad (70.95)$$

This is the functional form that expresses saturation kinetics with respect to substrate concentration. Generally, for determination of activities, enzyme reactions are performed in a fully saturated regime (i.e., $[S] \gg K_M$); otherwise, the kinetic rates need corrections and the Michaelis–Menton constant must be known or needs to be determined. For determination of substrate concentration, the analysis must account for the nonlinearity of V_i with respect to $[S]$.

Enzyme activity is defined in terms of units, rate of formation of product under given conditions, since the protein content in the enzyme preparation can be misleading — not all of the enzymes in a preparation need be active. Because enzymes are proteins, and in some cases rather delicate ones, great care must be exercised in handling and storing. The activities of enzymes are very sensitive to pH, salinity, and temperature. All of these factors must be precisely controlled for reliable kinetic determinations.

Temperature Dependence

Rate constants obey the Arrhenius relation:

$$k = A \exp \left\{ -E_a / RT \right\} \quad (70.96)$$

where E_a is the activation energy, R is the gas constant, T is absolute temperature, and A is a prefactor term. Knowledge of the activation energy allows for the extrapolation of a kinetic rate to any temperature. It is the lowering of this activation energy that is at the heart of catalysis and enzymatic reactions. Because of the exponential dependence, a reduction of the activation energy can lead to a rate constant increase of many orders of magnitude.

The prefactor A is determined by some collision frequency. However, in general, reactions proceed slower than the collision theory would predict. This is because, in addition to collisional frequency, there are also configurational and entropic terms that play a role in determining A . Nevertheless, it is useful to consider the concept of diffusion-controlled reactions. Here, it is the collisional frequency that dominates the reaction. In that situation, it is possible to utilize the diffusion theory of random motion in a medium to derive A such that:

$$A_{\text{diff}} = 4\pi \left(r_{ij} \right) \left(D_i + D_j \right) N_0 / 1000 \quad (70.97)$$

where N_0 is Avogadro's number, D_i , and D_j , are the diffusion constants for species **i** and species **j**, and r_{ij} is the encounter distance. For D of the order of $1.5 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$, which is a value appropriate for small molecules, A_{diff} is $10^{10} \text{ M}^{-1} \text{ s}^{-1}$. Reactions involving protonation or the OH^- ion proceed at this rate, but only a few enzyme-substrate complex formation reactions approach the diffusion limited rate [6].

Experimental

The kinetic methods can be further classified according to experimental approaches as presented in [Table 70.5](#).

TABLE 70.5 Classification of Kinetic Methods Based on Mixing Technique or Equilibrium Perturbation

Technique	Methods
Batch mixing (for slow reactions)	Stirring in cuvette or flask
Flow mixing (fast reactions)	Continuous flow Accelerated flow Pulsed flow Stopped flow
Thermodynamic jump	Temperature jump Pressure jump Electric current jump Concentration jump
Periodic relaxation	Cyclic voltammetry Dielectric relaxation
Pulse relaxation	Time resolved fluorescence Time resolved phosphorescence Flash photolysis Pulse NMR Pulse EPR

The principal instrumental elements of a kinetic apparatus are the mixing chamber, timing device and control of data acquisition, and detector. Automation and computer controls have allowed kinetic measurements to be done routinely and with great accuracy for even very fast reactions. We consider those aspects of instrumentation unique to the problem of mixing and proper fast sampling — the essential issues of the experimental method. The other components of instrumentation are beyond the scope of this chapter; the readers may refer to the monographs for more details on those topics [1,2].

Although the nature of kinetic measurements does not require absolute quantitation of a product, it does require care in accurate timing and fast mixing of reactants. For slow reactions, the mixing chambers can be closed systems without any need for elaborate devices or techniques to initiate the reaction of interest. So called “batch mixing” can be done in ordinary optical cuvettes with a suitable magnetic stirring rod or mixing plunger. These straightforward experimental techniques are not discussed here; rather, the time domain for which kinetic methods require specialized equipment will be considered. This domain is in the region of 1 ms to 1 s, for example. Reactions with time constants in this domain are very common in current applications of kinetic methods.

Mixing Methods

In the so-called open systems, there are three approaches to initiating and monitoring reactions: (1) continuous flow, (2) pulse and accelerated flow; and (3) stopped-flow.

In method (1), the reactants are brought together into a capillary under fast flow conditions and the product is monitored (by a photodiode for example) along the length of the capillary, thus tracing out the kinetics in so far as the time dependence of the reaction is transformed into distance along the capillary by:

$$t = d/v \quad (70.98)$$

where v is the flow velocity, and d is the distance along the capillary after the junction in which the reactants are introduced. A high flow rate ensures a high Reynolds number condition and the achievement of turbulent flow and good mixing in the capillary. This method has the disadvantage of requiring rather high molar extinction coefficient for the product to achieve sensitivity and the high consumption of sample and reactant. In addition, multiple measurements along the tube are required to trace out the kinetics.

Method (2), pulsed and accelerated flow, was devised to address these deficiencies. By accelerating the flow, it is possible to do a single point measurement: the kinetics can be deconvoluted from the known change of flow as a function of time. In addition, integrated detection can be used in which the light path of the detector and source look down the flow tube, thus affording much greater sensitivity by virtue of a long absorption path length. Rather small quantities of analyte and reactant are consumed by this method because the flow is not continuous and a single point measurement is sufficient for the measurement of the kinetic parameters.

Method (3), the stopped-flow method has all the advantages of method (2), is simpler analytically, and can measure even faster kinetics. In this method, reactant and analyte are combined from two syringes driven simultaneously by a push block as shown schematically in [Figure 70.28](#). As the stop syringe plunger hits a precalibrated stop position, the flow is halted. Data are accumulated after the flow is stopped, free from effects of flow turbulence and other time-dependent interferences. Dead times (i.e., the time between inception of mixing and start of measurements) can be as short as 0.5 ms. The steps involved in the measurements can be automated for multi-sample, high throughput applications. A particularly simple stopped-flow system has been described by Harvey [7]. The drive syringes are standard 10-mL syringes that are manually pushed by a plunger. The mixing chamber is at the bottom of a 3-cm² observation cell. As the mixed solution enters the cell, it pushes up a float past the level of the light beam by which the reaction is monitored. After the measurement, the spent solution is displaced by pushing down on the float. This very simple approach is adequate for reactions slower than some 100 ms or so.

FIGURE 70.28 Schematic diagram of stopped-flow system. The reactant solutions are taken up into the two drive syringes as shown. The charging of the syringes is accomplished by valves and reservoirs not shown in the schematic for simplicity. As the activator plunger pushes the solutions through the mixing chamber, which is designed for efficient and fast mixing through tangential injection and turbulent flow (as in the Dionex Corp. system, for example), the old spent solution in the observation chamber is forced out into the stop syringe. The stop syringe plunger hits a stop, which causes immediate cessation of flow and activates the data acquisition system, which may be an oscilloscope, strip chart, or computer. The observation chamber shown here is oriented parallel to the light beam path for maximum pathlength and maximum sensitivity to absorption changes. The deadtime of such a system can be as low as 0.5 ms and the quantity of solutions required can be as low as 100 to 500 μL . At the end of a measurement, the stop syringe is purged and the drive syringes are recharged for another measurement cycle.

Reactions as fast as 1 ms can be measured by the stopped-flow technique. Fully automated sampling and data acquisition systems have been implemented [8]. Computer-controlled, three-wave valves are used to charge up the drive syringes and to flush them clean between measurements. Very fast reactions such as those involved in the folding of proteins have been studied in this way [9].

Relaxation Methods

An entirely different approach to kinetics is to probe the reactions of two reacting species that are in equilibrium by perturbing the equilibrium by a sudden change of temperature or pressure. These methods, known as relaxation methods, have as their virtue the ability to resolve kinetics in the very fast time regime much shorter than 1 ms [10]. If the equilibrium is disturbed, the relaxation to the new equilibrium state will proceed with a time constant τ given by:

$$1/\tau = k_1 + k_{-1} \quad (70.99)$$

where k_1 and k_{-1} are the forward and back reaction rate constants between the two species, respectively. The magnitude of the response depends on the enthalpy change with temperature or volume change with pressure of the particular reaction under study.

In the temperature jump method, a pulse of energy is supplied to the sample, either by a current pulse if the solution is conducting or by a light pulse if the solution is absorptive at a suitable wavelength. Light pulses can be made extremely short with a suitable laser source — nanoseconds to picoseconds — and this approach lends itself to the examination of the very fast molecular processes such as the intermediate states in photoreception [11].

These methods are well suited for the study of fast reactions but less useful for compositional analysis. However, a type of relaxation that is well known (i.e., fluorescence and phosphorescence) have become very valuable analytical tools. In such methods, a light pulse populates and excited state of molecules

under study and the rate of decay of that state provides an identifying signature of the species, even in a background of other emissions at the same wavelength. This holds as long as the signal of interest decays with a different time constant from the background signals.

The steady-state aspect of fluorescence and phosphorescence spectroscopy is a well-established “equilibrium” analytical technique that relies on the spectral differences for identification and intensity differences for quantitation. Its application, however, becomes invalid when an analytical sample contains multiple species that have indistinguishable luminescence spectra. However, it is frequently the case that the different species have different luminescence lifetimes. Thus, time-resolved spectra may produce a resolution of the species. For example, some tetracyclines have overlapping phosphorescence spectra that prevent characterization of each individual tetracycline. By using time-resolved, room-temperature phosphorescence, simultaneous determination of these tetracyclines was achieved based on their decay times in a continuous-flow system [12]. Even if two species have similar lifetimes, one can attach luminescence groups with different lifetimes to differentiate them. For example, different antigens tagged with different dyes with different lifetimes [13] were used to allow simultaneous detection of the antigens.

There are many benchtop fluorescence instruments capable of measuring lifetimes as short as nanoseconds. However, most of them are capable of monitoring only one specific wavelength as a function of time. Recently, fast optical spectrometers have been developed that have nanosecond time resolution over the entire visible spectrum [3].

Catalytic Reactions

Catalytic methods are based on the kinetic determination of catalyzed reactions. Such reactions can be extremely sensitive when the **catalyst** is the analyte. For example, chemiluminescence reactions of the oxidation of luminol by hydrogen peroxide catalyzed by metal ions provides extremely low detection limits for Co(II), Cu(II), Ni(II), Cr(III), and Mn(II). It should be pointed out that the term “catalyst” is loosely defined here as a substance that modifies the rate of a reaction without altering its equilibrium. Thus, the term “catalyst” includes the notion of promotion, inhibition, and, of course, true catalysis in which the catalyst remains chemically unchanged at the end of the reaction. Catalysts are usually categorized into two groups: enzymatic and nonenzymatic. Discussed below are overviews of catalytic-based kinetic methods applied in both homogeneous and heterogeneous systems.

Homogeneous Systems

Most applications of homogeneous kinetic methods are based on rate determination of catalyzed indicator (or substrate) reactions. Most frequently, the catalyst is the analyte to be determined, although, occasionally, it may serve simply as a reagent. Enzymes are one special type of catalyst. They are proteins possessing a very high degree of specificity. For example, certain enzymes can only exert catalytic actions on particular chemical bonds or steric isomers. Homogeneous enzymatic methods are widely used in clinic diagnoses to determine enzyme activity as well as enzyme substrate concentrations. The theoretical aspects of enzyme kinetics have been discussed in the previous section. Analytical applications for both enzyme activity determination and enzyme substrate detection can be found in the literature [3,14].

Homogeneous nonenzymatic catalytic methods are mainly applied for detection of metal ions, and other simple inorganic and organic species [3,15]. There are three major types of indicator reactions: redox, chemiluminescence, and complexation. One popular redox indicator reaction is the reduction of hydrogen peroxide by iodide catalyzed by metal ions (Fe, Mo, W, and Zr) that are also the analytes. The most common chemiluminescence indicator reaction is the decomposition of luminol (5-amino-2,3-dihydrophthalazine-1,4-dione) accompanied by the generation of luminescence at 425 nm. This decomposition is achieved through the oxidation of the doubly charged anion by the oxidant in this reaction (metal ions in most cases.) Although the oxidant in this case is consumed during the reaction, it is often termed a “catalyst” in the literature because its consumption is negligible in the time frame of the initial rate measurement, principally because of the ultrasensitivity of the chemiluminescence measurement. For complexation reactions, there are two main groups: ligand-exchange and complex-formation reactions. They are less studied compared with the above two indicator reactions but have promising application in

the determination of non-transition metals. For example, a reaction involving ligand exchange can be used to detect 0.4 ppm Ca. The most widely used detection technique for the complexation indicator reaction is UV/VIS absorbance.

Heterogeneous Systems

Many kinetic methods depend on the application of different heterogeneous catalysis processes where the catalytic reaction takes place at the interface between two immiscible phases, usually between the liquid–solid phases. The discussion here focuses on two main areas of heterogeneous catalysis that are important in chemical analysis. The first encompasses immobilized enzymes in which the labeled enzymes are either physically or chemically attached onto a solid surface. The measurement of surface enzyme activity is then related to the analyte concentration. The second is the area of electrocatalysis, in which chemical reactions occur at the interface of an electrode and an electrolyte solution. The catalyst in this case is the charged electrode surface in either the intrinsic state or in a chemically modified state. The analyte concentration in the solution is determined by the electrode dynamic current.

The most widely used format for immobilized immunoenzymatic techniques is known as ELISA (enzyme-linked immunosorbent assay). This type of assay combines the great selectivity provided by specific antibody–antigen recognition, the high sensitivity provided by enzymatic amplification, and general applicability provided by the use of common detection methods. It has proven to be a very powerful technique for simple, rapid, and cost-effective trace analysis and is widely used today in clinical diagnosis [16], drug screening [17], food safety inspection [18], and environmental analysis [19,20].

ELISA can be operated in several different modes, depending on the nature of analyte, sample environment, and requirements on speed, cost, and detection limits. Different assays are usually classified according to their operating procedure (competitive or noncompetitive), to the signal detection technique used (calorimetric, luminescent, electrochemical, or radioactive), or to the physical arrangement of the antibody–antigen binding structure (single layer or sandwich layers). For a more detailed description, the reader is referred to several references [21,22].

A typical immunoassay procedure involves three steps: (1) immobilization of antibodies onto a solid surface, (2) competitive binding of analytes and enzyme-tagged conjugates to the antibody sites, and (3) rate measurement of a substrate reaction catalyzed by the enzyme. In most cases, only the latter two steps operate in a kinetic mode. Illustrated in [Figure 70.29](#) is the chemiluminescence ELISA developed for rapid field analysis for PCBs (polychlorobiphenyls) in which the kinetic response of the enzymatic reaction enables the quantitative determination of PCB concentration [19]. First, a solid support of specified material and format is chosen based on the analysis requirement. The support surface is then treated with protein-A, a procedure to allow for the immobilization of antibodies in the proper orientation as shown in [Figure 70.29](#). The third step is to immobilize the antibodies onto the protein-A coated surface. Then an enzyme–antigen conjugate (specifically the bromobiphenyl–alkaline phosphatase) is introduced to the well so as to saturate all of the antibody binding sites. After thorough rinse with pH 7 buffer solution, these conjugate treated well-plates are ready for use in analysis of samples. The analysis of PCB-containing samples proceeds simply by adding the PCB-containing solution into the well for a fixed time to allow the PCBs to displace the previously bound enzyme conjugates. The higher the PCB concentration in solution, the higher will be the displacement of the enzyme conjugates in a given amount of time. After a fixed time, the well is then thoroughly rinsed and a chemiluminescence substrate is added. Under the catalysis of alkaline phosphatase, the substrate is transformed into a luminescent species that is then detected. The initial luminescence generation rate or the total intensity within a fixed time is proportional to the surface alkaline phosphatase, and thus inversely related to the PCB concentration, as shown by the results in [Figure 70.30](#).

Electrocatalytic reactions have been widely used for measuring chemical variables for electroactive species. However, not all electroactive species can be measured by electrochemical methods because for some species the electrode reaction kinetics may be very slow. A simple example is the reduction of molecular oxygen (O_2) at bare Pt electrodes in an aqueous solution. Oxygen cannot be reduced at the thermodynamic potential of the electrode. In this case, one can apply a large overpotential to drive the O_2 reduction. Unfortunately,

FIGURE 70.29 Pictorial presentation of chemiluminescence immunoassay.

FIGURE 70.30 Dependence of chemiluminescence relative intensity on PCB Aroclor concentration. Plotted are chemiluminescence signals integrated during the first minute of enzymatic reaction (adamantyl dioctane decomposition catalyzed by alkaline phosphatase in pH 10 buffer.) Samples contain various amount of Aroclor 1232 in pH 7 PBS buffer solution containing 5% (open circles) or 10% (solid squares) methanol.

in many cases, a large overpotential cannot be used because of the limited available potential window or because of the interference from other electroactive species. Thus, to overcome this problem, electrochemists have chemically modified electrode surfaces in order to accelerate electron transfer rates at the electrode-solution interface [23].

Chemical modification is produced by coating a monolayer of atoms, molecules, or thin layers of polymers onto the electrode surface. These surface-attached molecules may or may not be electrochemically active, but they can accelerate electrode kinetics for the target analyte. When the surface species is electrochemically active, it is termed a mediator; when inactive, it is called a promoter. For example, cytochrome-c, like many other large macromolecules, has a large electron transfer rate in a homogenous solution phase, but it exhibits extremely slow electron transfer kinetics at many metal electrode surfaces. Eddowes and Hill, as well as Gui and Kuwana [24], have successfully demonstrated that by adsorbing a monolayer of heteroaromatic molecules such as 4,4'-bipyridyl and *trans*-1,2-bis(4-pyridine)ethylene onto Au or Pt electrode surfaces, electron transfer kinetics of cytochrome-c is significantly promoted. Recently, Dong, Cotton, and co-workers [25] have used a halide-modified Au electrode to study cytochrome-c electrode kinetics. They adsorb different halides onto the Au electrode and find that they all can accelerate the electron transfer rate for cytochrome-c and the promoting effort is of the order of $F^- < Cl^- < Br^- < I^-$. Various theories for the above phenomenon have been proposed. One possible explanation is that cytochrome-c and related electron transfer molecules can adsorb onto bare electrode surfaces in undesired orientations. Besides the above atomic and molecular modified electrodes, lipid modified electrodes [26] have also shown some promoting effect for cytochrome-c electron transfer. Direct immobilization of cytochrome oxidase in a lipid bilayer at an Au electrode has resulted in electrochemical reactivity of cytochrome-c in solution [27].

Electrochemical methods can also be applied to analyze electrochemically inactive species. The electrochemical immunoassay is a typical example. It combines the great selectivity provided by specific antibody-antigen recognition, the sensitivity provided by catalytic amplification, and the simplicity of electrochemical detection. It has proven to be a useful technique for measuring chemical variables for biological, clinical, and environmental samples. There are many forms of electrochemical assays: homogeneous vs. heterogeneous, competitive vs. noncompetitive, enzymatic vs. nonenzymatic, simple vs. sandwich. Details can be found in References 21, 28, and 29.

The great advantage of the electrochemical immunoassay compared with enzyme modified electrode methods is that it is a universal method and can be configured to analyze wide range of analytes, regardless of their electrochemical reactivity. For example, Heineman and co-workers have used this technique to detect dioxin, with a detection limit of one attomole using alkaline phosphatase as enzyme to convert 4-aminophenyl phosphate to the electroactive species 4-aminophenol [28]. They also used multiple metal labels rather than enzyme labels for simultaneous detection of multiple analytes [29].

Noncatalytic Reactions

As stated earlier, most kinetic-based analytical methods are catalytic systems. Noncatalytic systems have more limited applications because equilibrium methods are usually adequate in providing the necessary accuracy and sensitivity, and the noncatalytic kinetic methods do not provide any advantages of sensitivity. However, kinetic methods have been found to be more valuable or even the only choice in some special cases, as illustrated by the following examples:

1. When a sample contains hard-to-separate interference species that demand laborious and time-consuming separation before final measurement with a classic equilibrium method. A kinetic method may provide a simpler and faster determination by not requiring a prior separation.
2. When the equilibrium method is based on a very slow reaction or a reaction cannot proceed to completion due to side reactions. In this case, an initial rate measurement is much preferred and may be the only method of analysis.
3. When the species of interest has an extremely short lifetime, such as in the case of a reaction intermediate.

Table 70.6 lists some vendors of appropriate apparatus and assay kits for performing kinetic determinations.

TABLE 70.6 Companies Providing Kinetic Instrumentation or Kinetic Assay Materials

Instrument	Company
ELISA apparatus	Dynatech Laboratories 14340 Sullyfield Circle Chantilly, VA 22021
Immunoenzymatic assays	Becton Dickinson Microbiology Systems P.O. Box 243 Cockeysville, MD 21030
Enzyme assay kits, ELISA kits	Pierce Chemical Co. 3747 N Meridian Rd. P.O. Box 117 Rockford, IL 61105
Electroanalytic instruments	EG&G Princeton Applied Research P.O. Box 2565 Princeton, NJ 08543
Stopped-flow apparatus	Dionex Corp 1228 Titian Way Sunnyvale, CA 44088
Spectrometer with stopped-flow attachment	On-Line Instruments, Inc. 130 Conway Drive Bogart, GA 30622
Time-resolved spectrometers	Perkin-Elmer Corp. 761 Main Ave. Norwalk, CT 06859

Note: As examples, one company is listed for each category. For more complete listings, the reader is referred to the latest buyer's guide of *Analytic Chemistry*.

Defining Terms

Antibody: One of a class of immunoglobins produced by an animal's immune response to antigens (i.e., substances foreign to the body). Antibodies bind to molecular determinants of the antigen with great specificity.

Catalyst: A substance that accelerates a chemical reaction but is not itself consumed by the reaction.

Enzyme: A protein molecule that catalyzes reactions with great specificity.

Substrate: That which is being transformed by an enzyme-mediated reaction.

70.4 Chromatography Composition Measurement

Behrooz Pahlavanpour, Mushtaq Ali, and C. K. Laird

During the early development of modern analytical chemistry, the study of natural materials was a primary concern of organic chemists and biologists. A major problem facing these scientists was the formulation of methods to separate and analyze the complex mixtures encountered in biological research.

Chromatography (literally “color-writing”) is a physical or physicochemical technique for separation of mixtures into their components on the basis of their molecular distribution between two immiscible phases. One phase is **stationary** and is in a finely divided state to provide a large surface area relative to volume. The second phase is mobile and is caused to move in a fixed direction relative to the stationary phase. The mixture is transported in the mobile phase, but interaction with the stationary phase causes the components to move at different rates.

Origination of the technique, early in the 20th century, is generally attributed to Tswett, who separated plant chlorophylls by allowing solutions in petroleum ether to percolate through a vertical glass tube or column, packed with calcium carbonate. The separated components formed colored bands that were later isolated. Chromatography was adapted for qualitative or quantitative analysis of mixtures by inclusion of a suitable detector at the downstream end of the column and allowing the separated components to pass completely (elute) through the column and detector.

To analyze a sample, a suitable volume is injected into the stream of mobile phase or onto the upstream end of the column and the output of the detector is continuously monitored. The composition of the stream (eluent) passing through the detector then alternates between the pure mobile phase and mixtures with each of the components of the sample. The output record of the detector (chromatogram), plotted as a graph of response vs. time, shows a series of deflections or peaks, spaced in time and each related to a component of the mixture. For a given column, mobile phase, and set of operating conditions, the time for a component to pass through the column (retention time) is characteristic and can be used to identify the component. The peak area is proportional to the concentration of the component in the mobile phase.

In modern instrumental applications of chromatography, the stationary phase is either a solid or a liquid, and the mobile phase either a liquid or a gas. The various types of chromatography are classified according to the particular mobile and stationary phases employed. The solid stationary phase may be a granular solid packed in a tube (column), or coated as a thin layer on a suitable supporting plate (thin layer chromatography, TLC). Liquid stationary phases may be coated onto granular solids or bonded as a thin film to the inner wall of a capillary tube. In gas chromatography, the mobile phase is a gas (carrier gas), and the stationary phase is either a high-boiling liquid (gas-liquid chromatography, GLC) or a solid (gas-solid chromatography, GSC). In liquid chromatography (LC), the mobile phase is a liquid and the stationary phase is either a solid (liquid-solid chromatography) or a second liquid, immiscible with the mobile phase, coated on a granular solid (liquid-liquid chromatography).

Principles

Chromatographic theory is given in general textbooks [1,2], and also in specialized texts on different types of chromatography [3,4]. Chromatographic separation involves continuous interchange of solute

molecules between the mobile and stationary phases. Four principal processes are involved: **adsorption**, liquid-liquid partition, ion exchange, and size exclusion. In gas chromatography, the predominant processes are adsorption, while liquid chromatography may involve all four processes. Where liquid-liquid partition is the predominant separation mechanism, the sample components are **eluted** in order of increasing boiling points.

Since the **analyte** is transported in the mobile phase, chromatography is limited to solutes that are distributed between the two phases. In practice, this means that gas chromatography is limited to substances that are thermally stable in the vapor phase and are volatile at temperatures up to the maximum operating temperature of the GC column (about 350 to 400°C for most columns and packings, although some metal columns can be operated at higher temperatures). Liquid chromatography can be used for analysis of thermally labile and high molecular weight materials such as polymeric materials and proteins, at temperatures below their boiling point and that of the **eluent**.

The separating power of a chromatographic column is described by analogy with distillation separation processes. It is given as the number of theoretical separation plate (either per meter of column length or in total for the column), and depends on its length, internal diameter, and on the stationary phase employed. The height equivalent to a theoretical plate (HETP) value may also be quoted. Separating power is enhanced by use of long, narrow-bore columns with packings of the finest possible mesh size to allow intimate contact between the mobile and stationary phases, but these columns require higher operating pressures to overcome the column resistance, and analysis times increase with column length.

The chromatographic separation process is highly dependent on the temperature of the column, and temperature effects can be related to the temperature dependence of the distribution or adsorption equilibria of the solute between the stationary and mobile phases. However, in practice, the choice of column operating temperature involves a compromise between resolution and speed of analysis. Liquid chromatography is commonly carried out with the column at ambient temperature, although applications requiring operation at temperatures up to 100°C are becoming more common. In gas chromatography, the column temperature has a major influence on the speed of elution and the separation of sample components. Gas chromatography can be carried out at a single controlled temperature (isothermal) or the oven temperature can be increased during the analysis in one or more linear ramps (temperature programming). Temperature programming speeds the elution of later components relative to early ones and enables mixtures containing a range of components to be separated more quickly than would be possible with isothermal operation. The broadening of later peaks due to diffusion in passing through the column is also minimized by temperature programming.

Gas Chromatography

A block diagram of a gas chromatograph is shown in [Figure 70.31](#). The essential components are the column or columns; the carrier gas supply and flow and pressure controllers to enable carrier gas to be delivered to the column at a constant, controlled, and known rate; and the detector or detectors and associated electronics and data recording and processing system. An injector or facility for introducing suitable volumes of sample must be provided at the upstream end of the column. The column must be contained in an environment whose temperature can be held at a constant known value or heated or cooled at known rates. Temperature control in the range 25°C to 400°C (–0.1°C) and heating and cooling rates of 0.1°C to 40°C min^{–1} are typically required. Subambient operation at temperatures down to about –30°C may be required for separation of some volatile materials or for certain specialized eluents such as liquid carbon dioxide. Both injectors and detectors must be temperature controlled to allow rapid volatilization of the sample in the injector and to prevent condensation in the detector.

Columns

In gas chromatography, the processes involved in separation are predominantly adsorption and liquid-liquid partition when the eluent is liquid CO₂. Separation is almost entirely dependent on the nature of the stationary phase, with the gas phase acting mainly as an inert carrier. Separations of permanent gases

FIGURE 70.31 Functional diagram of process gas chromatography. The system consists of gas flow control, sample injection, separation of the components through the column, and a detector. Carrier gas at high pressure is used to move the sample through the column.

are carried out by gas-solid chromatography (GSC) using adsorbents such as silica gel, alumina, or synthetic zeolites (molecular sieves, particularly MS 5A and MS 13X) as the stationary phase. Proprietary porous polymers, such as Porapak (styrene-divinylbenzene copolymer), Chromosorb, and Tenax (polymer of 2,6-diphenyl-*p*-phenylene oxide), and various “carbon molecular sieves” are also used, and some of these materials are also used in separation of liquid samples.

In gas-liquid chromatography (GLC), the stationary phase is a high-boiling liquid, coated to a few percent by weight on an inert granular support such as silica, firebrick, diatomaceous earth, or Teflon. A wide range of liquids, gums, and waxes have been employed that provide stationary phases which are usable over different temperature ranges and with different polarities. Examples include silicone oils and gums, hydrocarbons, polyphenyl ethers, high molecular weight polymeric alcohols, etc.

Originally, in both GLC and GSC, the stationary phase or coated support was packed into a column, typically a glass or stainless steel tube, 1 to 3 m long, and coiled to fit the chromatograph oven. Developments in column technology have led to the gradual, but not yet complete, replacement of the packed GC columns by capillary columns. These columns are usually formed from drawn silica tubing, typically 10 to 100 m long, 0.2 to 0.5 mm o.d. with an outer protective coating of polyimide or, for operation above about 350°C, aluminium. The stationary phase is often a silicone oil — for example, polydimethylsiloxane, which instead of being coated on a granular support is present as a film, 0.1 to 5 μm thick, chemically bonded to the inner wall of the column (wall-coated, open tubular or WCOT column). Such open tubular columns operate at lower carrier gas pressures [typically 34 to 69 kPa (5 to

10 psig) instead of 138 to 340 kPa (20 to 50 psig) and carrier gas flow rates (1 mL min⁻¹ or less instead of 20 to 30 mL min⁻¹) than packed columns. Capillary GC columns can typically have 3000 theoretical plates per meter (50,000 plates per column), compared with 1000 plates per meter or 2000 plates per column for a typical packed column. The capacity of the column (i.e., the size of sample that can be separated) depends on the thickness of the film of stationary phase, but is of course smaller than for a packed column and is typically in the microgram to nanogram range. Columns with thicker films have higher capacity, but lower resolving power, than thin film columns. Chemical bonding reduces the loss of stationary phase (“column bleed”), especially during temperature programming, and bonded columns are almost essential for critical applications such as coupled gas chromatography–mass spectrometry. Although low- or medium-polarity general-purpose capillary columns have high performance and can be used with a variety of samples, customized columns are available with stationary phases developed and optimized for particular analyses.

As an alternative to coating the inner wall of the capillary column with liquid stationary phase, the column wall can be coated with finely divided support, which is itself coated with stationary phase (support-coated open tubular or SCOT column). SCOT columns are one category of the more general group of porous-layer, open-tubular (PLOT) capillary columns where the inner wall of the capillary is coated or bonded with the stationary phase. PLOT columns are available with a range of solid adsorbents, including Porapak, molecular sieve, carbon molecular sieve, and alumina suitable for separation of mixtures of permanent gases and gaseous hydrocarbons, and bring the separating power of capillary columns to gas-solid chromatography. However, the difficulty of reproducibly injecting gas samples into these columns has meant that packed columns are often still favored for separation of gaseous samples.

Carrier Gas

The theory of the influence of carrier gas on the separation process was given by van Deemter, Zuidweg, and Klinkenberg [5]. The van Deemter equation combines rate theory and plate theory and gives the relation between carrier gas velocity, u , and HETP, H , for a given carrier gas and column. The equation has the form

$$H = A + B/u + Cu \quad (70.100)$$

where A , B , and C are constants. A depends on the particle diameter and irregularity of column packing; B depends on the tortuosity of the channels and the first power of the diffusion coefficient of solute molecules in the gas phase; and C depends on the distribution coefficient of the solute, the ratio of stationary-phase and gas-phase volumes, the effective film thickness, and inversely on the diffusion coefficient of the solute in the gas phase.

Plots of H versus u show a minimum value for H corresponding to an optimum carrier gas flow rate, where:

$$u_{\text{opt}} = (B/C)^{1/2} \quad (70.101)$$

The van Deemter equation shows that, for a given column, a carrier gas of higher molecular weight can give a more efficient separation (lower value of H_{min}) than one of lower molecular weight, and H_{min} occurs at higher gas velocities for carrier gases of lower molecular weight. However, the equation refers to a single solute, and since chromatography involves separation of several solutes, the optimum carrier gas velocity is necessarily a compromise. The van Deemter equation also shows that for low molecular weight carrier gases, particularly hydrogen and helium, the minimum is less pronounced; that is, that carrier gas flow is less critical to column performance, and these two gases are the preferred choice, especially for capillary chromatography. Where hydrogen or helium are not suitable for the detector in use, a separate “make-up” gas supply is provided at the downstream end of the column; for example, nitrogen make-up is necessary for capillary operation of an electron capture detector.

The H vs. u curve is not symmetrical, carrier gas flow rates being more critical at values below u_{opt} than above. Thus, analyses may be speeded by increasing carrier gas flow rates above the optimum without much deterioration in column performance, but operating at flow rates that are too low leads to a relatively rapid loss of separating power.

Detectors

Detectors for gas chromatography should ideally have high sensitivity, rapid and reproducible response, and a wide range of linear response to concentration. Early detectors had universal or near universal response to all solute molecules; more recently, the emphasis has been on development of detectors with some selectivity to particular groups of compounds.

Thermal Conductivity Detector (TCD).

The thermal conductivity detector or katharometer was one of the earliest GC detectors and utilizes the change in thermal conductivity of a gas mixture with composition. The detector consists of either two or four electrically heated filaments, or for highest sensitivity especially at low temperatures, thermistors. The filaments or thermistors are connected in a Wheatstone bridge circuit, with external resistors to complete the bridge if there are only two sensing elements. The filaments or thermistors are mounted in a metal block to provide thermal stability, and provided with channels to allow the effluent from the GC column, and a separate, controlled "reference" flow of pure carrier gas to pass over the sensors or pairs of sensors. The loss of heat from the filaments depends on the filament temperature and on the conductivity of the surrounding gas. The katharometer can be operated under constant current or constant voltage conditions, or feedback circuitry can be used to maintain the filament resistance constant; but in each case, changes in gas composition lead to an out-of-balance voltage in the Wheatstone bridge circuit.

The TCD is a universal detector; however, it is less sensitive than other detectors such as the FID, and is principally used for detection and measurement of permanent gases such as oxygen, argon, nitrogen, carbon monoxide, and carbon dioxide, which either cannot be measured by the FID or require special pretreatment of the effluent gas (see below). It can be shown that the sensitivity is greatest when the filaments are operated at the maximum possible current, and when the difference in conductivity between the carrier gas and sample components is greatest. Both these conditions are fulfilled by use of helium or, better, hydrogen as the carrier gas, as these two gases have higher thermal conductivities than other common gases.

Flame Ionization Detector (FID).

The flame ionization detector (FID) is one of a group of gas detectors in which changes in the ionization current inside a chamber are measured. The ionization process occurs when a particle of high energy collides with a target particle that is thus ionized. The collision produces positive ions and secondary electrons that can be moved toward electrodes by application of an electric field, giving a measurable current, known as the ionization current, in the external circuit.

The FID utilizes the fact that, while a hydrogen–oxygen flame contains relatively few ions, it does contain highly energetic atoms. When trace amounts of organic components are added to the flame, the number of ions increases and a measurable ionization current is produced. The effluent from the GC column is fed into a hydrogen–air flame. The flame jet serves as one electrode, and a second collector electrode is placed above the flame. A potential is applied between the electrodes. When sample molecules enter the flame, ionization occurs — yielding a current that can be amplified and recorded.

The main reaction in the flame is:

However, the FID also gives a small response to substances not containing hydrogen, such as CCl_4 and CS_2 . It is probable that the reaction above is preceded by hydrogenation to form CH_4 or CH_3 in the

reducing part of the flame. In addition to the ionization reactions, recombination also occurs, and the response of the FID is determined by the net overall ionization process.

The FID is a mass-sensitive detector; that is, the response is proportional to the amount of organic material entering the detector per unit time. For many substances, the response is effectively proportional to the number of carbon atoms present in the flame, and the detector sensitivity can be expressed as the mass of carbon per second required to give a detectable signal. A typical figure is 10^{-11} g C s⁻¹.

The FID responds to practically all organic molecules. It is robust, has high sensitivity, good stability, and wide range of linear response, and is widely used.

The FID is insensitive to inorganic molecules and water. However, it can be used for measurement of carbon oxides (CO and CO₂) by mixing the effluent from the GC column with a controlled stream of hydrogen. The mixed gas is passed over a heated catalyst to convert the CO or CO₂ to methane (methanation), followed by FID measurement of the methane generated. This allows GC determination of these gases at lower concentrations than can be detected by the thermal conductivity detector.

Photoionization Detector (PID).

The photoionization detector has some similarities to the FID, and like the FID, it responds to a wide range of organic and also to some inorganic molecules. An interchangeable sealed lamp produces monochromatic radiation in the UV region. Molecules having ionization potentials less than the energy of the radiation can be ionized on passing through the beam. In practice, molecules with ionization potentials just above the photon energy may also be ionized, due to a proportion being in excited vibrational states. The ions formed are driven to a collector electrode by an electric field, and the ion current is measured by an electrometer amplifier.

The flame in the FID is a high-energy ionization source and produces highly fragmented ions from the molecules detected. The UV lamp in the PID is of lower energy, leading to the predominant formation of molecular ions. The response of the PID is therefore determined mainly by the ionization potential of the molecule, rather than the number of carbon atoms it contains. In addition, the ionization energy in the PID can be selected by choice of the wavelength of the UV source, and the detector can be made selective in its response. Commonly available UV lamps for the PID have energies of 11.7, 10.2, and 9.5 eV. The ionization potentials of N₂, He, CH₃CN, CO, and CO₂ are above the energy of all the lamps, and the PID does not respond to these gases. The 10.2-eV lamp is particularly useful as it allows ionization, and thus detection of alkynes and alkenes (except ethene), but not alkanes.

The PID is highly sensitive, typically to picogram levels or about 1 order of magnitude more sensitive than an FID, and has a wide linear range. Any of the commonly used carrier gases is suitable, although some gases (e.g., CO₂) absorb UV radiation and their presence may reduce the sensitivity of the detector. The main disadvantage of the detector is the fragility of the UV lamp, the need for periodic cleaning of the UV window, and the difficulty in cleaning the window if the detector becomes heavily contaminated.

Electron Capture Detector (ECD).

The electron capture detector is an ionization chamber in which molecules of electronegative species are allowed to attach to or "capture" electrons that have been slowed to thermal velocities by collision with inert gas molecules. The detector consists of a cell containing an emitting radioactive source (usually ⁶³Ni) and purged with inert gas. Electrons emitted from the source are slowed to thermal velocities (thermalized) by collision with the gas molecules and are eventually collected by a suitable electrode, giving rise to a standing current in the cell. If molecules with greater electron affinity are introduced into the cell, some of the electrons are "captured," forming negative ions that are more massive and less mobile than the free electrons, and the current in the cell is reduced. This effect is the basis of the electron capture detector.

Originally, the ECD was operated under dc conditions, potentials up to 5 V being used; but under some conditions, space charge effects produced anomalous results. Modern detectors operate under constant current conditions and use a pulsed supply, typically 25 V to 50 V. The pulse width and/or frequency are varied by feedback circuitry to maintain the ionization current in the cell at a constant level. This extends the linear range of the detector response and ensures optimum response for a range

of molecules. The ECD must be used with a suitable inert gas, usually either an argon–methane mixture or nitrogen, either as the chromatograph carrier gas or (more usually) as an auxiliary gas supply.

The ECD is extremely sensitive to electronegative species, particularly halogenated molecules. It is widely used in the analysis of pesticides and some trace atmospheric components such as halocarbons, halogenated solvents, and nitrous oxide. The selectivity and extreme sensitivity is valuable, but the use of a radioactive source is a disadvantage. In certain cases, the detector response is highly sensitive to the cell temperature. The cell may be contaminated by “dirty” samples, and cleaning can be difficult or impossible.

Flame Photometric Detector (FPD).

In the flame photometric detector (FPD), the column effluent is passed through a fuel-rich hydrogen–air or hydrogen–oxygen flame, where the sample molecules are broken into simple molecular species and excited to higher electronic states. Under these conditions, most organic and other volatile compounds containing sulfur or phosphorus produce chemiluminescent species. The excited species return to their ground state, emitting characteristic molecular band spectra. The emission is monitored by a photomultiplier through a suitable filter, thus making the detector selective to either sulfur or phosphorus.

The FPD is most commonly used as a detector for sulfur-containing species. In this application, the response is due to the formation of excited S_2 molecules, S_2^* , and their subsequent chemiluminescent emission. The original sulfur-containing molecules are decomposed in the hot inner zone of the flame, and sulfur atoms are formed, which combine to form S_2^* in the cooler outer zone. As the S_2^* revert to their ground state, they emit light in a series of bands in the range 300 to 450 nm, with the most intense bands at 384.0 nm and 394.1 nm. The 394-nm band is monitored.

The FPD is highly sensitive (typically 10^{-11} g S s^{-1} or 10^{-12} g P s^{-1}), selective, and relatively simple. However, the response is nonlinear, given by:

$$I_s = I_0[S]^n \quad (70.103)$$

where I_s is the observed emission intensity (photomultiplier tube output), $[S]$ is the mass-flow rate of sulfur atoms, and n is a constant (value of 1.5 to 2, depending on flame conditions). Some systems incorporate circuitry to produce a linear output over 2 or 3 orders of magnitude concentration range.

Other Detectors.

A number of other GC detectors are available, but are less frequently used than those listed above. Examples include the nitrogen phosphorus detector, which is selectively sensitive to analytes containing those elements, and is used in pesticide analysis; and the helium ionization detector, in which the ionization process is due to highly energetic metastable helium atoms. The helium ionization detector is the only GC detector that permits analysis of the permanent gases at ppb levels. However, it is difficult to use, as the response is highly susceptible to the presence of trace impurities in the helium carrier gas. Additionally, gas chromatographic separation can be combined with detector systems specifically developed to measure a particular analyte. For example, trace levels of carbon monoxide in air can be measured by passing the effluent of the GC column through a heated bed of mercuric oxide. Carbon monoxide reduces the mercuric oxide, liberating mercury vapor, which is detected with high sensitivity by UV atomic absorption spectrometry.

Sample Injection

The purpose of the injection system is introduce defined and reproducible aliquots of sample into the chromatograph column. To minimize loss of resolution by diffusion, the sample must be injected as quickly as possible, and as a sharply defined slug. For analysis of liquids using packed columns, the injector is usually a zone heated to a temperature to ensure rapid volatilization of the sample, swept by carrier gas and fitted with a silicone rubber septum cap. Liquid injections are made by microsyringe through the septum cap. The syringe can be manual or controlled by an autosampler. Gas injections can

also be made by syringe, but this is unsatisfactory for quantitative work as the compressive effect of the column head pressure in the injector makes syringe injections of gas unreproducible, and valve injection is preferable.

The injection valve is a six-port changeover valve that allows a fixed volume of gas, defined by a length of tubing (the sample loop), to be connected in either one of two gas streams with only momentary interruption of either stream. The valve is connected in the carrier gas stream just upstream of the column. The sample loop is filled with sample gas and the valve is operated to connect the loop into the carrier gas stream.

Injection into capillary columns is more difficult than into packed columns due to their smaller sample capacity. An internal standard (i.e., a compound similar to the analyte but separated from it by the chromatograph) is often added to the sample to enable correction to be made for random differences in injection volume. The most widely used injection technique is the so-called split–splitless injector. In the “split” mode, an aliquot of liquid sample is injected into a heated zone at the head of the column. The injector is swept by carrier gas at constant pressure. A valve allows a variable but known proportion of the carrier gas to flow to waste. Carrier gas flow rates through the column are typically 1 to 2 mL min⁻¹ and the “split” flow is typically 30 to 50 mL min⁻¹. Thus, only a few percent of the aliquot of sample injected actually passes through the column. In the “splitless” mode, the valve controlling the waste stream of carrier gas is momentarily closed for a fixed time after injection, thus increasing the amount of sample transferred to the column for increased sensitivity.

Split/splitless injectors are relatively simple and can be used with conventional syringes. However, the injector must be carefully designed to obtain reproducible results, and there may be some discrimination (particularly loss of high boiling components) in samples containing components with a wide range of boiling points. Techniques where the sample is injected directly onto the column, without splitting, can give less discrimination and better sensitivity and reproducibility, but are more difficult to use. Examples include cold on-column or programmed temperature injectors. In this technique, a length of column at the head is cooled to trap the sample. The injector is subsequently flash-heated to a high temperature to release the sample.

Alternative injection techniques include headspace analysis, where the vapor in equilibrium with a volatile liquid is sampled, and purge-and-trap techniques, where volatile components are purged from a liquid sample by a stream of inert gas. The purged components are trapped in a cooled zone at the head of the GC column and subsequently released by rapid heating for chromatographic separation and determination.

Liquid Chromatography

In early applications of liquid chromatography, the adsorbent was contained in a vertical column through which the liquid phase was passed under gravity. The performance of such systems is limited by the tortuosity of the passage of the liquid phase through the column and by the efficiency and speed of solute exchange between the mobile and stationary phases. Column performance is enhanced by use of micro-particulate packings; but to achieve reasonably rapid separations in such systems, the mobile phase must be pumped through the column under pressure. The technique is known as high-performance (or sometimes high-pressure) liquid chromatography (HPLC).

High-Performance Liquid Chromatography (HPLC)

Figure 70.32 provides an illustration of process high-performance chromatography.

Columns.

HPLC columns are formed from precision-bore stainless steel tubing, 30 cm to 3 cm long, with 25 cm and 12.5 cm being the most common lengths. Standard columns have bores in the range 3.0 mm to 4.6 mm. Narrow-bore (2 mm) or microbore (1 mm) columns give increased sensitivity and higher chromatographic performance, together with reduced consumption of mobile phase, but require higher operating pressures and specially designed detector systems. The columns are packed under controlled

FIGURE 70.32 Functional diagram of process high-performance chromatography. The system consists of pump, sample injector, separation column, and detector. Mobile phase is liquid and wash solvent is used for cleanup. The used solvent can be recovered.

conditions with granular packing material of controlled size range, particle shape, and porosity. The “standard” particle diameter for packing materials is 5 μm , as it allows good column performance at moderate operating pressures, but columns packed with 10 μm or 3 to 4.5 μm particles can also be used.

A wide range of general-purpose and specialist packing materials have been developed for HPLC. The most widely used base material is silica, as it has high efficiency and physical rigidity, good solvent compatibility, and can be bonded with organosilanes for reversed-phase chromatography (see below). Other base materials include ceramics such as alumina, polymers, and graphitic carbon. Alumina has better pH stability than silica, but cannot be bonded with organosilanes. Polymers have limited organic solvent compatibility but tolerate strong alkali; they are less robust than silica and cannot be used at high operating pressures.

In liquid–solid chromatography, the samples are retained by adsorption on the support surface. The support may be coated with a liquid phase (liquid–liquid chromatography). In bonded phase HPLC, the support (usually silica, although alumina has also been used) is derivatized with a functional group covalently attached to the surface. In both coated and bonded phases, the separation is predominantly by partition; but like their counterparts in gas chromatography, bonded phases are inherently more stable than coated phases and can be used with a range of solvent and buffer systems.

In “normal” or traditional liquid chromatography, the stationary phase is polar and the mobile phase relatively nonpolar. The polar surface may be silica, or may be modified by chemical bonding of a suitable functional group. In reversed-phase chromatography, the stationary phase is nonpolar and the mobile phase is relatively polar. Reversed-phase chromatography is almost always carried out on modified silica columns, with octadecylsilyl (ODS or C18) or C8 groups being most commonly used, and the development of these systems has been largely responsible for the present popularity of HPLC.

Mobile Phase.

In contrast to gas chromatography, the mobile phase in HPLC plays a vital role in the separation process, with the rate and order of elution being determined by the relative polarities of the mobile and stationary phases, and by the nature of the sample components. In normal phase chromatography, the eluting power of the mobile phase increases with polarity; while in reversed-phase chromatography, the reverse situation applies, and eluting power decreases with increasing solvent polarity. Most of the common solvents can be used as mobile phase, but *n*-hexane is a common nonpolar solvent, while polar solvents in reversed-phase chromatography are often mixtures of water and methanol or acetonitrile. When a single solvent or mixture of fixed composition is used throughout a separation, the process is referred to as isocratic. In gradient elution procedures, the composition of the solvent is changed continuously during the separation

process. The change in solvent composition can be either linear with time or according to a predetermined profile. Gradient elution has some similarities in its effects to temperature programming in gas chromatography.

In HPLC, the mobile phase is pumped through the column. Flow rates for mobile phase are 0.5 to 10 mL min⁻¹ for conventional columns and 50 µL to 5 mL min⁻¹ for narrow-bore columns at pressures up to 48263 kPa (7000 psi). The flow rate must be precisely controlled and the outlet stream must be pulse-free. Metered mixing of up to four solvent streams may be required for gradient elution and column washing. HPLC pumps must be capable of delivering a pulse-free stream of mobile phase, at pressures up to 48263 kPa (7000 psi). Variations in mobile phase flow rate lead to irreproducibility in chromatographic retention times, and pulses in the flow give noise in the detector baseline.

To ensure optimum pump performance and to remove dissolved oxygen, the mobile phase must be degassed. Degassing can be by vacuum, but periodic purging with helium is more usual. Dissolved oxygen causes noise and drift in UV detectors, quenching in fluorescence detectors, and high background currents and noise in electrochemical detectors.

Detectors.

Performance requirements for HPLC detectors are similar to those in GC, and the detector system should be sensitive, have a rapid and reproducible response, and have a wide linear range of response. The following types are most commonly used:

1. **Refractive index:** Detectors based on measurement of the refractive index of the mobile phase are applicable to a wide range of solutes. However, they are temperature sensitive, are generally less sensitive than UV or fluorescence detectors, and cannot easily be used with gradient elution systems.
2. **UV-VIS:** UV or visible detection is the most common detection technique. Photometers or spectrophotometers measure the absorption of UV or visible radiation in the range 190 nm to 700 nm by the solute molecules. Detectors can be either fixed or variable wavelength. Fixed-wavelength detection at 254 nm is suitable for many solutes. The response is linear according to the Beer Lambert law and detection limits are subnanogram in favorable cases. "HPLC grade" solvents that have been specially purified to remove UV-absorbing impurities may be required.
3. **Diode array:** The diode array, or photodiode array (PDA), detector allows the UV or UV-VIS spectrum of the mobile phase to be repeatedly scanned during the elution. The resulting spectra are stored by the data system and are useful for checking or monitoring peak purity during elution and may provide some information on the identity of the analyte. Diode array detectors are typically two or three times less sensitive than conventional, single-wavelength UV or visible detectors.
4. **Fluorescence:** Detection of suitable molecules by fluorescence is typically one or two orders of magnitude more sensitive than UV-VIS detection, allowing detection down to low picogram levels in favorable cases. The fluorescence cell volume can be made as small as 5 µL, making fluorescence detection suitable for use with narrow-bore columns.
5. **Electrochemical:** Electroactive (oxidizable or reducible) substances can be detected by electrochemical techniques. The flow-cell volume may be as low as 1 µL, making the detectors suitable for narrow-bore columns. By choice of working conditions, the detector can be made specific to particular compounds or groups of compounds. Examples of suitable compounds for electrochemical detection include aromatic amines, phenols, and chlorinated phenols.

Injectors.

The injection process is critical in obtaining good performance in HPLC. Injection may be made directly by syringe; but for optimum results, valve injection is essential and is now almost universal. The injection valve is a six-port changeover valve, which allows a defined volume of liquid sample, contained in a sample loop, to be injected into the mobile phase. The sample loop typically has a volume in the range of 10 to 100 µL for conventional HPLC columns, and is loaded by a syringe.

Ion Chromatography (IC)

Ion chromatography (IC) is a variant of HPLC in which inorganic and some organic cations and anions are separated on columns packed with high-efficiency pellicular ion-exchange resins. Anion separator columns are resin-based with positively charged fixed ionic sites, usually quaternary amines. The eluent is commonly dilute aqueous sodium hydroxide or sodium carbonate/sodium bicarbonate mixture. Cation separator columns have negatively charged fixed ionic sites, usually sulphonic acid groups, with methane sulphonic acid as eluent. Although conductimetric, amperometric (polarographic), UV–VIS photometric, and fluorescence detectors can all be used in ion chromatography, conductimetric detection is the most commonly used technique. When conductimetric detection is used, the sensitivity of the measurement is increased by reduction of the conductivity of the mobile phase (suppression) before detection. The conductivity is suppressed by conversion of the eluent to the corresponding acid or base form in a suppressor column, or membrane suppressor, downstream of the separation column. Thus, for anion analysis, the suppressor is a cation exchanger that replaces sodium ions in the eluent with hydrogen ions. Ion chromatography allows detection and measurement of anions and cations in solution, typically down to ppb ($\mu\text{g L}^{-1}$) levels. The common inorganic anions can be determined in a single sample aliquot. The technique is particularly useful for routine analysis of water and environmental samples.

Gel Permeation and Size Exclusion Chromatography

Gel permeation chromatography (GPC) and size exclusion chromatography (SEC) separate sample molecules on the basis of their effective molecular size in solution in aqueous or nonaqueous media. Column packings are porous materials with pores in controlled size ranges and can be either resin (e.g., styrene-divinylbenzene copolymers) or silica based. The solute molecules interact with the column packing. Small molecules are “trapped” in the pores and pass through the column more slowly than larger molecules that do not interact so strongly. GPC was developed for polymer chemistry and is useful for the determination of the molecular weight distribution of polymers, but the techniques are also finding other applications; for example, size separation of small organics and petrochemicals and in sequential analysis and sample cleanup of environmental samples.

Hyphenated Techniques

Chromatographic methods give powerful techniques for separation of mixtures. However, the commonly used detectors give little information about the identity of the separated components, and identification from retention times may be incomplete or ambiguous. The so-called “hyphenated techniques,” in which chromatographic separation is combined with another, usually spectrometric, technique, have been developed to combine chromatographic separating power with spectrometric identification.

Gas Chromatography–Mass Spectrometry (GC–MS)

Developments in column, mass spectrometer, and computer technology have made GC–MS the most widely used of the hyphenated techniques. Modern systems commonly incorporate the following features:

1. Capillary column gas chromatograph, with the column effluent fed directly to the ion source of the mass spectrometer through a heated transfer line
2. Miniaturized quadrupole or quadrupole-type mass spectrometer, optimized for use as a GC detector, and limited to this application. The mass spectrometer may have a limited mass range (maximum mass 650 or 700), corresponding to the maximum molecular weight of compounds that can commonly be analyzed by gas chromatography.
3. Control of the mass spectrometer and gas chromatograph, data recording, and mass spectral library searching by dedicated computer.

Such so-called “benchtop” GC–MS systems typically have sensitivities in the nanogram to picogram range, and unit mass spectral resolution. They give a valuable means of identification and quantitative determination of a variety of analytes, particularly in complex matrices such as biological or environmental

samples. However, for applications requiring the highest sensitivity or mass spectrometric resolution, gas chromatographs coupled to high-resolution magnetic sector mass spectrometers must still be used. If it is necessary to use a packed chromatograph column, the carrier gas flow rate is likely to be too high for direct coupling to the mass spectrometer, and an interface, which allows selective removal of carrier gas, will be required.

Gas Chromatography–Infrared Spectrometry (GC–IR)

Coupling a gas chromatograph with an infrared spectrometer is an alternative to GC–MS. The effluent from the GC column is fed to a miniaturized flow-through absorption cell (light pipe) where the infrared spectra are measured. Fourier transform infrared (FTIR) spectrometry is used to achieve the combination of high spectral scan rates and resolution required to measure spectra from peaks eluting from capillary columns. Computer control and data processing are used, together with computer matching with stored libraries of IR spectra. The IR spectra are vapor-phase, and differ in some respects from liquid- or solid-phase spectra. GC–IR is to some extent complementary to GC–MS in that some molecular properties, particularly those relating to overall structure or shape, which may be lost in the fragmentation process in the mass spectrometer, may be identified in the IR spectra. However, the technique is some three or more orders of magnitude less sensitive than GC–MS, and has received less attention. GC-IR-MS can be used for particularly complex mixtures.

Liquid Chromatography–Mass Spectrometry (LC–MS)

Coupling a mass spectrometer to a liquid chromatograph, in principle, offers the advantages of GC–MS to the greater range of materials that can be analyzed by liquid, compared to gas, chromatography. However, interfacing a liquid chromatograph to a mass spectrometer is more difficult than a gas chromatograph; and while GC–MS is a well-established technique, LC–MS is only now becoming a useful routine method.

The principal difficulty in interfacing LC and MS lies in the very different physical conditions required for operation of the two techniques. Liquid chromatography uses relatively large quantities of liquid mobile phase, which may include inorganic buffers, while the mass spectrometer operates under vacuum. An interface must be used to selectively remove mobile phase before sample can be introduced to the mass spectrometer. Direct liquid injection and moving belt interfaces have been used but are unreliable. Three main types of interface are currently in use:

1. **Thermospray.** The LC effluent is passed through a probe, heated to 350°C to 400°C, in an evacuated region just outside the source of the mass spectrometer. The mobile phase, which often includes a volatile buffer such as ammonium ethanoate, is vaporized, and the sample molecules are ionized by a chemical ionization (CI) process. A series of lenses focuses a proportion of the ions into the mass spectrometer, while the solvent is pumped away. Under these conditions, the ionization is soft, i.e., there is little fragmentation in the mass spectrometer and the principal peak in the mass spectra is the molecular ion, M^+ , MH^+ , or MNH_4^+ . This can be useful for molecular weight determination, but fragmentation may be increased; and in some cases, sensitivity enhanced, by including a filament in the ion source to give electron impact (EI) mass spectra. The thermospray interface is suitable for ionic and nonvolatile compounds. However, it requires the use of volatile buffers and the spectra are dependent on the solvent matrix.
2. **Particle beam interface.** The particle beam interface utilizes the principle of momentum to separate the solvent from the heavier solute molecules. The column effluent, mixed with helium in some designs, is passed through a series of chambers under pressure, exiting through a nozzle. As the effluent emerges, the solvent is vented while the solute molecules continue on their original trajectory and pass into the ion source of the mass spectrometer. The interface allows the use of a standard ion source in either EI or CI modes. It can therefore be used to produce standard library-searchable mass spectra, and is the only commonly used interface where this facility is routinely available. The interface requires some sample volatility, and some compounds (such as complex sugars) do not give satisfactory spectra.

3. **Electrospray.** In the electrospray interface, the column effluent is mixed with a nebulizing gas and passed through a jet nebulizer into a high-voltage electric field. Drop formation and ionization, by a chemical ionization process, occur. The ions enter the mass spectrometer through a capillary tube charged to a different voltage from the remainder of the interface, while the solvent is pumped away. Electrospray interfaces have, thus far, mainly been used for very high molecular weight analytes, although systems for lower molecular weights are being developed. Atmospheric pressure chemical ionization (APCI) is somewhat similar to electrospray except that the ionization process takes place at atmospheric pressure. Both systems can be used for polar compounds, molecular weights up to 100,000 Daltons, and are highly sensitive. However, ionization and separation involve a complex series of mechanisms, and setup and operation of the system, and interpretation of the spectra produced, may be difficult.

Applications in the Electricity Industry

Dissolved Gas Analysis (DGA)

Gas chromatography analysis of gases dissolved in transformer oil has been used for condition monitoring since the early 1970s [6–8]. The large volumes of gas often generated during a transformer fault have been used to trip mechanical relay for some 60 years [9]. It was later realized that if gases are evolved from the oil in sufficient quantities to operate a Buchholz relay, then slowly developing faults would also produce decomposition gases that would be dissolved in the oil. They only appear in the Buchholz at the end of a complicated system of interchange between the gases contained in bubbles rising to the surface and the less soluble atmospheric gases dissolved in the oil. It should therefore be possible to detect any incipient faults which may be present in the transformer early by analysis of the gases dissolved in the oil, using a gas chromatograph. Thermal and electric faults in a transformer produce various characteristic gases that are, to some extent, soluble in the oil. Extraction and GC analysis of dissolved gases can be used for monitoring of transformer condition. Dissolved gas analysis has been accepted as an important and vital condition monitoring technique for power transformers [10–12].

Oil samples can be collected from the equipment using syringes, bottles, or other sampling techniques, as described in IEC 567 [13]. The analysis requires extraction of the dissolved gases from the oil and then injection into a GC. The details of extraction of the gases from the oil are given in IEC 567. Generally, gases are extracted under vacuum using a mercury Toepler pump and the total volume of the extracted gas is measured by bringing to atmospheric pressure. The gases are then separated and determined by gas chromatography. An automated mercury-free instrument can also be used for extraction of dissolved gases [14] and other techniques have been used for extraction of the gases from the oil [15]. A static headspace sampling technique has been combined with capillary gas chromatography to allow dissolved gases and furan-related compounds to be determined in power transformer oils in a single GC run [16].

Regardless of the technique used for the extraction of the gases from the oil, gas chromatography is used for analysis of the gases. Alternative techniques such as mass spectrometry, although very sensitive, have not been used for routine analysis. Infrared spectrometry has been used for detection of gaseous hydrocarbons and carbon oxides [17]. The technique is rapid and accurate, and the detector is very stable. However, it cannot detect hydrogen and atmospheric gases. Hydrogen is a very important incipient gas for transformer condition monitoring. The ratio of oxygen to nitrogen dissolved in the oil is also used as an indication of oil or paper degradation in the transformer (the oxygen is used by reaction with the cellulose).

The gas chromatograph used for analysis of the gases is usually dual channel with FID and TCD detectors. A Porapak column is used for separation of hydrocarbons, and a methanizer is used for converting carbon oxides to methane followed by FID detector, while hydrogen, oxygen and nitrogen are separated on a molecular sieve column and measured by TCD. Other arrangements such as column switching, back flushing should be used if a single detector is going to be used. In such cases, a TCD is usually used as a detector. Infrared detection of hydrocarbons followed by TCD is an alternative arrangement.

A combination of Porapak and molecular sieve column is used for separation of hydrogen, oxygen, and nitrogen, followed by TCD detection. This arrangement requires a flash backflush system to prevent carbon dioxide from entering the molecular sieve column — where it would be so strongly adsorbed that it would require prolonged heating at a high temperature to remove it. The system is capable of detecting 1 ppm hydrocarbons and carbon oxides and 5 ppm hydrogen in the oil. Oxygen and nitrogen in the oil are usually present at high concentration and therefore their detection does not present any problem. High concentrations of acetylene gas in the oil may present some problems, such as poisoning the methanizer catalyst and it may stay in the column for a long time. In such cases, a longer isothermal time and higher oven temperature for cleaning of the column is the recommended technique.

Water has been determined in transformer oils with an accuracy better than 3%, precision better than 4% at the 10-ppm level and detection limit of 0.3 ppm, by headspace sampling and capillary chromatography with TCD detection. The technique could be automated using the headspace GC system proposed for dissolved gas analysis [18].

Furfuraldehyde Analysis (FFA)

Under normal operating conditions, the insulation system of transformers gradually deteriorates and produces various degradation byproducts. Thermal degradation, or aging of the paper insulation, is one of the most important factors in limiting the lifetime of a transformer. Detection and analysis of the degradation byproducts have been widely used to evaluate and monitor the degradation state of the insulation. The aging process of the paper is accompanied by the production of several byproducts — mainly carbon monoxide, carbon dioxide, and furfurals. Carbon oxides can be monitored by DGA, but their production is not specific to paper degradation. The measurement of furfurals could provide an early indication of paper degradation and their analysis by HPLC has been used as a tool for the monitoring of transformer performance [19-22]. A spectrophotometric method has also been used for analysis of furfuraldehyde [23]. The method is only capable of measuring furfuraldehyde and not other furanic compounds present in the oil.

The oil is dissolved in cyclohexane for HPLC analysis and passed through a solid-phase silica cartridge, where the furfurals, phenol, and *m*-cresol (which are products of degradation of phenol-formaldehyde resins in the transformer) are retained. The remaining oil in the cartridge is removed by washing with the solvent. The furfurals, phenol, and *m*-cresol are extracted from the cartridge with water:acetonitrile. The collected extracts are analyzed by HPLC. For separation of furfuraldehyde and other compounds, a C18 column is recommended. A UV detector at 276 nm is usually employed for detecting these compounds. The use of a UV photodiode array detector gives improved discrimination of products in what is often a complex chromatogram at the expense of some slight loss of sensitivity.

Analysis of Antioxidants in Oil

The presence of antioxidants is a key factor in controlling the oxidation of an insulating oil. Their use results in substantial savings by prolonging the oil service life and slowing down the transformer aging process. A large number of antioxidant additives are used, and HPLC is a useful technique for quantitative determination of their concentrations in insulating oil [24,25]. Thin-layer chromatography (TLC) has also been used for quantitative determination of antioxidant in insulating oil [29].

HPLC is also used for evaluation of the quality of mineral insulating oil [26,27]. The presence of certain characteristic chemical compounds is of considerable importance in the electric industry. This technique is also used to identify the presence of some byproducts of oil under electric stress, such as x-wax and fluorescence materials. Polar compounds, such as acids and aldehydes, are also products of oxidation of oil and they can also be determined by HPLC. Early detection of such products is important in transformer condition monitoring to provide prior warning of a developing fault and to enable appropriate corrective action to be taken.

HPLC is also used for health and safety monitoring of the polyaromatic hydrocarbon (PAH) content of transformer oils [28]. The toxic and carcinogenic nature of PAH compounds is well established.

Molecular Weight Distribution of Insulating Paper

Gel permeation chromatography has been used to measure the change in molecular weight distribution of insulating paper during aging [30]. This technique has been used for measurement of the degree of polymerization of the paper, but requires a sampling of the paper in the transformer, which is not generally practical. Measurement of paper degradation by analysis of products dissolved in the oil, such as FFA, although much easier, is indirect and therefore dependent on a knowledge of the history of the transformer and its components. GPC can provide direct information of the state of the paper and the average molecular weight of the cellulosic chains, and currently is mostly used as a forensic analysis tool for the investigation of failures.

Two techniques are available for getting the paper into solution for analysis. Direct dissolution into dimethylacetamide/8% lithium chloride is possible for most forms of cellulose, followed by dilution to 1% lithium chloride for analysis. However, high levels of lignin (3–4%) in the paper interfere with the dissolution process. The alternative is to derivatize the cellulose to the tricarbonyl in pyridine. The product can then be analyzed in solution in tetrahydrofuran, but there is evidence in the literature that the derivatization process itself degrades the paper.

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) are synthetic materials with dielectric and chemical properties that in the past made them attractive alternatives to petroleum-based products. However, they have since been identified as environmental pollutants and possible health hazards. PCBs are not used today, but their use in the past has led to widespread contamination of mineral oil with PCBs. Current legislation requires that oil in service shall have a PCB content of less than 50 ppm. Therefore, the PCB content of insulating oil in the transformer must be measured quantitatively and capillary GC is the technique currently used [31].

The sample is diluted in hexane and deoxygenated. A small volume of the resulting solution is injected into a narrow-bore capillary gas chromatographic column. The capillary column separates the PCBs into individual or small groups of overlapping congeners. Their presence in the effluent is measured by an electron capture detector (ECD).

Feedwater and Boiler Water Analysis

Ion chromatography (IC) is well suited to the analysis of highly pure water such as boiler feedwater, and often gives better precision, sensitivity, and speed of analysis than established techniques. For example, IC has been used for the determination of carbonic acid in steam-condensate cycles [32].

Morpholine is added to the thermal cycle of some CANDU reactors, and has been determined, together with its amine breakdown products, by reversed-phase HPLC on a C18 column with visible detection at 456 nm [33].

Other Applications

The size and scope of the electricity supply industry imply that it has a major effect on the environment. Chromatographic techniques are widely applied in environmental monitoring and research, and the electricity industry is both a major user of standard techniques and sponsor of research.

Defining Terms

Adsorption: The noncovalent attachment of one substance to the surface of another.

Analyte: The substance that is being analyzed.

Baseline resolution: Separation of components at the peak base (no overlap of any peak area).

Chromatography: The physicochemical technique for separation of mixtures into their components.

Column: A steel, glass, or plastic tube containing the stationary phase.

Detector: A device for monitoring the separated compounds from the chromatography by sensing chemical or physical properties of the sample.

Eluent: The moving solvent in a chromatographic column.

Elute: To travel through and emerge from the column.

Gel permeation chromatography (GPC): A mode of LC in which samples are separated according to molecular size.

HPLC: High-performance liquid chromatography.

IC: Ion chromatography.

Mobile phase: The following solvent.

Stationary phase: The material that is contained in the column and does not move during the chromatographic process.

The measurement of pH is arguably the most widely performed test in the chemical laboratory, reflecting the importance of water as a ubiquitous solvent and reactant. In the 90 years since the first use of an electrode to determine hydrogen ion concentration, the glass electrode and its variants have matured into routine tools of analytical and process chemists. Yet, there continue to be developments that promise to broaden the scope and reach of these measurements. Among recent developments are miniature pH-sensitive field-effect transistors (pHFETs) being incorporated into pocket-sized pH “pens,” metal/metal oxide pH sensors for measurements at high temperatures and pressures, and flexible fiber-optic pH sensors for measuring pH within the body. This chapter discusses electrochemical and optical methods for pH measurement, and is by necessity limited in scope; readers interested in a more comprehensive treatment may wish to refer to the recent text by Galster [1].

71.1 Definition of pH

In its most common interpretation, pH is used to specify the degree of acidity or basicity of an aqueous solution. Historically, pH was first defined as the negative logarithm of the hydrogen ion concentration (*pondus Hydrogenii*, literally hydrogen exponent), to simplify the handling of the very small concentrations (on the order of 10^{-7} moles liter⁻¹) encountered most commonly in nature. This definition of pH is expressed as Equation 71.1, where $[H^+]$ is the molar concentration of solvated protons in units of moles per liter.

$$\text{pH} = -\log [H^+] \quad (71.1)$$

As a greater understanding of the behavior of ionic solutes in solution developed, chemists recognized that the measurement techniques used to determine hydrogen ion concentration were in fact measuring the hydrogen ion activity, often referred to as the “effective concentration.” This led to the adoption of the more rigorous definition of pH as the negative logarithm of the hydrogen ion activity in solution,

$$\text{pH} = -\log a_{H^+} = -\log \gamma [H^+] \quad (71.2)$$

TABLE 71.1 pH of Common Substances

Substance	pH
Soft drinks	2.0–4.0
Lemon juice	2.3
Vinegar	2.4–3.4
Wine	2.8–3.8
Beer	4.0–5.0
Cow's milk	6.3–6.6
Pure water	7.0
Blood	7.3–7.5
Sea water	8.3

Note: D. R. Lide (Ed.), *CRC Handbook of Chemistry and Physics*, 74th ed., Boca Raton, FL: CRC Press, 1993.

where a_{H^+} is the hydrogen ion activity and γ is the activity coefficient. The two definitions expressed in Equations 71.1 and 71.2 are equivalent in dilute solution where concentration approximates activity, a_{H^+} . In practice, the routine measurement of pH is not accomplished by the direct determination of the hydrogen ion activity. Rather, pH is determined relative to one or more standard solutions of known pH.

The hydrogen ion activity of common substances ranges over many orders of magnitude, as evidenced from the tabulation presented in Table 71.1. Water, in the absence of other chemicals that might alter its equilibrium, contains 10^{-7} molar hydronium ions $[\text{H}^+]$ and 10^{-7} molar hydroxonium ions $[\text{OH}^-]$ at 25°C . Under these idealized conditions, water has a pH of 7.0, and is said to be neutral.

The addition of acids or bases to pure water increases or decreases the hydrogen ion activity, respectively. The resulting pH depends on a number of factors, such as the concentration of the added acid or base and the strength as quantified by its dissociation constant [2].

71.2 Electrochemical Methods of pH Measurement

Electrochemical measurement of pH utilizes devices that transduce the chemical activity of the hydrogen ion into an electronic signal, such as an electrical potential difference or a change in electrical conductance. The following sections review electrochemical pH measurement, with emphasis on the glass membrane electrode. Also discussed is the operation of hydrogen ion-selective pHFETs, metal/metal oxide electrodes, and other approaches used in specialized applications. Table 71.2 provides a listing of sources, features, and key properties of selected, commercially available pH electrodes.

The Glass Membrane Indicator Electrode

The most widely used method for measuring pH is the glass membrane electrode. As illustrated schematically in Figure 71.1(a), a pH meter measures the electrical potential difference (voltage) that develops between a glass membrane pH *indicator* electrode and a *reference* electrode immersed in the sample to be tested. The indicator and reference electrodes are commonly combined into a single, functionally equivalent, probe, referred to as a combination electrode. The glass membrane of the indicator electrode develops a pH-dependent potential, as a result of ion-exchange between hydrogen ions in solution and univalent cations in the glass membrane. The sensitivity of the glass electrode membrane potential to changes in pH is small, so a suitably designed reference electrode and a high input impedance meter are required in order for the potential to be precisely measured.

The construction of a typical pH indicator electrode is illustrated in Figure 71.1(b). The glass membrane at the tip of the electrode, which acts as the transducer of pH, is approximately 0.1 mm thick. One

FIGURE 71.1 pH measurement using a glass membrane electrode: (a) measurement system comprising a pH meter, indicator, and reference electrodes; (b) indicator electrode construction; (c) reference electrode construction; and (d) amplifier circuit.

side of the membrane contacts the sample while the other contacts the electrode filling solution, an electrolyte of defined composition and pH. A reference element (e.g., a silver chloride coated silver wire) immersed in the filling solution makes a stable electrical contact between the potential measuring circuitry of the pH meter and the electrolyte in contact with the inner side of the glass membrane.

The reference electrode illustrated in [Figure 71.1\(c\)](#) provides a means of making electrical contact between the meter and the sample that is in contact with the external side of the indicator electrode's pH-sensitive glass membrane. Like the indicator electrode, the body of the reference electrode is filled with an electrolyte into which a reference element is immersed. The electrode also has a means, such as a porous ceramic frit, by which the reference electrode filling solution can make physical and electrical contact to the sample. The importance of this "liquid junction" cannot be understated, as it is a potential source of sample contamination, measurement errors, and reliability problems.

The electrical potential difference between the pH indicator electrode and the reference electrode provides a measure of pH. [Figure 71.2](#) provides an illustration of the potential differences, the origin of which will be discussed below, that contribute to the measured potential. The main function of the pH meter of [Figure 71.1\(a\)](#) is to measure this difference, with a precision of 0.1 mV or better. The amplifier circuit of [Figure 71.1\(d\)](#) illustrates how this may be done. Due to the high electrical resistance of the indicator electrode's glass membrane, the meter must have a correspondingly high input impedance. Most pH meters currently sold contain built-in microprocessors that simplify pH measurement by performing and storing calibrations, doing diagnostics, and implementing temperature compensation.

Glass Membrane Indicator Electrode Construction

The hydrogen-ion selective glasses used to construct pH indicator electrodes are formed by fusing silica, alkali metal oxides, and alkali earth oxides. The silica component, SiO_2 , makes up approximately 70% of the glass. The alkali metal oxide contributes mobile ions such as sodium or lithium, which act as electrical charge carriers, or are exchanged for protons in the hydrated glass layer. Components such as calcium oxide (CaO) are added to incorporate multivalent ions into the glass; these act to modify the network structure of the glass, imparting characteristics such as processability and chemical resistance.

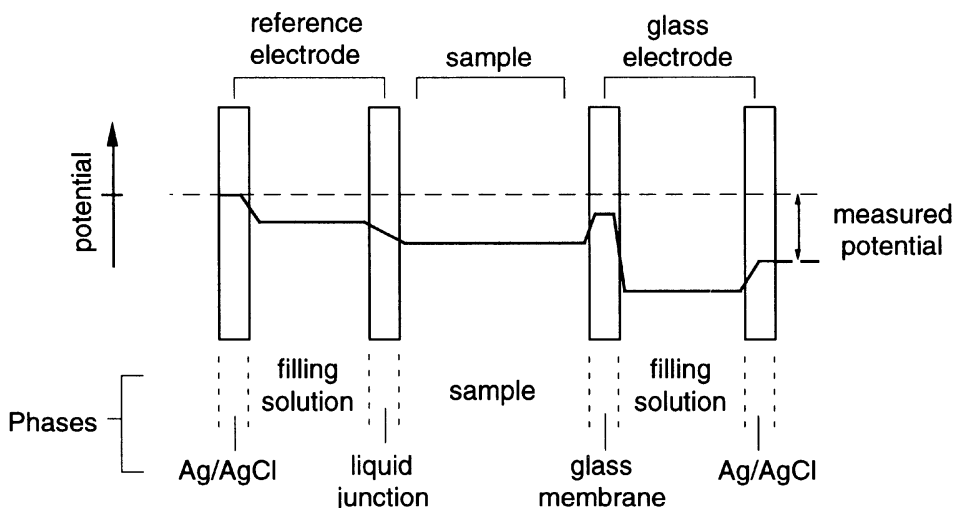

FIGURE 71.2 Schematic illustration of potential differences contributing to the measured potential between a glass membrane electrode and a reference electrode.

Glass Membrane Indicator Electrode Response to pH

When the membrane glass is immersed in aqueous solution, a gel-like hydrated layer on the order of 100 nm thick forms at the surface of the glass. Within this hydrated layer, the exchange of sodium ions in the glass for hydrogen ions in the solution produces a potential difference between the hydrated layer and the solution which depends on the hydrogen ion activity. The net potential developed across the entire glass membrane, ϕ_{net} , is the sum of boundary potentials, ϕ_b , at the inner (reference element side) and outer (sample side) extents of the membrane.

$$\phi_{\text{net}} = \phi_{b,\text{inner}} - \phi_{b,\text{outer}} \quad (71.4)$$

Under conditions where, at the outer surface, the exchange of sodium ions for hydrogen ions is complete (typically for pH less than 10), the hydrogen ion activity at the surface of the gel layer will be constant. The boundary potentials will then depend in a logarithmic manner on the hydrogen ion activity of the solution contacting the membrane, a function known as the Nernst equation.

$$\phi_b = \text{constant}' + \frac{RT}{F} \ln a_{\text{H}^+} \quad (71.5)$$

The net potential developed across the membrane is then proportional to the log of the ratio of the hydrogen ion activities of the sample and the electrode filling solution. The hydrogen ion activity of the filling solution is constant, so the membrane potential will depend linearly on pH.

$$\phi_{\text{net}} = \text{constant}'' + \frac{RT}{F} \ln \frac{a_{\text{H}^+, \text{sample}}}{a_{\text{H}^+, \text{inner}}} = \text{constant}''' - 2.3 \frac{RT}{F} \text{pH} \quad (71.6)$$

The dependence of membrane potential on pH is proportional to absolute temperature and, at 25°C, the factor 2.3 RT/F is equal to 59 mV per pH unit. Many pH meters that perform two point calibrations calculate a slope and display it as a percentage of this theoretical value. For an electrode in good condition,

this will be in the range of 90% to 105%; values considerably different from this indicate a problem with the electrode.

While the membrane potential responds principally to changes in hydrogen ion activity, it also responds to sodium and other monovalent cations. These effects are most noticeable at high pH where hydrogen ion activity is small, and is referred to as alkaline error. A more detailed analysis of the membrane response, which considers the effects of interfering ions, can be found in reference texts [3].

Reference Electrodes

A reference electrode, such as that pictured in Figure 71.1(c), is used to make a stable, low resistance electrical contact between the external measuring circuit and the sample, establishing a reference potential against which the indicator electrode can be referred. In the metallic conductors of the pH meter circuitry, current is carried by electrons, while in the sample electrolyte current is carried by ions. The difference between reference electrodes is primarily the oxidation or reduction reactions that effect charge transfer across the reference element/electrolyte interface. The species participating in these reactions must be present in the electrolyte contained within the body of the reference electrode. As a result, the composition of the reference electrode filling solution is, in general, different from that of the sample, and the physical contact between the two dissimilar electrolytes forms what is known as a liquid junction. The two phase boundaries (reference element/filling solution and filling solution/sample) necessary to make electrical contact to the sample each introduce an additional potential, which adds to that of the indicator electrode, but proper design of the reference electrode ensures that these potentials remain constant and can be calibrated out.

Reference Elements

The most widely used reference electrode for pH measurement is the silver/silver chloride electrode. The electrode is constructed from a silver wire that has been coated with silver chloride and immersed in an electrolyte saturated with silver chloride. Current is readily passed across the electrode/electrolyte interface by the reduction of silver chloride to form silver metal and chloride ion.

At equilibrium, the phase boundary potential developed at the interface depends in a Nernstian manner on the chloride ion activity of the filling solution. Maintaining a constant chloride ion activity in the filling solution ensures that this potential remains constant. This type of electrode is easily and reproducibly constructed, and the phase-boundary potential has a smaller temperature coefficient than the calomel reference electrode. The principal disadvantages of the Ag/AgCl electrode include the possibility that samples, biological samples in particular, may be contaminated with silver ion, and that precipitates (silver sulfide and nitrate) may form that can clog the liquid junction.

Another commonly used reference electrode is the calomel electrode, based on the reduction of mercuric chloride to mercury.

Like the silver/silver chloride electrode, the potential of the calomel electrode depends on the chloride ion activity of the filling solution. It is more stable than the silver/silver chloride electrode, due to favorable reaction kinetics, and is therefore preferred for high-precision electrochemical determinations. However, the operating temperature of a calomel reference electrode is limited to 70°C, compared to greater than 100°C for the silver/silver chloride electrode.

A number of reference electrodes use a platinum reference element. Ross described a reference electrode based on the reduction of iodine to iodide [4]. The nature of the redox reaction differs from the Ag/AgCl and Hg/HgCl₂ electrodes, in that both the iodine and iodide are soluble in the filling solution, yielding

an electrode potential that is relatively insensitive to temperature. The hydrogen reference electrode consists of a platinum electrode immersed in aqueous solution, over which hydrogen gas is bubbled. The platinum catalyzes the reduction of hydrogen ion to hydrogen gas. Historically, the standard hydrogen electrode has served as the primary reference electrode for precise electrochemical determinations. The role played by the hydrogen electrode in pH measurement, however, is primarily in its use as an indicator electrode for the determination of the hydrogen ion activity of primary pH standard solutions.

Liquid Junctions

The necessary contact between the filling electrolyte of the reference electrode and the sample forms a liquid junction, and results in the development of a junction potential that depends on the compositions of the two electrolytes. The junction potential can be minimized by filling the reference electrode with an electrolyte having high concentrations of an anion and cation of comparable diffusivities. For Ag/AgCl and calomel reference electrodes, potassium chloride at concentrations ranging from 3M to saturation is most commonly used as the filling electrolyte, as the diffusivities of the two ions are approximately equal. The stability of the liquid junction potential depends on the constancy of the interface between the filling electrolyte and the sample. A number of approaches exist to allow the filling electrolyte to controllably leak into the sample for this purpose. These include cracked bead, porous ceramic, and annular sleeve junctions. Leak rates range from less than $1 \mu\text{L h}^{-1}$ (cracked bead) to greater than 100 (annular sleeve) $\mu\text{L h}^{-1}$.

Selection, Use, and Care of Reference Electrodes

Reference electrode selection is dictated by the sample to be studied and the measurement conditions, such as temperature. Silver/silver chloride electrodes are preferred over calomel for general-purpose use, and at high temperatures (70°C or greater). Calomel electrodes are preferred for high-precision determinations, and where silver contamination of the sample presents a problem. An Ag/AgCl reference electrode incorporating a double junction is also another means of preventing silver contamination of the sample. The type of liquid junction and its flow rate is important; a high flow rate may contaminate the sample and deplete the electrode, while a low flow rate may lead to clogging. Viscous, semisolid samples or low ionic strength samples require a high flow rate junction. The reference electrolyte fill port should remain open during use of the electrode to insure adequate flow through the junction. Leaving the fill port open at all times will prevent any contaminants from entering the body of the reference electrode and reduce the likelihood of junction clogging, at the expense of more frequent refilling. "Low maintenance" reference electrodes use a polymer gel saturated with electrolyte within the body of the electrode, and will perform properly if stored in filling solution.

Instrumentation

The pH meter pictured in Figure 71.1(a) measures the potential developed between the pH indicator and reference electrodes, from which the pH of the sample is determined using a previously established calibration and possibly the sample temperature. The measurement of the potential, which may range in magnitude up to a few hundred millivolts, is complicated by the large electrical resistance presented by the glass membrane. This may range from $100 \text{ M}\Omega$ to greater than $1000 \text{ M}\Omega$, and necessitates the use of high input impedance amplifiers with FET input stages if the glass membrane potential is to be accurately measured. While the relatively low cost and high performance of commercially available meters obviates the need for amplifier construction, Figure 71.1(d) presents a simple amplifier suitable for use with a glass electrode. The amplifier circuitry of commercial pH meters incorporates additional functions to improve the accuracy and stability of the measurement, such as a driven shield to reduce noise pickup and chopper stabilization to reduce drift.

Calibration

The glass indicator electrode is calibrated using standard buffer solutions of known pH. A two point calibration procedure is illustrated schematically in Figure 71.3. A pair of standards is chosen to bracket

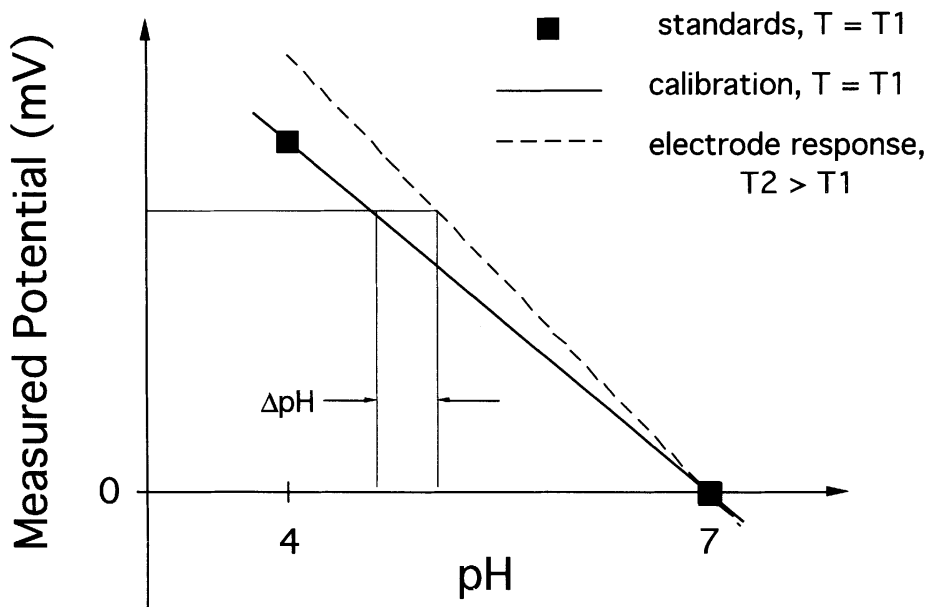

FIGURE 71.3 Calibration and temperature compensation of a glass pH electrode.

the pH range of interest. The response of the electrode is measured in each, and a calibration function is determined by linear interpolation. The slope can be compared to that expected from the Nernst equation to provide an indication of the performance of the electrode. The newest microprocessor-controlled pH meters simplify calibration by automatically recognizing the pH of standards, and constructing calibration curves from as many as five buffers.

Temperature Compensation

The potential developed across the pH indicator glass electrode membrane is temperature dependent, with a temperature coefficient of approximately 0.3% per °C, as follows from Equation 71.6. The effect of temperature on the electrode calibration is illustrated in Figure 71.3. Most pH meters have provision for temperature compensation, which corrects the slope of the measured potential versus pH calibration. Manual compensation permits the user to dial in the temperature at which the measurement is going to be made. Meters equipped with automatic temperature compensation (ATC) use a platinum resistance thermometer to directly measure the temperature of the sample. The instrumentation within the meter then corrects the calibration function such that the millivolt reading is correctly interpreted as the pH of the sample at the measurement temperature.

pHFETs

A relatively recent development in pH measurement is the introduction of systems based on the use of ion-selective field-effect transistors (ISFETs) as the sensing element. ISFETs, of which the hydrogen ion-sensitive pHFET is one variant, are derived from the metal-oxide-semiconductor FET (MOSFET), the basic building block of integrated circuits. These silicon “chips” combine a pH-responsive membrane much like that of the glass electrode with the amplification of a field-effect transistor. The integral amplification and small size have led to the development of inexpensive, battery-powered, pocket-sized pH measurement systems. These devices have found unique and expanding niches, including the food industry where the measurement of pH using breakable glass electrodes presents an unacceptable safety hazard, the measurement of the pH of gels, pastes, and slurries, and for the measurement of strongly alkaline solutions where conventional glass bulbs respond to the sodium ions and give an erroneously low reading. The following

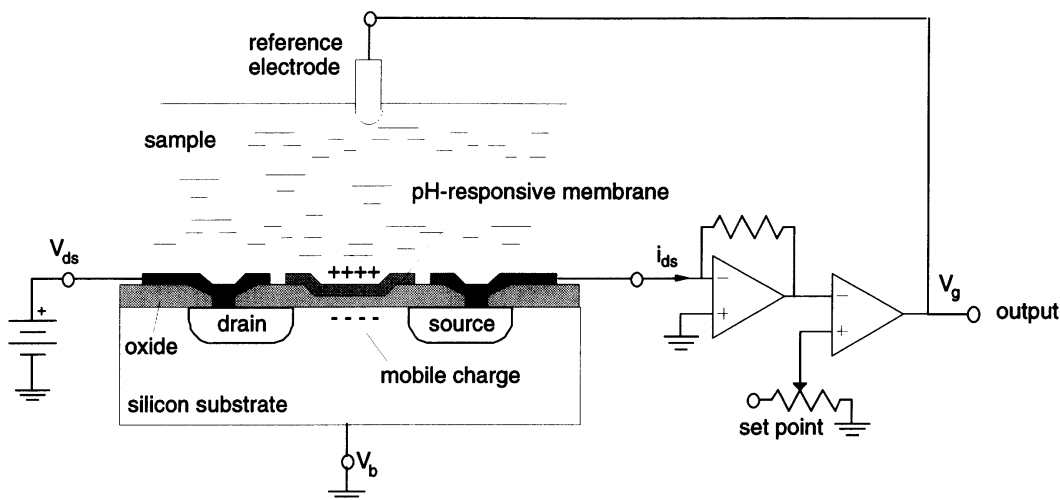

FIGURE 71.4 pH measurement using an ion-selective field effect transistor, including an amplifier circuit for constant drain current operation.

sections cover the basic operation of these devices, instrumentation, and applications. Additional details can be found in reference texts [5].

Construction and Operation

A schematic cross-section of a pH-sensitive ISFET is presented in Figure 71.4. The pHFET differs from a MOSFET in that the metal gate of the MOSFET is replaced by a pH-responsive membrane material such as silicon nitride, aluminum oxide, or tantalum oxide, which contacts the sample solution directly. As with the glass electrode, electrical contact is made to the sample through a reversible reference electrode. A suitable voltage applied to the reference electrode (relative to the silicon substrate) will charge the capacitor formed by the solution, insulating layers, and silicon substrate, and create mobile charge in the channel region. A potential simultaneously applied between the drain and source electrodes will result in current flow. Using a “charge imaging” model [6], this drain current, i_{ds} , can be described by:

$$i_{ds} = A V_{ds} Q_c = A V_{ds} C_2 \left(V_g - V_T - \frac{V_{ds}}{2} \right) \quad (71.9)$$

where the constant A includes geometrical factors, V_{ds} is the voltage applied to the drain, and Q_c is the mobile channel charge. The mobile charge is a function of V_g , the voltage applied to the reference electrode; V_T , the “threshold voltage” needed to produce mobile charge, and C_2 , the capacitance of the gate region. The threshold voltage includes a number of terms, one of which is the phase-boundary potential at the interface between the sample and the pH-responsive insulating layer. Adsorption of protons at the surface of this layer leads to a Nernstian dependence of this potential on hydrogen ion activity with the result being that changes in pH modulate the drain current of the device.

$$i_{ds} = A V_{ds} C_2 \left(V_g - V_T + 2.3 \frac{RT}{F} \text{pH} - \frac{V_{ds}}{2} \right) \quad (71.10)$$

Instrumentation

Equation 71.10 illustrates the dependence of ISFET current on pH. The preferred method of operation of the pHFET is to operate at a constant drain current. A circuit for doing this is illustrated schematically

in Figure 71.4. A transconductance amplifier converts the drain current to a voltage, which is referenced against a setpoint. The output of the comparator drives the reference electrode, V_g . Since the mobile channel charge Q_c is constant, as are V_{ds} and V_T , changes in the comparator output directly reflect changes in the hydrogen ion activity. That is, a 59-mV change in output corresponds to a change in pH of one unit. Interface circuitry similar to that of Figure 71.4 allows the device to be connected directly to a glass electrode pH meter. As with the glass electrode, temperature compensation is required if the device is to be used at temperatures different from that of calibration.

Other Electrochemical pH Electrodes

There are a number of other approaches for electrochemical measurement of pH [1]. Two that deserve mention, as they are commercially available, either directly or incorporated within another product, are metal/metal oxide and liquid membrane electrodes.

Metal/metal Oxide pH Sensors

A pH indicator electrode with application to measurement at high temperature and pressure can be constructed from metals coated with an oxide. These metal electrodes may take the form of a wire, polished disk, or sputtered thin film, on which an oxide has been formed through thermal oxidation, chemical vapor deposition, or electrochemical oxidation. Electrodes have been constructed from systems including W/W₂O₃, Sb/Sb₂O₃, Pt/PtO₂, Ru/RuO₂, Pb/PbO₂, and Ir/IrO₂. In aqueous solution, the metal oxide can be reduced to a lower oxidation state with the consumption of a proton in solution. Using an iridium/iridium oxide (Ir/IrO₂) electrode as an example, this redox couple is believed to be represented by an Ir(III)/Ir(IV) half-cell reaction of the form:

The Ir/IrO₂ electrode shows a near Nernstian response of -59 mV per pH unit [7]. The chemical resistance, high temperature and pressure performance, the nonglass construction, and the considerable potential for miniaturization suggests that these pH sensors will find application in areas not typically employed by glass membrane electrodes or pHFETS.

Liquid Membrane Electrodes

Another type of electrochemical pH electrode is based on polymeric “liquid membranes,” most commonly used to construct ion-selective electrodes for ions such as potassium [8]. The membranes consist of a plasticized polymer film into which an ionophore has been incorporated. The ionophore is a molecule that selectively binds and transports a given ion across the membrane, making the membrane selectively permeable to the ion of interest. The ionophore N-tridodecylamine binds hydrogen ions and has been used in the construction of a pH sensor incorporated into a disposable cartridge device for measuring blood electrolytes [9].

71.3 Optical Methods of pH Measurement

For some applications, optical methods offer advantages over the use of the glass electrode or other electrochemical devices for the measurement of pH. Organic dye molecules with pH-dependent spectral properties have been routinely used for decades in acid-base titrations and in pH indicator papers. These dyes, many of natural origin, have more recently been put to use as indicators to measure localized pH within living cells and in the development of fiber-optic probes for measuring pH within the body. The following sections cover the basic principles and major applications of optical pH measurement; more detailed treatments may be found in Reference 10.

TABLE 71.2 Sources, Features, and Key Properties of Selected pH Electrodes

Manufacturer	Reference	Range	Accuracy pH Units	Cost (\$U.S., 1997)	Key Features
Glass combination electrodes					
ABTECH Scientific, Inc. ^a Miniature Combination pH electrode, CPE 905-X	Ag/AgCl	0–14	±0.1	\$285	Handheld Refillable bulb Min. vol. = 10 µL

Indicator Dyes

Optical measurement of pH is based on the use of organic dye molecules that are weak acids or bases. The loss or gain of a proton changes the electronic structure of the molecule, producing a measurable change in the manner in which the molecule interacts with light. This interaction can be the absorption of light at a particular wavelength, or fluorescence by one form of the molecule. An equilibrium exists between the acid and base forms of the dye, whether free in solution or chemically attached to a supporting membrane, and can be described by the equilibrium:

where z represents the valence of the molecule. The interrogation of the solution or membrane with light will produce a response that is weighted by the relative proportions of the acid and base forms of the molecule, which in turn depends on pH. Inspection of Equation 71.12 shows that the ratio of the two forms, and hence color, varies continuously with hydrogen ion activity. The sensitivity of the measurement is greatest when the acid and base forms of the dye are present in approximately equal concentrations. This will occur when the pH of the solution is close to the $\text{p}K_a$ ($-\log [K_a]$) of the dye. Limitations of the human eye restrict detectable changes in color to a tenfold excess of one species over the other. This corresponds to a change of ± 1 pH unit. Thus, an indicator with a $\text{p}K_a$ of 1×10^{-5} will display a color change if the solution in which it is dissolved changed from 4 to 6 pH units. The pH of interest therefore dictates selection of the particular dye.

An understanding of possible interactions between the indicator dye and the sample is important in the effective use of optical indicator dyes for pH measurement [11]. Factors such as temperature, electrolyte concentration, and the presence of organic solvents may cause a shift in $\text{p}K_a$ of the indicator dye; the shift could be as much as one or more pH units. As weak acids and bases, the addition of indicator dyes to a sample can change the pH, particularly in weakly buffered samples. This effect is important when using pH papers or optical sensors to measure small samples, where the potential exists for the buffering capacity of the sample to be exceeded by the amount of dye immobilized in the paper or on the sensor. As a general rule, potential errors can be minimized by calibrating in solutions similar in composition to the sample to be measured.

Absorption Indicator Dyes

The conjugate acid and base forms of absorption indicator dyes differ in the characteristic wavelengths at which they absorb light energy. A number of common absorption indicator dyes are listed in [Table 71.3](#), and their $\text{p}K_a$ s span the range of pH from approximately 1 to 13. The absorption spectra of a solution of the dye phenol red at a number of different pHs is shown in the inset of [Figure 71.5](#). The acid form of the dye has an absorption maxima at $\lambda_{\text{max}} = 435$ nm, while the base form absorbs maximally at $\lambda_{\text{max}} = 565$ nm. As the pH of a phenol red solution is increased from 6 toward the $\text{p}K_a$ of 7.9, the equilibrium of Equation 71.12 shifts to the basic form of the dye. The relative heights of the absorption peaks change, reflecting a shift in concentrations of the two forms. For quantitative pH measurement, the absorption of light by the indicator is measured by a spectrometer or reflectometer at a specific wavelength or narrow set of wavelengths corresponding to the wavelength of maximum absorption, λ_{max} for the acidic or basic

TABLE 71.3 Acid-Base Indicator Dyes

Indicator	pK _a	λ _{max} (nm)	
		Acid Form	Base Form
Thymol blue	1.7	544	430
Methyl orange	3.4	522	464
Bromphenol blue	3.9	436	592
Bromcresol green	4.7	444	617

^a 2',7'-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein.

^b (7-hydroxycoumarin-3-carboxylic acid).

^c (8-hydroxy-1,3,6-pyrenetrisulfonate).

magnitude of the absorption peak heights at 565 nm, plotted in Figure 71.5 as a function of pH, reflects the changing concentration of the basic form of the dye as the equilibrium of Equation 71.12 shifts.

Fluorescent Indicator Dyes

Fluorescent indicator dyes absorb light of a particular color (or wavelength) and re-emit some of the absorbed energy as light of a different color. Absorption of light by the indicator promotes the molecule from the ground state energy, E_g , to a higher energy state, E_1 . Subsequent processes such as molecular collisions lead to a transition to a lower energy excited state, E_2 . The molecule can then emit a photon of energy $E_2 - E_g$, resulting in the return of the molecule to the ground state from this intermediate state. The emitted light is at a longer wavelength than the exciting wavelength, and the difference is known as the Stokes shift. In principle, a fluorescence measurement is more sensitive than an absorption measurement because the only light measured by the detector originates from fluorescing molecules. Table 71.4 lists a number of common fluorescent pH indicators used for measurement of pH in the physiological range. Fluorescein is widely used because the absorption maximum at 490 nm of the fluorescent dianion is readily excited by the 488-nm emission of argon ion lasers.

Indicator Papers

Indicator papers are a simple, rapid, and inexpensive means of measuring pH when the precision of an instrumental measurement is not necessary. These are constructed from a strip of paper or plastic that has been impregnated with one or more absorption indicator dyes chosen to span the pH range of interest. The dyes are generally covalently attached to the strip, to prevent contamination of the sample by leaching of the dyes. A strip for indicating pH in the range of 5.5 to 9.0 can be constructed using the dyes bromocresol purple, bromothymol blue, and phenol red [1]. The pH of a sample is determined to a precision of typically 0.5 units by comparing the color of the strip to a color calibration chart provided by the manufacturer.

Fiber-Optic pH Probes

Optical pH sensors, often referred to as optrodes, represent some of the most sophisticated pH sensors, finding use for remote sensing in the body or industrial plants due to their small size and lack of electrical connections. They are typically constructed by immobilizing an indicator dye at the tip of a light guide formed from one or more optical fibers, which are used to couple light between the indicator and the measurement instrumentation, as illustrated schematically in Figure 71.6(a). The resulting probes can be made very small, and with high-quality optical fibers, pH can be measured over considerable distances in electrically noisy environments that would interfere with potentiometric-type electrodes.

Construction and Instrumentation

The pH indicator dye must be immobilized in close proximity to the fiber tip. The method of immobilization impacts the sensor's response, response time, long-term stability, and mechanical integrity. The dye can be immobilized to a solid support, such as a membrane or porous glass bead, which is then

FIGURE 71.6 Optical fiber sensors: (a) generic; (b) based on absorption indicator dyes [13]; and (c) based on fluorescent indicator dyes [14].

attached to the end of the fiber. Indicator dyes have been covalently linked to the tip of glass fibers, or entrapped within polymer films formed at the tip using light energy from the fiber to initiate polymerization. The construction of probe tips and the instrumentation used for a fiber-optic pH probe depend on the type of indicator being used. Unlike the glass electrode, which has remained largely unchanged for more than 75 years, there is considerable variety in the design of fiber-optic pH sensors. While a complete review of the literature is beyond the scope of this work (interested readers may wish to consult Wolfbeis [10] and a recent review of chemical sensors by Janata [12]), the following examples illustrate the approaches to construct optical fiber pH sensors using absorption and fluorescent dyes.

Absorption optodes measure the change in intensity of light returned from the fiber tip/sensing region relative to the interrogating light of specific (or a narrow band) wavelength. These require a separate collection fiber or fibers and a means to reflect the light, such as a reflector or the use of scatterers such as polystyrene beads. In the example of Figure 71.6(b) [13], polyacrylamide beads containing the indicator dye phenol red were mixed with white polystyrene latex microspheres that served as scatterers. The beads were contained within dialysis tubing attached to the end of a pair of plastic optical fibers, one used for excitation, the other to collect scattered light. Light from a lamp was filtered to alternately select the λ_{max} of the base form of the dye (565 nm), and a wavelength (600 nm) where the absorbance is pH independent as a reference. (The isosbestic point at 480 nm could also have served as a reference.) The intensity of light scattered back into the second detector fiber was quantified by a photodiode. The ratio of the scattered intensities at the two wavelengths was then related to the pH of the sample.

Fluorescent indicator optrodes measure the Stokes-shifted fluorescence emission by the indicator and may use a single fiber to both interrogate and collect signal-carrying light. The amount of fluorescent pH indicator at the fiber tip must be maximized since fluorescence is emitted omnidirectionally and only a small fraction of the emitted fluorescence will be captured by the fiber. In the example of [Figure 71.6\(c\)](#) [14], the indicator dye was entrapped within a polymer gel formed at the tip of a glass fiber. The source of excitation light is typically a high-intensity lamp or a laser. If a lamp, its output is filtered to select a narrow band of wavelengths at the absorption maximum of the specific form of the indicator, that is then introduced into the fiber to excite the fluorophore at the tip. Emitted light collected by the fiber exits the fiber and is incident on a dichroic mirror, which reflects the long-wavelength light and passes shorter wavelengths. A filter then selects a narrow band of emission wavelengths, and finally, the light is detected. Due to the relatively small light intensities, the detector is typically a photomultiplier tube rather than a photodiode.

71.4 Frontiers of pH Measurements

Because of its wide-ranging importance, there is likely to be continued innovation in both approaches and opportunities for pH measurements. Some important developments, such as pHFETs and metal/metal oxide pH sensors, have already occurred and are now achieving noteworthy commercialization. Investigators continue to seek new materials for constructing transducers. Examples include electroconductive (electroactive and inherently conductive) polymers such as polyaniline [15] and polyelectrolyte hydrogels [16], which form pH-responsive membranes suitable for the construction of microsensors.

A noteworthy innovation is the application of pH measurement devices as transducers that are integrated into more complex analytical systems directed at other analytes. A pH indicator dye forms the basis of the pCO₂ measurement in an indwelling fiber-optic catheter [17]. Because protons are generated and/or consumed in many biological reactions involving enzymes, pH sensors have found use as transducers in biosensor devices.

An expanding area for pH measurement is likely to be the study of biological systems. The light-addressable potentiometric sensor is a device that measures the pH change resulting from the metabolic activity of cells, with application to examining cellular response to toxins and infectious agents [18]. The measurement of intracellular or subcellular pH using pH-sensitive fluorescent indicators [19] can provide insights into the physiology of the cell.

Environmental Engineering*

Whether one likes it or not, water and water vapor can be found everywhere. Because of the asymmetrical distribution of their electric charge, water molecules are easily adsorbed on almost any surface, where they are present as a mono- or multimolecular layer of molecules. Water vapor in the air or any other gas is generally called *humidity*; in liquids and solids, it is usually designated as *moisture*. The determination of humidity and moisture, as in prediction of floods, fog, conditions for the appearance of plant diseases, etc., is of great economic importance. Stored foodstuffs or raw materials may dry up at low humidity or get moldy at high humidity. In many industrial processes, the measurement of moisture and humidity is important for the maintenance of the optimum conditions in manufacturing. Humidity and moisture content can be expressed in a number of ways, and the number of methods for measuring them is even greater. An engineer whose main concern is to avoid condensation no matter where in his system will be interested in the *dewpoint* of the gas flow. A chemist may be interested in the mere *quantity* of water vapor, whereas in a printing-office or a storage-room, the *relative humidity* is of more importance.

Water vapor is one of the constituent gases of the Earth's atmosphere, the total pressure P of which is, according to Dalton's law, the sum of the partial pressures. This means that:

$$P = P_{\text{N}_2} + P_{\text{O}_2} + P_{\text{H}_2\text{O}} + P_{\text{other gases}} \quad (72.1)$$

Like other gases, water vapor can be considered to behave as an ideal gas, except near saturation. In average environmental conditions, water can also be present in the liquid and solid phase, the reason to

speak of water vapor rather than of water gas. An empty space in equilibrium with a flat water (or ice) surface can, at a given temperature, hold a well-defined maximum quantity of water vapor [1,2,3]. When this *saturation vapor pressure* is reached, any further addition of water vapor results in condensation. In the presence of air molecules at atmospheric pressure, the saturation vapor pressure is about 0.4% higher (expressed by the so-called enhancement factor [4]). The saturation vapor pressure for water is about 611 Pa at 0°C, 2339 Pa at 20°C, and 7383 Pa at 40°C. So, one can say that the average water vapor pressure in the Earth's atmosphere around us ranges from about a half to a few percent of the barometric pressure.

There are several ways to express humidity:

1. The *vapor pressure* is that part of the total pressure contributed by the water vapor.
2. The *absolute humidity* (or vapor concentration or vapor density) is the mass of water vapor per unit of volume. Effects of temperature and pressure are, except near saturation, according to gas laws.
3. The *relative humidity* is the ratio of the actual vapor pressure and the saturation vapor pressure at the prevailing temperature. It is usually expressed as a percentage. Since the maximum water vapor pressure depends on temperature, the relative humidity (r.h.) also depends, at a given water content, on temperature. At constant temperature and a given water content, the r.h. is, according to the equation for P mentioned above, dependent on total pressure.
4. The *dewpoint temperature* is the temperature to which a gas must be cooled, at constant pressure, to achieve saturation. When the condensate is ice, it is called *frost-point*. It is, with unchanging composition of the gas, independent of temperature. It changes with pressure since $P_{\text{H}_2\text{O}}$ is proportional to P . Of course, condensation will occur if saturation vapor pressure is reached.
5. The *mixing ratio* is the mass of water vapor per unit mass of dry gas, usually expressed in grams per kilogram. If the ratio is related to a unit mass of humid air, it is called the *specific humidity*.
6. The *mole fraction* is the ratio of the number of moles of a component to the total number of moles present.

Conversions between the different parameters used to be cumbersome. They are now becoming standard since the introduction of the microprocessor.

Concentrations of water in a *liquid* or a *solid* are normally given in kg/kg. Except in soil physics, volumetric units are rarely used. The expression *equilibrium relative humidity* (e.r.h.) refers to a condition where there is no net exchange of water vapor between a moisture-containing material (paper, medicines, foodstuffs, tobacco, seeds, etc.) and its environment. It is the equivalent for *water activity*, a_w , used in the fields of biology or food technology, generally expressed as a ratio rather than a percentage (i.e., 0.6 instead of 60%).

It is probably difficult to find a material that is inert to water molecules and with which it would be impossible, with some physical method, to measure the presence of water. Water molecules change the length of organic materials, the conductivity and weight of hygroscopic materials and chemical absorbers, and in general the impedance of almost any material. Water absorbs infrared as well as ultraviolet radiation. It changes the color of chemicals, the refractive index of air and liquids, the velocity of sound in air or electromagnetic radiation in solids, and the thermal conductivity of gases as well as that of liquids and solids. More fundamentally, the water content can be measured by removing the water (vapor) from the sample and measuring the change of weight (or the change of pressure in a gas). Other fundamental principles are the evaporation from a water surface into the stream of sample gas (*psychrometer*) and the cooling of the gas sample until condensation is detected. Microwave absorbance, the measurement of capacitance and nuclear magnetic resonance have found application in the measurement of moisture in liquids and solids.

After an engineer has decided which parameter has to be measured, he has to realize a few things [5].

First, what is the minimum range of operation required? Over-specification can be expensive. Besides, instruments suitable for drying processes at high temperatures and, at the same time, trace detection of water vapor in dry gases do not exist.

Second, unlike a temperature sensor, a humidity sensor can, at least in air, essentially not be shielded from its direct environment. The question of how to measure humidity cannot be separated from the measuring problem in question (contamination, condensation, etc.). A question might be: is there a danger of condensation before or after the period of real measurement?

Third, the accuracy that may be expected in the field of hygrometry is considerably lower than that in other fields of measurement. One should be careful not to ask or to expect accuracies better than 2% or 3% r.h. or 0.5°C in dewpoint. Before deciding to use a certain method or to buy a particular instrument, it is very useful to go once more through things like humidity as well as temperature and pressure range, possible contaminants in the process, and accuracy and response time really needed. After this a consideration of frequency of service and calibration, cost of sensor replacement, etc. has to be made. At the end, it is sensible to find a supplier or manufacturer that is willing to think along with the customer. [Table 72.1](#) provides a selective listing of the methods, ranges, and manufacturers for measuring humidity and moisture. The methods are discussed below.

72.1 Gases

There are several methods of measuring humidity, the most important of which are described here. The scope of the present survey is limited. More can be found in the literature [6,7,8,9,10]. Reference 9 covers measurement in liquids and solids as well.

The Gravimetric Method

The gravimetric method is the most fundamental way of accessing the amount of water vapor in a moist gas. In a gravimetric hygrometer, the water vapor is frozen out by a cold trap or absorbed by a chemical desiccant and weighed, while the volume or the mass of dry gas is measured directly. Since the result of a measurement gives the average value over an extended time, the instrument is used in combination with a humidity generator, capable of producing a gas of constant humidity. The method is used for primary standards of, among others, NIST in the U.S., NPL in the U.K., and NRLM in Japan. Achievable accuracies are approximately 0.1% to 0.2% in mixing ratio, or 0.04°C in the range of -35°C to +50°C dewpoint, increasing to 0.08°C at +80°C and 0.15°C at -75°C. The operation of such a standard requires high skill and sophisticated hardware.

Precision Humidity Generators

For less elaborate calibration work, a precision humidity generator is preferred. The best ones are reported to have an accuracy comparable to that of a gravimetric standard [11]. Therefore, such a generator may be considered as a primary standard as well. Three practical methods to produce an atmosphere of known humidity are described by Hasegawa [12]: the two-flow, the two-temperature, and the two-pressure method. Briefly, in the first method, a test chamber is fed by two streams of air, one being dry, the second one saturated with water at a known temperature. The resulting humidity can be calculated from the two flow rates. The two-temperature method uses air that has been saturated with water vapor at a well-known temperature, after which the air is heated to a higher temperature. In the two-pressure method, air is saturated with water vapor at an elevated pressure, and expanded isothermally to a lower, normally atmospheric pressure. Both temperature and pressure of the saturator and the test chamber are measured accurately. In general, precision generators are not transportable, so intercomparisons have to be made with a transfer standard of high accuracy. A good, if not the only, choice is a standard mirror dewpoint meter.

The Condensation Dewpoint Hygrometer

The saturation vapor pressure in air increases with temperature (Figure 72.1). This means that the air under test can be cooled to a temperature where it is just saturated with water vapor. If this is done at constant pressure and specific humidity, the true dewpoint temperature is obtained. In practice, a sample of the gas is usually drawn over a thermoelectrically cooled metal mirror. The mirror is cooled until dew or frost is detected, by optical means. In some cases, where the mirror is replaced by an inert substrate, the formation of dew is detected by electrical means or the use of surface acoustic waves. The temperature is maintained such that the thickness of the deposit is neither increasing nor decreasing. The highest accuracy of a transfer standard can be expected to be 0.03°C to 0.05°C in the range of -20°C to +40°C dewpoint. Industrial optical condensation dewpoint hygrometers claim accuracies up to 0.2°C, which may be true in case of a clean mirror; in practice 0.5°C is often more realistic. Advantages of this principle are its fundamental nature and the wide range: dewpoints to 90°C under ambient temperature can be measured. One of the disadvantages is the susceptibility of the mirror to contaminants, especially soluble salts. The sensor may measure the dewpoint of another condensable vapor if its dewpoint is above that of the water. A good control of the mirror temperature requires a temperature difference between dewpoint and ambient temperature of the sensing head. This means that at high relative humidities, the gas must be heated and measured outside the process stream. At temperatures below 0°C, there may be

FIGURE 72.1 Saturation water vapor pressure above pure water and above a saturated solution of lithium chloride. In order to be in equilibrium with a gas sample at condition **a**, a saturated solution of LiCl has to be heated to temperature **b**. A free water surface must be cooled to a temperature **b**, as is the case in a mirror dewpoint hygrometer.

supercooled water instead of ice on the mirror. Observations have shown that below -25°C , the deposit will usually be ice. As the saturation vapor pressures over water and ice differ, one has to know the nature of the condensed layer; thus, for accurate measurements, a microscope is required. A rule of thumb is that the difference between water and ice on the mirror means a difference in dewpoint of one tenth of the temperature in degrees Celsius below zero, the dewpoint above water being the lower. Where low water content has to be measured, special attention should be given to the material and cleanliness of the pipes used. Stainless steel, polished at the internal surface, is to be preferred. The lower the moisture content, the more significant the effects are (Figure 72.2).

The Psychrometer

Two thermometers are ventilated with the gas of unknown humidity. One sensor, the dry bulb, measures the gas temperature t . The other sensor, the wet bulb, is surrounded by a wick saturated with pure water. The energy required to evaporate water into the air stream cools the wet bulb to a temperature t_w . The vapor pressure e in the sampled gas is calculated with the psychrometer equation:

$$e = e_w - A \cdot P \cdot (t - t_w) \tag{72.2}$$

where e_w is the saturated vapor pressure at temperature t_w , P is the total atmospheric pressure, and A is the psychrometer coefficient. A depends on ventilation speed, dimensions of the wet bulb, and radiative

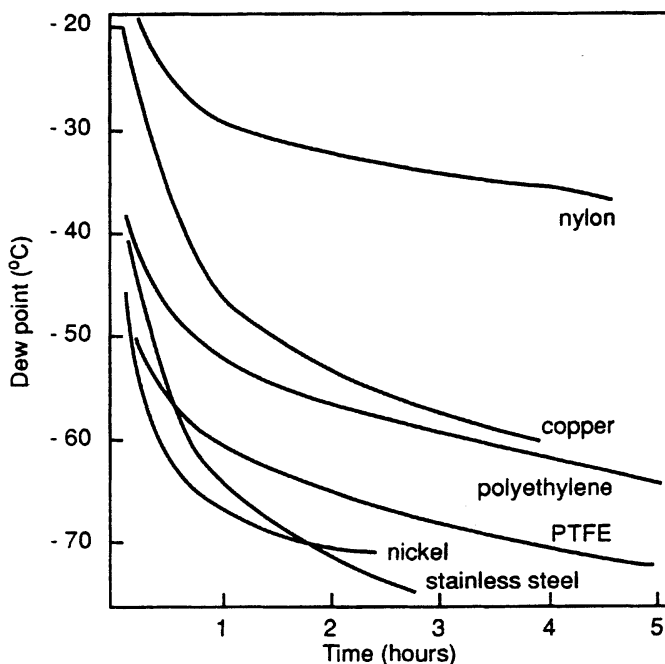

FIGURE 72.2 Illustration of the moisture given off by different tubing materials when flushed with very dry gas after being at ambient humidity. (From Reference 8.)

heat exchange between both dry and wet bulbs and their surroundings. The attractiveness of the psychrometric method lies in the fact that it is a direct and relatively simple method, with a theoretically strong basis. The accuracy of the method is determined by the accuracy of both dry and wet bulb sensors, the maintenance of a minimum ventilation speed, and a clean wick. With a ventilation speed of more than 3 m s^{-1} and a bulb diameter of 3 mm to 5 mm, A can, according to recent investigations, be assumed to be $(6.35 \pm 0.15) \times 10^{-4} \text{ }^{\circ}\text{C}^{-1}$, for Assmann-type psychrometers with a polished internal screen as well as sensors in a transverse air stream in a “black” radiation environment [13,14]. The radiation environment for axially ventilated psychrometers is of crucial importance. Especially when $t-t_w$ is measured directly the psychrometer is the preeminent instrument to measure near or at 100% r.h. The principle can be used up to a wet bulb temperature of 100°C at atmospheric pressure; dry bulb temperature may exceed 100°C (up to 165°C , Ultrakust, Germany). Depending on the dry bulb temperature, the wick may have problems with water supply at strong evaporation. Frozen wet bulbs, already possible at ambient temperatures below 9°C , can also lead to problems. Generally, this method adds water vapor to the atmosphere, which might be undesirable in specific applications.

Mechanical Hygrometers

Although mechanical hygrometers are losing ground, they are still widely used, mainly in room conditions. The principle relies on the elongation with r.h. of mainly human hair, textiles, or plastic fibers, the effect of which can be amplified mechanically to move a pen on a recorder. The best accuracy is 2% to 3% r.h. (for hair, in the range between 35% and 95% r.h., if regenerated at regular intervals); in general, it is wise not to expect better than 5% r.h. In the case of hair, one must be aware of the fact that the hair may be in a state different from that during calibration. Hair exhibits a dry and a wet curve; the transition takes place below 35% r.h. Once at the dry curve, the instrument may read to 20% r.h. too high if it was calibrated at the wet curve as is usually done. If the instrument is kept overnight under a wet cloth, the wet curve calibration will be re-established. The response time strongly depends on temperature: it ranges from a few minutes at 20°C to 20 or 30 min at -10°C . Temperature limits are -60°C to $+90^{\circ}\text{C}$.

TABLE 72.2 Equilibrium Relative Humidities (%)
Over Some Saturated Salt Solutions

Salt	Temperature (°C)			
	10	20	30	40
LiCl	11.3	11.3	11.3	11.2
MgCl ₂	33.5	33.1	32.4	31.6
Mg(NO ₃) ₂	57.4	54.4	51.4	48.4
NaCl	75.7	75.5	75.1	74.7
KCl	86.8	85.1	83.6	82.3
K ₂ SO ₄	98.2	97.6	97.0	96.4

Although the initial costs of a mechanical hygrometer are low, the long range costs of calibration and maintenance are considerable.

The Lithium Chloride Dewpoint Meter

Addition of a hygroscopic soluble salt to pure water decreases the equilibrium saturation vapor pressure above the solution (*Raoult's law*). In Figure 72.1, this change is illustrated for a saturated lithium chloride solution, which has an equilibrium relative humidity of about 11% (see Table 72.2). A gas sample at condition *a* is in equilibrium with a saturated LiCl solution of a (higher) temperature *b*. (It is also in equilibrium with pure water at a lower temperature *c*; note the similarity with a mirror dewpoint meter.) The application of this principle led to a simple and effective sensor. A fabric sleeve over a bobbin with a bifilar winding of inert electrodes is coated with a dilute solution of lithium chloride. As the bobbin is heated by an alternating current, its resistance increases sharply at the point where the surface begins to dry out, the heating stops, the sensor begins to cool, attracts water vapor, etc., until an equilibrium temperature has been reached. This is measured by, for example, a resistance thermometer sensor in the bobbin. The sensor is simple, rugged, relatively cheap and, after some calamity, it can be reactivated by recoating it. The dewpoint range goes from -40 to $+90^{\circ}\text{C}$, with a claimed accuracy of about 0.5°C . This estimate is often too optimistic because the influence of ambient temperature cannot be neglected. Moreover, LiCl has hydrates with one, two, three, and five molecules of water per molecule of salt. In the dewpoint regions between 34°C and 41°C , the ambiguity leads to a possible error in that area of up to 1.5°C in dewpoint. Below -12°C , the error can rise to 3.5°C . Low flow rates can cause stratification around the sensing surface, high rates can cool it too much, resulting in too high and too low readings, respectively. Flow rates somewhere between 0.05 and 1 m s^{-1} are generally recommended. Response times of commercially available sensors are on the order of minutes. Disadvantages include: the lower limit lies at 11% relative humidity, the sensor is washed out by accidental immersion, and the power supply should not be turned off accidentally. From an ionic standpoint, the sensor can be considered precontaminated and therefore, according to the manufacturer [5], relatively insensitive to contamination. Another source [9] reports a number of gases, like sulfur vapors, ammonia, high concentrations of carbon dioxide, chlorine, hydrogen sulfide, and condensable hydrocarbons, that could attack the lithium chloride sensor.

Electric Relative Humidity Sensors

Talking about numbers, the category of electric r.h. sensors is certainly by far the greatest part. The sensors are generally small, fast responding, do not dissipate heat, and can be used in confined spaces. Until 1975, the rights in this field were almost exclusively claimed by two resistance types: the Dunmore and the Pope sensor. The Dunmore sensor uses a dilute lithium chloride solution in a polyvinylacetate binder on an insulating substrate, with the danger of washout at saturation. The resistance of the sensor, measured between a bifilar grid, is a function of the r.h. of the surrounding air. This also applies to the Pope sensor, where a polystyrene substrate itself is the sensitive part of the sensor, after treatment with sulfuric acid. This sensor is less sensitive to washout, and has a wider range (15% to 99% r.h.) than the

Dunmore type. Modern bulk sensors, based on the measurement of the change in resistance, are manufactured by, for example, Shinyei Kaisha and Elmwood Sensors. Since 1970 a lot of work has been done in the development of capacitive sensors, where the stability, the influence of temperature, the temperature range, and the susceptibility for condensation conditions could be greatly improved. Since the 1980s, this sensor type has surpassed the mentioned resistance types. Basically, this type of sensor consists of a thin polymer layer between two electrodes of various materials. The types differ mainly in polymer type and electrode material, resulting in sensors with different characteristics to withstand pollution and temperatures up to 190°C. A drawback that still seems not completely under control is the fact that a polymer swells at high humidities, causing an undesirable shift in capacitance of the sensor.

Aluminium Oxide Hygrometers

Briefly, a sheet or wire of aluminium is anodized, producing a thin layer of water-sensitive pores. Subsequently, a conductive, water-permeable gold film is deposited over it. The radius of the pores is such that the sensor is specific for water molecules, and the amount absorbed is directly related to the dewpoint of the gas. The dewpoint range goes from -110 to 20°C, measured as a change in capacitance between the aluminium base and the gold electrode. The sensor works up to high pressures (30 MPa). The response time depends on the dewpoint, ranging from seconds at 10°C to minutes below -40°C. Stated accuracies are $\pm 1^\circ\text{C}$ at higher dewpoints to $\pm 3^\circ\text{C}$ at -100°C. The sensors show slow drift, and recalibration at least twice a year is generally recommended. Where chemical attack of the aluminium can be expected, silicon capacitive type sensors may be an alternative. A commercially available type of MCM (Moisture Controls & Measurement Ltd., U.K.) is temperature controlled, and has a very short response time: less than 15 s to a level of 1 ppm. Both aluminium and silicon sensors can withstand immersion in water.

Coulometric Method

In an electrolytic hygrometer, water in a sample stream is quantitatively absorbed by a phosphorous pentoxide layer. At the moment water molecules are present, the probe becomes electrically conducting. With a dc voltage over the sensor, water is electrolyzed and, according to Faraday's law, a current with a well-defined magnitude occurs ($1 \text{ mA} \triangleq 0.0935 \mu\text{g H}_2\text{O/s}$). For the measurement of the mixing ratio, the flow through the cell must be measured accurately. Further calibration is, in principle, not necessary. At higher flow rates and moisture content (3000 ppm to 10,000 ppm by volume), the water vapor may not be absorbed quantitatively, so this method is especially suited for low water contents, beginning at 1 ppm. The response time is about 1 min. Typical measurement uncertainties are 10% at 1 ppm, decreasing to 5% at higher values.

Crystal Oscillator

Even lower concentrations (down to 0.02 ppm by volume) can be detected with a hygroscopic coating on the surface of a quartz crystal. The resonant frequency of the crystal is a function of the mass of the coating — in other words, the moisture content of the gas. The crystal is alternately exposed to dry and humid gas, and the shift in frequency is measured. The response time is 1 min. Typical measurement uncertainty is 1 ppm or 5%. The instrument is relatively expensive (Du Pont).

Infrared Methods

Like any heteroatomic gas, water vapor absorbs radiation in the infrared region. So, if the gas is led through the optical path between an infrared source and a detector, there is a reduction of the transmitted radiation. The source can be dispersive, that is, generated by a monochromator, or nondispersive, wide-band radiation, generated by a heated tungsten or nichrome wire. In the monochromatic mode, the transmittance ratio at two different wavelengths is measured. In the nondispersive (NDIR) method,

usually another path through a reference gas is taken. The detector can be gas-filled, solid-state, or pyroelectric, with adequate optical or gas filters in the right wave bands. A popular detector was and still is the Luft type. A Luft detector has two radiation-absorbing chambers containing the specific gas of interest, separated by a thin membrane. Since the detector is a dynamic device, the radiation paths are chopped, allowing the measurement of the change in capacitance. This method allows measurement over a wide range, from ppm level up to saturation. It can be used in corrosive gases, the concentration of which can be measured simultaneously by the use of another detector. The instrument must be calibrated at regular intervals; typical measurement uncertainty is 1%. Response times to less than 1 s are possible, depending on the attainable refreshment time in the measuring chamber. Since the absorption depends on the number of atoms, transmittance depends on pressure. The method used to be relatively expensive, even compared with a mirror dewpoint meter, but developments in the field of inexpensive semiconductor detectors and better optical filters have reduced prices. Further developments are going on in the direction of fiber-optic probes.

Miscellaneous Methods in Air

- The zirconia cell, acting as a battery on the presence of oxygen ions, is generally used in a mixture of air and steam. The sensor can be mounted directly in a hot gas stream (600/1700°C). Acceptable accuracies are reached at dew points of 70°C or higher.
- The frequency of a signal, generated by an acoustic source, depends on the mixing ratio. Measurements in gases up to 250°C, to dewpoints of about 70°C (0 to 30 vol.%, in special cases to 100 vol.%, Mahlo).
- The Lyman alpha hygrometer uses the 121-nm emission line of hydrogen, which is strongly absorbed by water vapor. Extremely small response times (milliseconds) can be obtained. The instrument is relatively expensive.
- The difference in thermal conductivity of dry and wet air allows the measurement of absolute humidity with two sensitive temperature sensors in a Wheatstone bridge (Shibaura).

72.2 Liquids and Solids

Gravimetric

Drying of a material at a controlled temperature and taking the difference in weight before and after drying is the most fundamental method, greatly improved by microprocessor-based instruments. The assumption is that the loss in weight is caused by water only and that no other volatile components have been removed. Another problem can arise if water present by surface adsorption or crystal water is removed.

Karl Fischer Method

A chemical method for the determination of water in solids and organic solvents is the Karl Fischer method. The Karl Fischer reagent is composed of iodine, sulfur dioxide, pyridine, and methanol. Addition of this reagent to water causes a chemical reaction in which, in excess of the other components, one mole of iodine is used for each mole of water. The reagent is added in a controlled way to a mixture of reagent and sample, while a current between two electrodes is measured. If all the water has been used, a sudden change in the current through the mixture is observed.

Infrared Techniques

The infrared technique is applied to liquids and solids as well, in the wavelength bands of 1.45, 1.94, and 2.95 μm . For liquids, the transmission mode described is used, leading to particular problems because of the small optical path needed. Even smaller transmittance paths would be necessary for solids, one of

the reasons to choose reflectance from the surface as a measure for water content. The surface has to be representative for the material in question. The system needs to be calibrated for each material. Concentrations as low as 0.02% to 100% can be measured. In case of specular reflection, the method cannot be used. A relatively new development is the attenuated total reflectance crystal (ATR) method. The crystal is inserted in the liquid, which may be opaque or semiopaque, or a slurry. A beam with two wavelengths, for reference and measurement entering the crystal is reflected on the internal surface, penetrating the solution one-half wavelength at each reflection point. The amplitude of the reflected signal decreases at each reflection. The number of reflections is determined by the length of the crystal and the angle of incidence, so the sensitivity can be changed. The measuring range is claimed 0% to 100% water in solutions; measuring water in emulsions requires some precautions. The response time is negligible.

Microwave Absorbance

Microwave absorbance is generally used in materials with a more or less constant composition, apart from the moisture content. Microwave radiation from a low-power, solid-state generator is absorbed by the sample and detected by a solid-state detector. The commonly used frequencies where water strongly absorbs are 1 to 2 GHz and 9 to 10 GHz, the latter being less dependent on the composition of the material. Operating ranges from 1% to 70% of water are mentioned, with achievable accuracies of $\pm 0.5\%$ of water. The attenuation is influenced by bulk density, bulk material, and temperature. The path between source and detector should not contain any metallic material.

NMR

Hydrogen atoms in the field of a permanent magnet are allowed, according to quantum mechanics, to have some defined orientations in that field. To shift an atom from one orientation to another requires a defined amount of energy, dependent on the strength of the magnetic field. If electromagnetic radiation at the right frequency is applied, resonance of the hydrogen atoms occurs, and a loss in frequency power can be detected. It is specific for all hydrogen atoms, so interference with liquids other than water in the sample can be expected. Temperature and flow must be controlled. Magnetic materials must be avoided. Measuring ranges of 0.05% to 100% have been reported [9].

Neutron Moderation

This method is, like NMR, specific to hydrogen atoms. Neutrons of high energy are slowed by nuclei of hydrogen atoms. The main components are a detector of slow neutrons, next to a source of fast neutrons. The measuring range goes from 0.5%. The sensor can be made very rugged. The measured volume is a sphere of up to tens of centimeters in diameter. The method is dependent on the bulk density of the material, but largely independent of the properties of the material being analyzed [9]. The method is not suitable for foodstuffs. It suffers from necessarily severe government regulations and low acceptance by the public and the operator.

TDR

Time domain reflectometry (TDR) measures the propagation velocity of electrical pulses, mainly between 1 MHz and 1 GHz. This method is well established, especially for the measurement of water content in soil. With certain limitations, it is proven suitable for automatic installations. The main disadvantage is the complexity of the data analysis [15].

FD

The general features of the FD (frequency domain) technique are comparable to those of TDR; however, there are some important differences. The dielectric properties of the material (soil, concrete, grain, oil,

etc.) can be measured at a single frequency. The ability to choose a whole range of frequencies makes the frequency domain (FD) sensor suitable for spectroscopic measurements. A sensor of this type has recently been developed by IMAG-DLO, Wageningen (The Netherlands). It is simple and inexpensive, and available for many purposes. The sensor uses a single application-specific integrated circuit (ASIC) and is suitable for the measurement of other properties of materials as well [15].

Measurement of Thermal Conductivity

The thermal conductivity of a material is related to the amount of water it contains. Heat pulses are supplied by a needle probe, and the cooling of the needle after ending the pulse is measured. It is a simple and inexpensive method, that needs calibration for the material in which it is going to be used.

Water Activity or Equilibrium Relative Humidity

A material enclosed in a measuring chamber is, after some time, in equilibrium with its environment. The moisture content of the material can be derived from the so-called adsorption isotherms for that specific material, which must be determined experimentally. The method is used for many materials, such as foodstuffs, chemicals, grains, seeds, etc., with electric humidity sensors described earlier. In cases where the water potential of living material like potatoes and leaves must be measured, thus at very high relative humidities, the junction of a small thermocouple is cooled by an electric current and, after the current has been turned off, used as an unventilated wet bulb psychrometer. It is an excellent method that requires skill.

72.3 Formulae

A relatively simple equation for the calculation of the saturation vapor pressure $e_w(t)$ in the pure phase with respect to water is the *Magnus formula*:

$$\ln e_w(t) = \ln 611.2 + 17.62t / (243.12 + t) \quad (72.3)$$

where t is the temperature in °C (on ITS-90) and $e_w(t)$ is in pascals. Equation (72.3) covers the range between -45°C and +60°C, with a maximum standard deviation of 0.3%. Over ice Equation (72.3) changes to:

$$\ln e_i(t) = \ln 611.2 + 22.46t / (272.62 + t) \quad (72.4)$$

covering the range between -65°C and 0°C with a standard deviation of less than 0.5%.

Equation 72.3 can easily be converted for the calculation of the dewpoint t_d :

$$t_d = \left[243.12 \ln(e/6.112) \right] / \left[17.62 - \ln(e/6.112) \right] \quad (72.5)$$

where e is the saturation vapor pressure e_w at dewpoint temperature t_d . The standard deviation in the range mentioned is less than 0.02K. The *frost point* t_f can be calculated from Equation 72.6:

$$t_f = \left[272.62 \ln(e/6.112) \right] / \left[22.46 - \ln(e/6.112) \right] \quad (72.6)$$

where e is the saturation vapor pressure e_i at frostpoint temperature t_f , in the range mentioned within a standard deviation of 4 mK.

More accurate formulae, given by Hyland and Wexler, updated by Sonntag can be found in Reference 7. The uncertainties mentioned above, given by Sonntag [7], are valid for the pure water system. In the presence of air, the uncertainties can only be maintained if the water vapor enhancement factor is taken into account.

72.4 Calibration

A few words about calibration, a most important and too often forgotten subject in humidity and moisture measurement. The gravimetric method has already been described, as well as some principles of humidity generators, which could be used as standards. Another method is the humidity chamber, with both temperature and humidity control, where an instrument is compared with a calibrated standard instrument like a mirror dewpoint meter or a psychrometer. Saturated (or diluted) salt solutions can be used to create a constant relative humidity in a confined space. Some values are listed in Table 72.2 (from Reference 16). The user should have knowledge of some critical factors like temperature, etc. for the application of this method. Permeation tubes are used where a repeatable, accurate, and low concentration flow is required. Unlike with temperature or pressure sensors, it is, except at the highest national level, not realistic to expect a reference or standard for humidity with an accuracy a factor 5 or 10 times better than the required accuracy for a measuring instrument. A good calibration guarantees traceability to a higher standard. This means, in general, that the calibration should be performed by a national or accredited laboratory. A rule of thumb for the intervals of calibration of humidity meters is as follows: condensation dewpoint meters and psychrometers require calibration once every 1 to 2 years; electric relative humidity sensors need calibration every 6 to 12 months; and less stable types like aluminium oxide sensors must be calibrated every 6 months, or sooner if desired [8]. A comprehensive treatment of calibration of hygrometers and attainable accuracies has been given by Wiederhold [10].

72.5 Developments

- Fiber optics are beginning to find their way in hygrometry, resulting in explosion-proof models. Changes in refractive index by the use of micropores are used in an instrument recently developed by Ultrakust (Germany). Fiber lengths go to 1000 m. The measuring range is 0% to 20% r.h. in a dewpoint range of -90°C to 20°C .
- A rapidly developing field is that of the monolithic integrated circuit sensors. Hycal (U.S.) manufactured a capacitive relative humidity sensor, while a recent commercial development in Germany reports the use of a monolithic integrated sensor instead of a mirror in a miniature dewpoint meter, with an accuracy of better than 0.5°C . Since the use of porous silicon allows the development of smart sensors, developments in that area will undoubtedly continue [17].
- The progress in the theoretical background of many water-related processes, made possible by an advanced FD sensor mentioned earlier, is of great importance for future development of simple, cheap, stable, and reliable sensors that can be used for many purposes.

73.1 Meteorological Measurement

John D. Garrison and Stephen B. W. Roeder

Meteorological measurements are measurements of the physical properties of the atmosphere. These measurements are made at all elevations in the troposphere and the stratosphere. For measurements made at elevations above ground or tower level, instruments can be carried aloft by balloons, rockets, or airplanes. Ground radar is used to detect the presence of water in the form of droplets or ice crystals at all elevations and the winds associated with them. Lidar (optical radar) of selected wavelengths is used to detect the presence and amount of aerosols and other constituents of the atmosphere and to determine cloud height. Instruments on satellites measure properties of the atmosphere at all elevations.

Quantities measured are: temperature, pressure, humidity, wind speed, wind direction, visibility, the presence and amount of precipitation, cloud amount, cloud opacity, cloud type, cloud height, broadband solar (or shortwave) radiation, longwave radiation, ultraviolet radiation, and net radiation, sunshine duration, turbidity, and the amounts of trace gases such as NO, NO₂, SO₂, and O₃. Some of the methods and instruments used to measure a number of these variables are discussed in this handbook in sections on pressure, temperature, humidity and moisture content, and air pollution monitoring. Additional information of interest is in sections on resistive sensors, inductive sensors, capacitive sensors, satellite navigation and radiolocation, and the sections under signal processing.

Meteorological measurements are made at individual sites, at several or many sites forming a local network, or at much larger networks. Much of the emphasis now is on global networks covering the entire northern and southern hemispheres. Individuals and groups can make measurements for their own purposes or they can use data provided by the various weather services. Weather service data are

stored in archives that can cover many years of measurements. The U.S. National Climatic Data Center, Asheville, NC, has archived data produced from measurements at U.S. weather stations and other National Oceanic and Atmospheric Administration (NOAA) measurement sources, including satellites. It also has non-U.S. data. These data can be purchased. The Web site where information concerning NOAA data can be obtained is: <<http://www.ncdc.noaa.gov/>>. The U.S. National Renewable Energy Laboratory has information on solar radiation and wind at Web site: <<http://www.rredc.nrel.gov/>>. Data at Web sites can often be retrieved by anonymous File Transfer Protocol (FTP).

Fabrication of meteorological instruments is usually done by companies specializing in these instruments. It is generally not economically feasible for individuals to fabricate their own instruments, unless their particular application cannot use commercially available instruments. The problem usually reduces to the determination of which commercial instruments to purchase. This determination depends on cost, durability, accuracy, maintenance requirements, ease of use and the form of the output signal. A number of instrument manufacturers and distributors market complete weather stations.

The instruments used for meteorological measurements are fabricated for use in the special environment of the atmosphere. This environment varies with the latitude and longitude of the site and the elevation above the ground and above sea level. A common requirement is that the instruments be protected from adverse conditions that can cause errors in the measurement of the meteorological variables. For proper operation, some instruments (e.g., spectroradiometers) need to be in a temperature-controlled environment. The sun's heating can cause errors. Solar radiation can cause weathering of the instruments and shorten their useful life. Moisture from precipitation or dew can affect measurements adversely and also cause weathering and corrosion of the instruments. Blowing dust or sand can cause weathering of the instruments and affect the operation of mechanical parts. Insects, birds, and ice can also affect instruments adversely. Some gaseous constituents of the atmosphere can be corrosive. Packaging of the sensors and housing of the instruments in enclosures can protect them, but this protection must not interfere with the measurement of the meteorological variable. Packaging a sensor and putting the sensor in protective housing generally increases the response time of the sensor to changes in the meteorological variable it is measuring. Solar heating can be reduced by covering the sensor, its protective packaging, or housing with a white coating. Generally, housing or enclosures used to protect the instruments should be well ventilated. Sometimes a fan is used to draw air through the housing or enclosure to reduce solar heating and make the air more representative of the outside air. Loss of measurement caused by loss of electric power can be avoided by having backup power from batteries or motor-generators.

Another common requirement of meteorological measuring instruments is that they be calibrated before installation in the field. This is usually done by the manufacturer. For some applications, it may be important that the calibrations are traceable to NIST (National Institute of Standards and Technology) standards. The calibration should be checked routinely. Some instruments are constructed to be self-calibrating.

Generally, there is no reason to measure many of the meteorological variables to high precision. The temperature, humidity, and wind, for example, can vary in relatively short distances and sometimes in relatively short times by amounts that are large compared to the accuracy of the measuring instruments. This is especially true near ground level. The exact value of a meteorological variable at a particular site has little meaning unless the density of measuring sites is very high. A mesoscale network with high density of measuring sites over a relatively small area might be of interest for ecological studies. Larger-scale or global networks have widely separated sites. For these networks it is important to install all of the instruments in a standard manner so as to reduce the effect of local fluctuations on the variation of the meteorological variables from site to site. Usually, this is done by placing them on a level, open area away from surrounding buildings and other obstructions and at a fixed distance above the ground. The ground should be drained ground and not easily heated to high temperature by the sun. In comparing temperatures, one must be aware of the "heat island effect" of large cities; furthermore, an increase in the degree of urbanization of a given site over time may affect the interpretation of the temperature trends observed.

The current trend is toward automatic measurement of meteorological variables at unattended sites with automatic data retrieval and computer processing and analysis of the data. Large-scale networks

consisting of many stations covering a large area (e.g., the Northern Hemisphere) are used for regional, national, and global weather forecasting.

Measurement of the Atmospheric Variables

Temperature

The mean temperature of the atmosphere for each hour of the day at a particular site has a fairly regular annual and a diurnal variation when this mean temperature is an average over many years for each hour and day of the year. The temperature at a given site and time is a superposition of the mean temperature and the fluctuations from this mean temperature caused by current cloud and wind conditions, the past history of the air mass passing over the site, and interannual variations that are not yet well understood.

More detailed sources of information on temperature measurement include the earlier section in this handbook on temperature measurement and References 1 through 5. The common methods of measuring atmospheric temperature include the following:

Electric Resistance Thermometer (RTD).

The variation of the resistance of a metal with temperature is used to cause a variation in the current passing through the resistance or the voltage across it. The electric circuit used for the measurement of temperature can utilize a constant current source, and temperature is determined from the voltage across the resistance after the circuit is calibrated. Alternatively, a constant voltage source can be used with the current through the resistance determining the temperature. Once the instrument is calibrated, it is generally expected to keep its calibration as long as electric power is supplied to the instrument. Commonly, platinum RTD thermometers are made of a fixed length of fine platinum wire or a thin platinum film on an insulating substrate. The variation of the resistance as a function of temperature is approximately linear over the range of temperature found in meteorological measurements. The quadratic correction term is quite small. The accuracy and reproducibility of the measurements and the ease of using an electric signal for transmission of data from remote unmanned sites makes electric resistance thermometers desirable for meteorological applications. Platinum is the best metal to use. With careful calibration and good circuit design, platinum resistance thermometers can measure temperature to a small fraction of a degree, much better than the accuracy needed for meteorological measurements.

Thermistors.

Thermistors usually consist of an inexpensive mixture of oxides of the transition metals. The log of their resistance varies inversely with temperature. The change in resistance with temperature can be 10^3 to 10^6 times that of a platinum resistance thermometer. Their change in resistance with temperature is used to determine temperature in the same manner as metal resistance thermometers. They are somewhat lower in cost and are somewhat less stable than platinum resistance thermometers.

Bimetallic Strip.

Bimetallic strips are discussed elsewhere in an earlier section. They are usually used for casual monitoring of inside and outside temperatures at dwellings and office buildings and for heating and cooling controls. The accuracy is generally about $\pm 1^\circ\text{C}$. They are low in cost.

Liquid in Glass Thermometer.

These are a well-known method of measuring temperature. They are usually used for casual monitoring of inside and outside temperatures at dwellings or office buildings. These thermometers are more difficult to read than meter or dial readings of temperature, do not lend themselves to electric transmission of their readings, and are easily broken. Their cost can be low.

Pressure

One standard atmosphere of pressure corresponds to 1.01325×10^5 pascals (N m^{-2}) (14.6960 pounds per square inch, 1.01325 bars, 1013.25 mbars, 760.00 mm Hg, or 29.920 in. Hg). This is approximately the mean atmospheric pressure at sea level. Atmospheric pressure at sea level usually does not deviate more

than $\pm 5\%$ from one standard atmosphere. Atmospheric pressure decreases with altitude. Altitude measurements in airplanes are based on air pressure measuring instruments called altimeters. At about 5500 m (18,000 ft), the atmospheric pressure is half its sea level value. The following instruments are used to measure atmospheric pressure.

Mercury Manometer

Originally, barometric pressure was measured with a mercury manometer. This is a tube, about 1 m in length, filled with mercury and inverted into an open dish of mercury. The height of the column of mercury that the external pressure maintains in the tube is a measure of the external air pressure. Hence, one standard atmosphere is 760 mm Hg. While accurate, this device is awkward and has been replaced for general use.

Aneroid Barometer.

It consists of a partially evacuated chamber that can expand or contract in response to changing external pressure. The evacuated chamber is often a series of bellows, so that the expansion and contraction occurs in one dimension. Basic aneroid barometers, which are still in use, have a mechanical linkage to a pointer giving a reading on a dial calibrated to read air pressure. High-quality mechanical barometers can achieve an accuracy of 0.1% of full scale. Aneroid barometers can also give electronic readout and eliminate the mechanical linkage; this is more the standard for serious meteorological measurements. In one method, a magnet attached to the free end of the bellows is in proximity to a Hall effect probe. The Hall probe output is proportional to the distance between the magnet and the Hall probe.

Barometric pressure is also measured with an aneroid type of device that consists of a rigid cylindrical chamber with a flexible diaphragm at its end. A capacitor is created by mounting one fixed plate close to the diaphragm and a second plate mounted on the diaphragm. As the diaphragm expands or contracts, the capacitance changes. Calibration determines the pressure associated with each value of capacitance. A range of 800 to 1060 millibars with an accuracy of ± 0.3 millibars for ground-based measurements is typical. Setra Corporation produces this type of instrument for the U.S. National Weather Service ASOS network, the latter produced by AAI Systems Management Incorporated. The ASOS network is discussed below. Measurement of pressure is also discussed elsewhere in this handbook.

Humidity

Instruments that determine the density or pressure of water in vapor form in the atmosphere, generally either measure relative humidity or they measure dewpoint temperature. The pressure of water vapor just above a liquid water surface when the vapor is in equilibrium with the liquid water is the saturated vapor pressure of the water. This saturated vapor pressure increases with the temperature and equals atmospheric pressure at the boiling temperature of water. Relative humidity is the ratio of the vapor pressure in air to the saturated vapor pressure at the temperature of the air. Relative humidity is usually expressed in percent, which is this ratio times 100. The dewpoint temperature is the temperature to which the air must be lowered, so the vapor pressure in the air is the saturated vapor pressure with the relative humidity at 100%. Knowledge of water vapor density is used in weather prediction and in global climate modeling. It also affects light transmission through the atmosphere. Relative humidity is an important meteorological variable. The temperature–dewpoint difference is an indicator of the likelihood of fog formation and can be used to estimate the height of clouds. More detailed sources of information on humidity measurement include the section on humidity in this handbook and References 6 to 9. Three common methods of measuring the vapor density in the atmosphere are given below.

The Chilled Mirror Method.

Chilled mirror instruments for measuring the dewpoint temperature are not sold by most instrument companies. A chilled mirror instrument developed by Technical Services Laboratory is used in the U.S. National Weather Service ASOS network discussed below. It has a mirror cooled by a solid-state thermoelectric cooler (using the Peltier effect) until water vapor in the air just starts condensing on the mirror. This condensation is detected using a laser beam reflecting from the mirror. When the reflected

beam is first affected by the condensed water vapor, the temperature of the mirror is the dewpoint temperature. The mirror temperature is controlled to remain at the dewpoint temperature by an optic bridge feedback loop. The mirror is a nickel chromium surface plated on a copper block. The temperature of the block is measured to $\pm 0.02\%$ tolerance by a platinum resistance thermometer imbedded in the block. An identical platinum resistance thermometer measures ambient air temperature. Outside air is drawn through the protective enclosure surrounding the instrument by a fan, so that the effect of solar heating on the measured values of the dewpoint temperature and ambient temperature is negligible and so that outside air is tested. The dewpoint temperature and ambient temperature are measured between -60 and $+60^\circ\text{C}$ to an accuracy of 0.5°C rms. Dewpoint errors are somewhat larger below 0°C . To avoid errors that might arise from deterioration of the reflective properties of the mirror, the mirror should be inspected periodically, particularly in dirty or salty environments. This method is of higher cost than other methods of measuring the amount of water vapor in the atmosphere.

Thin Film Polymer Capacitance Method.

The capacitance is formed with a thin polymer film as dielectric placed between two vapor-permeable electrodes. Water vapor from the air diffuses into the polymer, changing the dielectric constant of the dielectric and thus the capacitance. The capacitance can be measured electrically by comparison to fixed capacitance reference standards. The measured value of the capacitance is related to the relative humidity by calibration. Instruments using these capacitive sensors can measure relative humidity between 0 and 100% at temperatures between about -40 and $+60^\circ\text{C}$ to about $\pm 2\%$ of relative humidity. These sensors can be made very small for incorporation into integrated circuits on silicon chips [9]. They are low in cost. Usually, instruments measuring humidity also measure temperature separately. The circuits used to measure relative humidity using a thin polymer capacitance yield an electric output signal (often 0 V to 5 V), which lends itself to remote transmission of the relative humidity.

Psychrometric Method.

This method is discussed in the earlier section of this handbook on humidity. Errors are introduced if the water is contaminated, if the water level in the reservoir supplying water to the wick becomes low, or the reservoir runs dry. In extremely dry environments, it can be difficult to keep the wick wet, while salty environments can change the wet bulb reading. Accuracy is affected by air speed past the wet bulb. Because of these disadvantages, psychrometers have generally been replaced by more convenient methods of measuring humidity.

Wind Speed, Wind Direction, and Wind Shear

Anemometer.

Weather stations commonly employ a 3-cup anemometer. This consists of a vertical axis rotating collar with three vanes in the form of cups. The rotation speed is directly proportional to wind speed. [Figure 73.1](#) shows an instrument of this type. An alternative to the cup anemometer is a propeller anemometer in which the wind causes a propeller to rotate. There are several ways to obtain an electrical signal indicating the speed: a magnet attached to the rotating shaft can induce a sinusoidal electrical impulse in a pickup coil; a Hall effect sensor can be used; or the rotating shaft can interrupt a light beam, generating an electric pulse in a photodetector. Rotating anemometers can measure wind velocities from close to 0 up to 70 m s^{-1} (150 mph).

Ultrasonic Wind Sensor.

This sensor has no moving parts. Wind speed determination is as follows. An ultrasonic pulse emitted by a transducer is received by a nearby detector and the transit time calculated. Next, the transit time is measured for the return path. In the absence of wind, the transit times are equal; but in the presence of wind, the wind component along the direction between the transmitter and receiver affects the transit time. Three such pairs, mounted 120° apart, enable calculation of both the wind speed and direction. Heaters in the transducer heads minimize problems with ice and snow buildup. The absence of moving parts eliminates the need for periodic maintenance.

FIGURE 73.1 A cup type anemometer for measuring wind speed. (Courtesy of Kahl Scientific Instrument Corp.)

Wind Direction.

Wind direction sensors are generally some variant of the familiar weather vane. Sensitivity is maintained by constructing the weather vane to rotate on bearings with minimal resistance. Electronic readout can be achieved using a potentiometer (a “wiper” contact connected to the vane slides over a wire-wound resistor). The resistance between the contact and one end of the wire resistor indicates the position of the vane. Alternative methods of readout include optical and magnetic position sensors. Positional accuracy is $\pm 5\%$.

Combination Wind Speed and Direction Sensor.

A combination wind speed and direction sensor can be made in which a propeller anemometer is mounted on a weather vane. The vane keeps the propeller device pointed into the wind. Alternatively, two propeller anemometers, rigidly mounted in a mutually perpendicular arrangement can be used to determine direction and magnitude of the horizontal wind simultaneously. Rotating anemometers and weather vanes are susceptible to ice and snow buildup and can be purchased with heaters. They need periodic maintenance.

Wind Shear.

Wind shear occurs when wind direction and/or strength change significantly over a short distance. This can occur in horizontal or vertical directions or sometimes in both. Measurement of wind shear conditions is particularly important at airports. Wind shear is determined by comparing readings made at the center of the airfield with measurements made at the periphery. An automated system to perform this function, entitled Low Level Wind Shear Alert System (LLWAS), is found at some airports. Wind shear can also be detected by doppler radar. Doppler radar used by the U.S. National Weather Service is discussed below.

Precipitation

Precipitation measuring instrumentation includes devices that measure the presence of precipitation (precipitation sensors), those that determine the quantity of precipitation, those that measure rate of precipitation, and those that measure both quantity and rate.

Precipitation Presence Sensors.

These sensors usually consist of two electric contacts in close proximity. Moisture causes electric conduction that is detected by a circuit monitoring conductance. A typical application consists of a circuit board consisting of a grid of two arrays of strips separated by small gaps. If the surface of the detector is heated, then only current precipitation will be detected and dew will not form to affect the measurement.

Rain Gages.

These instruments measure amount of rainfall. A simple rain gage can consist of a cylinder, a funnel, and an inner collection tube of much smaller diameter than the funnel for amplification of the height of rain accumulation. The height of the water column in the inner tube is converted to total rainfall. Typical graduations on the tube enable determining rain accumulation to 0.025 cm (0.01 in.) of rain.

A tipping-bucket rain gage enables the measurement of both volume and rate of rainfall. A large funnel concentrates the precipitation, which is directed into one of two small buckets. When that bucket fills, it tips out of the way and empties, closing a switch to record the event, and another empty bucket moves into its place. Typical tipping-bucket gages respond to each 0.025 cm (0.01 in.) of rain. In conditions of snow and freezing rain, tipping-bucket rain gages can be equipped with heaters on the funnel to reduce snow and ice to water. The internal components are also heated to prevent refreezing. Reported accuracy for tipping-bucket rain gages is $\pm 0.5\%$ at 1.2 cm h^{-1} (0.5 in h^{-1}). Frise Engineering Company produces a tipping-bucket rain gage used in the ASOS network discussed below.

Highest accuracy rain gages that collect and concentrate precipitation should have their collection surfaces made of a plastic with a low surface tension for water. This minimizes losses from surface wetting.

Rain gages exist that do not rely on collection methods. Optical rain gages utilize an infrared beam. Drops falling through this beam induce irregularities in the beam that can be interpreted in terms of precipitation rate. This type of sensor is used for the precipitation identification or present weather sensor used in the ASOS network discussed below.

Solar Radiation

The mean annual intensity of solar radiation above the atmosphere (extraterrestrial solar radiation) continues to be measured to obtain a more precise value and to look for variations in the sun's energy output. It is called the solar constant. The solar constant is close to 1367 W m^{-2} . The intensity of solar radiation above the atmosphere varies approximately sinusoidally over the year with an amplitude of close to 3.3% of the solar constant and a maximum near the first of January. This variation arises from the variation of the distance of the Earth from the sun. The sun has a spectral distribution that is roughly that of a blackbody at 5777 K with a peak of the spectrum at a wavelength of about 500 nm. Solar radiation is attenuated by scattering and absorption in the atmosphere. Attenuation is greater at wavelengths corresponding to absorption bands of certain gases in the atmosphere. On a clear day near noon, the solar intensity at the Earth's surface can be as high as 1000 W m^{-2} . [Figure 73.2](#) shows a typical sea level solar spectrum with the sun about 48° away from the vertical (see, for example, References 10 and 11). This is called an air-mass 1.5 spectrum, because the distance the radiation travels through the atmosphere is 1.5 times the distance when the sun is vertical. About 99% of the spectrum is in the range of wavelengths shown by the figure. Measurements of the solar constant and the solar spectrum are scientific measurements made with specialized instruments. Additional information can be found in Iqbal [11] and Coulson [12].

Solar radiation instruments for general use in the field measure direct radiation from the sun, total or global radiation coming from the sky hemisphere, and diffuse or sky radiation (global radiation with the direct radiation removed). Solar radiation measuring instruments can be broadband instruments that measure the combined solar intensity (irradiance) at all wavelengths, or they can be spectrally selective instruments that measure the intensity at different wavelengths or in different wavelength bands. Only the much more common broadband instruments are discussed here. The instruments used for everyday measurement are field instruments. Field instruments are first class if they are of higher quality and provide greater accuracy and reliability (at higher cost).

FIGURE 73.2 The intensity of solar radiation as a function of wavelength for a pathlength through the atmosphere of 1.5 times the vertical path length. The dips in the spectrum are molecular absorption bands.

Direct radiation is radiation coming directly from the sun without scattering in the atmosphere. Instruments measuring direct solar radiation usually include radiation coming from the sky out to an angular distance of about 3° away from the center of the sun's disk. They are called pyrheliometers. The radiation coming from clear sky near the sun, rather than from the solar disk, is the circumsolar radiation. This radiation can be subtracted from the pyrheliometer measurement for a more precise determination of direct radiation. This correction is often not made for routine measurements. The clear sky correction is calculated using the angular distribution of the intensity of the circumsolar radiation [13,14].

Instruments measuring global radiation are installed in a level position with a plane sensor facing up toward the sky. These instruments measure solar radiation coming from the whole sky hemisphere. They are called pyranometers. Global radiation measuring instruments should be sited in a level elevated area with no obstructions obscuring the sky hemisphere.

Diffuse radiation is the radiation coming from the sky hemisphere with the direct radiation subtracted. Pyranometers are used for measuring diffuse solar radiation and should be mounted in the same manner as pyranometers used for measurement of global radiation. They have an occulting (shade) disk or shadow band to prevent direct solar radiation from reaching the radiation sensor. The measurement of diffuse radiation involves correcting the pyranometer measurement for the part of the sky radiation shielded from the sensor by the occulting disk or shadow band. For clear skies, the occulting disk correction is calculated using the angular distribution of intensity of the circumsolar radiation. Corrections for partially cloudy and cloudy skies depend on the particular cloud conditions. Corrections for the shadow band are often determined by temporarily replacing the shadow band with an occulting disk when the sky is clear and when it is overcast. Corrections for measurements under other sky conditions can be determined by interpolation. The shadow band correction is discussed by LeBaron et al. [15]. The occulting disk must have a tracking system to make the disk follow the sun over the sky. The shadow band removes solar radiation received from a narrow swath of the sky along the path the sun follows

during the day. The shadow band must be adjusted regularly during the year as the path of the sun changes over the seasons. The more common solar radiation measuring instruments include the pyranometer and pyr heliometer.

The Pyranometer.

The sensor is usually a thermopile, consisting of a number of thermocouples in series, with alternate junctions heated by the sun. The unheated junctions are near ambient temperature. This is sometimes arranged by putting the unheated junctions in thermal contact with a white surface. Heating by the sun is accomplished by placing the junctions in contact with a matte black surface of high heat conductivity or by a black coating on the junctions. The blackened surface has a constant high solar absorptance (usually ~99%) over the solar spectrum. A constant high solar absorptance over the solar spectrum is important. The solar spectrum at the surface of the Earth varies with the time of day and year and the amount of clouds, because of the spectrally dependent scattering and absorption of solar radiation by the atmosphere. An absorbing surface whose absorption of solar radiation varies with wavelength will cause the sensor to have a different sensitivity for different wavelengths of the solar spectrum. Some less expensive pyranometers use a silicon photovoltaic sensor (solar cell) to measure solar radiation. These sensors have zero sensitivity above about $1.2\ \mu\text{m}$ and the spectral response below $1.2\ \mu\text{m}$ is not constant. This limits the accuracy of measurements of solar intensity with photovoltaic sensors. Instruments with a thermopile sensor can use a combination of thermopiles and resistors to compensate for the variation of the output of a single thermopile with temperature. The hemispherical windows of pyranometers are usually made of a special glass which transmits solar radiation of wavelengths between about 0.3 and $2.8\ \mu\text{m}$. This includes ~99% of the solar intensity. The absorbing surface must have a cosine response as a function of angle away from the normal to the surface (Lambert law response), and a flat response as a function of azimuth around the normal to the absorbing surface, for the global radiation to be measured correctly. The degree to which the pyranometer response is linear follows the cosine law, and is temperature, spectrum, and azimuthally independent, determines whether the instrument is a first class instrument. [Figure 73.3](#) shows a Kipp and Zonen (Netherlands) first-class pyranometer.

FIGURE 73.3 A class 1 pyranometer used for the measurement of global and diffuse solar radiation. (Courtesy of Kipp & Zonen Division of Enraf-Nonius Co.)

FIGURE 73.4 An automatic solar tracker with normal incidence pyrheliometer and cavity radiometer mounted on it. The tracker is coupled to two shade disks that shield direct sunlight from a first class pyranometer and precision infrared radiometer facing the sky hemisphere. (Courtesy of Eppley Laboratories.)

The Pyrheliometer.

The field pyrheliometers usually have temperature-compensated thermopile sensors with flat spectral response and linear output. The sensor is placed at the bottom of an internally blackened, diaphragmed, collimator tube that limits the angular acceptance for solar radiation to be in the range of about 5° or 6° total acceptance angle. The pyrheliometer is mounted on an equatorial mount tracker that keeps the direct radiation from the sun parallel to the axis of the collimator tube. [Figure 73.4](#) shows an Eppley Laboratory (U.S.) normal incidence pyrheliometer (on right) and a cavity radiometer (on left) mounted on a solar tracker. Also shown are a first-class pyranometer and precision infrared radiometer shielded from direct radiation from the sun by shade disks coupled to the tracker.

FIGURE 73.5 The xenon flash instrument that determines atmospheric visibility at an ASOS system station. This system is produced by AAI Systems Management Incorp.

Visibility

Visibility in meteorology is a measure of how far one can see through the atmosphere.

Visibility Sensors.

Measurement of forward scattering of light by aerosols in a given sample volume is used to determine visibility. A pulsed beam of near-infrared light (typically 850 to 880 nm wavelength) generated by an infrared-emitting diode is projected into the ambient air. A detector (usually a silicon photodiode), placed between 1 and 2 m away and oriented between 30° and 40° off the axis of the pulsed beam, samples the scattered light. The intensity of scattering is proportional to the atmospheric extinction coefficient. The extinction coefficient (k) is related to visual range (VR) by $VR = 5/k$ (km). Visual ranges measurable by such a system lie between about 0.3 km. and 60 km. [Figure 73.5](#) shows the visibility sensor used in the ASOS network. A xenon flash lamp source is used with this system.

Transmissometers.

These measure the attenuation of a light beam to determine visibility.

Lidar Measurements

Lidar is optical radar in which a laser emits pulses of electromagnetic radiation. Scattered radiation that returns to an optimally tuned detector at the laser site for observation are called echos. The time from emission of the pulse to return of the echo determines the distance of the scatterer. The echos are sampled at all times between pulses, and thus all distances up to the maximum range. This provides information about the atmosphere along the pulse path. The strength of the echo is connected with the density, size, and shape of the scattering particles. Laser pulses are linearly polarized. Spherical scatterers return echos that have the same linear polarization. Nonspherical scatterers depolarize the echos. Thus, polarization of the echo also provides information concerning the scatterers. Using high spectral resolution lidar

(HSRL), the scattering by air molecules can be separated from the scattering by aerosols. Differential absorption lidar (DIAL) measures the concentration of gaseous species in the atmosphere. Stephens [16] discusses the HSRL and DIAL methods. Zhao et al. [17] present an application of the DIAL method to the determination of O₃ concentration in the atmosphere. Because of their high power output, ruby, dye, neodymium, yttrium-aluminum-garnet (YAG), and CO₂ lasers are commonly used for lidar. The use of lidars in the observation of aerosols injected into the stratosphere by volcanic eruption, and their subsequent decay has become quite common (see Post et al. [18] and Jager et al. [19] and other articles in the same journal issue).

Clouds

Observer Estimation.

For many years, observers at weather stations have estimated the amount, type, and sometimes the opacity of low clouds, middle clouds, and high clouds. Estimation is usually every hour or similar period with the estimate in tenths or eighths (octa) of the sky covered. Satellite, radar, and ceilometer data are replacing observer estimation. Observer estimates have been archived.

Ceilometers.

Ceilometers measure the altitude of clouds. Most ceilometers are based on lidar technology using an infrared pulsed laser diode, usually GaAs. Laser pulses are reflected back (echos) to a receiver, usually a Si diode detector. The round-trip time is converted into cloud height. Common ceilometers can measure cloud base altitudes to 4000 m (12,000 ft). Recent instruments developed by Vaisala can measure cloud bases up to 23,000 m (75,000 ft) with an error of $\pm 1\%$. The Vaisala ceilometer is used in the ASOS network discussed below. Maintenance includes cleaning of the window. Heaters and blowers respond to automatic sensing units to clear precipitation from the window and control instrument temperature.

Companies producing and marketing meteorological instruments are presented in [Table 73.1](#). For information on additional companies marketing meteorological instruments in the U.S., see *Thomas Register of American manufacturer's* and *Thomas Register Catalog File* found in most major libraries. For manufacturers in other countries, search library catalog files under “manufacturers.”

United States Weather Service Facilities

The U.S. National Weather Service, the U.S. Federal Aviation Administration, and the U.S. Department of Defense have joined in an upgrade of weather instrumentation and analysis for U.S. weather stations. Other national weather services are upgrading their facilities. The new U.S. National Weather Service system has four components to obtain weather data throughout the United States and its possessions:

1. The Automated Surface Observing Systems (ASOS): These systems, produced by AAI Systems Management Incorporated, are installed at over 850 sites. Each system usually measures visibility, surface temperature, dewpoint temperature, pressure, wind speed and direction, visibility, cloud height, precipitation identification, freezing rain, and precipitation accumulation. Instruments used for each ASOS site are discussed above with other meteorological measuring instruments. [Figure 73.6](#) shows the arrangement of instruments at an ASOS site.
2. Doppler weather surveillance radar (NEXRAD — WSR-88D): Doppler radar are produced by Lockheed-Martin Corporation and installed at approximately 160 sites in the U.S. Doppler radar surveys the weather out to about 300 km from the radar. The standard radar scans angles above the horizon up to about 6° in six ~1° intervals with a 360° azimuth. Rain scans go up to about 20°. Radar echos are reflection of the pulsed radar microwave signal from water drops in the form of rain or cloud. Ice crystals and snow reflect radar pulses with lower echo strength. Doppler radar can detect short-lived, possibly catastrophic events such as tornados, downbursts, and flash floods in real-time. The doppler shift of the echo determines the radial component of the wind velocity at the height and distance of the source of the reflected echo. The strength of the echo provides information on the precipitation rate. Powerful computers and sophisticated computer programs

^a Complete weather station available.

FIGURE 73.6 A view of an ASOS system sited at an airport near San Diego. The instrument of Figure 73.5 is seen in the foreground. A stand for the freezing rain sensor is not used. The next instrument is the ceilometer. Behind that is a metal box containing connections to the sensors and instruments to transmit the data to a remote collection and processing station. Along the same line of instruments beyond this is the precipitation identification or present weather sensor. This is followed along the same line by the sensor measuring ambient and dewpoint temperatures and a tipping bucket rain gage. To the north of the line of instruments is a pole with a cup anemometer, weather vane, flashing red lights, and lightning rod at the top.

are used to analyze the radar signals. Additional discussion of the use of radar for weather observations can be found in Stephens [16]. NEXRAD is discussed in References 20 to 23, for example.

3. Radiosonde upper air sounding: The northern hemisphere has a network of about 700 radiosonde sites, including the U.S. network, where soundings are generally made twice daily. The northern hemisphere is largely decoupled from the southern hemisphere for weather development. Radiosondes provide information on wind velocity, temperature, and humidity at all elevations up to 30 to 40 km. A temperature sensor, humidity sensor, and pressure sensor are carried aloft by

balloon at 0000 and 1200 UTC (± 1 h). The wind velocity at different altitudes is measured by determining the radiosonde position at all times during the flight. The horizontal position of the radiosonde can be obtained by OMEGA, LORAN, or VLF global positioning systems. Additional information on global positioning is found in the section of this handbook on satellite navigation and radiolocation. Pressure can indicate the altitude of the radiosonde. Radar or GPS can measure the radiosonde position in three dimensions. Radiotheodolites can track the radiosonde to receive the data transmitted by radio transmitter. The radiosonde manufactured by Viz Manufacturing Co. called Bsonde is used by the U.S. National Weather Service. The instruments are mounted on a lightweight white styrofoam container. The temperature sensor is a thin, 50-mm long rod thermistor painted white to minimize heating by solar radiation. It is mounted outside the container. It measures temperature to $\pm 0.5^\circ\text{C}$. The container has an air flow duct for ventilation of the relative humidity sensor mounted inside. The relative humidity sensor consists of an insulating strip coated with a film of carbon that measures relative humidity from 0 to 100% to $\pm 5\%$. The pressure sensor is a nickel, C-span aneroid pressure sensor coupled mechanically to a 180 contact baroswitch providing the output pressure signal. Pressure is measured from 1060 mb to 5 mb with an accuracy of ± 0.5 mb. Sensor signals are sent to the receiving station by an amplitude modulated transmitter operating from 1660 to 1700 MHz. The Vaisala Inc. radiosonde sensors used by the U.S. National Weather Service differ from Bsonde by use of a capacitance temperature sensor, a capacitance with polymer dielectric humidity sensor, and a capacitive aneroid pressure sensor.

4. Satellite remote sensing: Meteorological variables are deduced from measurements of the electromagnetic radiation coming from the atmosphere and the surface of the Earth using satellite based sensors. Usually, three or more different detector wavelength bands are used. The interpretation is difficult because the electromagnetic radiation can come from many levels of the atmosphere or the Earth's surface, all at different temperatures, and may have undergone multiple scattering in the atmosphere and Earth reflection. The energy coming from the atmosphere and the Earth's surface is mostly reflected and scattered solar radiation for wavelengths up to about $4\ \mu\text{m}$. Longer wavelength energy is mostly associated with thermal emission from the Earth and its atmosphere. Thermal emission from the atmosphere and the surface of the Earth consists of overlapping blackbody spectra of different temperatures. Absorption spectra characteristic of various gases in the atmosphere and their temperatures are superimposed on the overlapping blackbody spectra. Visible wavelengths from about $0.4\ \mu\text{m}$ to $0.7\ \mu\text{m}$ are useful for determining cloud coverage and cloud type. Infrared wavelengths from about $6\ \mu\text{m}$ to $7\ \mu\text{m}$ can be used to determine water vapor density. Infrared in the range from about $10\ \mu\text{m}$ to $12\ \mu\text{m}$ can be used to look at high clouds. It is also useful for night observation. Satellite measurements show the motion and development of the clouds and storm systems. More detailed discussion is available [16,24-27].

73.2 Air Pollution Measurement

Michael Bennett

There is a huge range of atmospheric pollutants and for a given pollutant there may be a several commercially available detection systems. In a document of this size, it is clearly not feasible to discuss in detail the theory of operation of every possible system. After some general remarks about air pollution monitoring, a broad introduction to the physics of molecular spectroscopy (the most widely used

detection principle) will be presented. The detection of individual pollutants will then be discussed. Most of the practical examples given will refer to British experience, since this reflects the author's background. The principles involved, however, are universally applicable. The EPA's Web site (Table 73.5) provides a useful gateway to American legislation and practice.

Before spending money on a detection system, it is essential that the user understands the purpose of the measurement. This will affect both the choice of instruments and the location of monitoring sites. In general, active monitors with short response times will be more expensive than passive, slow-response instruments. A survey intended to determine spatial variations of an ambient pollutant might therefore be best to employ very many cheap, slow-response instruments. A classic example would be current national surveys to measure indoor radon pollution. In the U.K., the National Radiological Protection Board (NRPB) will supply householders with two passive detectors, each consisting of a strip of plastic inside a protective container. These are left in a living room and a bedroom for 3 months, at the end of which they are mailed back to the NRPB for analysis. (The number of α -particle trails in the plastic is counted). The householder is then reassured (or not) as to the safety of the dwelling; the authorities, meanwhile, can build up a national map of Rn concentration in relation to geology, building type, etc. The essence of the system is that the individual detectors are so cheap that the authorities can afford many thousands, such a number being necessary to provide realistic spatial coverage.

Identification of a particular source in the presence of background emissions, however, requires a sensor with a response time of minutes, or 1 h at most, supplemented by meteorological measurements. This need arises because, at temperate latitudes, the wind direction changes by 15° in 1 h and 90° in 24 h. Unless a source dominates local pollution, its impact is unlikely to be demonstrable through daily sampling.

Some applications may require response times of seconds or less. Odors are a very common cause of complaint. In this case, the complainant perceives fluctuations in concentration over periods of a few seconds, while he may become inured to steady concentrations over periods of minutes. It is also the case that many toxic gases are more damaging in high doses over short periods than at a steady concentration over some hours [1]. Flammability, of course, also depends on peak rather than mean concentrations.

Central to obtaining reliable information from such measurements is the protocol for the siting of instruments. This naturally depends on the objectives of the survey. The U.K. national survey for smoke and SO_2 [2], for example, was highly successful in demonstrating the effects on background pollutant concentrations of the 1956 Clean Air Act and (from the late 1960s) the availability of natural gas (cf. Figure 73.7). Sites were chosen so as not to be dominated by individual local sources, being typically in backyards or on the roofs of municipal buildings. By the early 1980s, however, urban air pollution had become increasingly dominated by road traffic emissions and the earlier network of sites no longer seemed appropriate [3,4]. Many roadside measurements have now also been made in addition to more general urban or rural surveys [5]. It should be noted that a *typical* site is not necessarily a *representative* one [6]. The former is what we experience about our daily lives. The latter is chosen through a protocol so that measurements from one site can be compared with those from another. Depending on the application, representative sites may be more or less typical.

A protocol is important not only for comparing one place with another, but also for comparisons between different times. One should not be dismissive of the old technology of the national SO_2 survey; the conservatism of the design allows one to rely on the time series of concentrations over the last 60 years. Clearly, there are advantages in keeping up with the latest technology. But, if interested in long-term trends, one must be very sure of the relative responses of "improved" instruments and methods.

The deployment of fast-response instruments around individual sources gives rise to somewhat different problems. Given the high cost of such instruments, one must be sure that statistically useful measurements of environmental impact will be made over the course of the survey. Concentrations should ideally be measured simultaneously upwind and downwind of the source. For an elevated buoyant source, it is desirable to measure downwind concentrations over a range of distances; atmospheric dispersion models are not yet so foolproof that the calculated distance from the stack to the peak ground-level

FIGURE 73.7 Annual average SO₂ concentrations in Central London, 1933–1997. The curve shows the average from two sites.

concentration can be relied on. At a given point on the ground, pollution from such a source can typically be detectable on only a few percent of hours. Mobile laboratories are therefore commonly used to enhance the capture of data, but it is then essential that some statistical and climatological analysis be applied to extrapolate the measurements obtained to long-term means at fixed target points on the ground. The protocol and analysis should be planned before the instruments are purchased.

Spectroscopic Principles

The most common principle employed for the detection of contaminants in air involves the interaction of the trace species with light. The advantages are obvious: with careful choice of system, the interaction can be made specific to the chosen molecule, and the photon will then transport itself from the point of interaction to the detector. Reference 7 provides a general undergraduate-level introduction to molecular spectroscopy, while Reference 8 describes specialized applications to atmospheric measurement.

The specificity of the interaction of light with a molecule arises from quantum theory. Light is absorbed or emitted as photons, of energy hc/λ , while individual atoms or molecules can only exist at discrete levels of energy or angular momentum. Light is thus only absorbed or emitted by gaseous species at discrete values of wavenumber, $1/\lambda$ (usually quoted in cm^{-1}). Generally, different molecular energy levels arise through three processes:

- Rotational. A molecule can spin with an angular momentum equal to a discrete value of $h/2\pi$. Transitions between angular momentum states are typically equivalent to photon energies of 1 to 100 cm^{-1} , i.e., microwave wavelengths.
- Vibrational. The atoms in a molecule can vibrate relative to one another. Transition energies between modes are typically on the order of 10^3 to 10^4 cm^{-1} , i.e., infrared wavelengths.

- Electronic. The electrons can occupy different orbitals within an atom. Transitions between these would typically take place at UV wavelengths.

Photons can initiate transitions between combinations of the above levels; observed molecular spectra thus tend to be extremely complicated, having structure over all scales of wavenumber. Atomic spectra, for example, from a monatomic gas like Hg, are simpler, since there are no vibrational or rotational modes. Nevertheless, even for molecular spectra, “selection rules” permit only a limited number of transitions to occur; a single photon can only effect a transition if the initial and final dipole moments of the molecule are different. (The direction of the change of dipole depends on the polarization of the associated photon.) Conservation of angular momentum also requires that a molecule’s spin can only change by one unit at a time.

Photon energies are broadened by temperature (which causes a Doppler shift in frequency) and by pressure (which shortens the lifetime of the excited state). In practice, of course, any commercial measurement system also has a finite resolution. Parts of the spectrum may thus contain so many possible transitions that it becomes impractical to distinguish individual lines. The specificity of molecule–photon interactions promised by quantum theory is thus seen to be rather limited in practice. Spectroscopic identification of a particular species relies on the existence of resolvable structure in an accessible part of the spectrum where there is no serious interference from other common gases. In general, this search must be solved individually for each analyte — with no guarantee of the existence of a satisfactory solution.

Absorption Techniques

Detection of a specific molecule may be through either its absorption or emission of light at a particular wavelength. Consider monochromatic light of flux I passing through a gas of concentration χ . In so far as each interaction between a photon and a molecule is an independent event, the rate of interaction is separately proportional to the number of photons and the number of gas molecules. Thus,

$$\frac{\partial I(x, \lambda)}{\partial x} = -\sigma(\lambda) I(x, \lambda) \chi(x) \quad (73.1)$$

where $\sigma(\lambda)$ is the absorption cross-section. For constant gas concentration, this can be integrated as a function of path length, x , to give the Beer-Lambert law:

$$I(x, \lambda) = I(0, \lambda) e^{-\sigma(\lambda)\chi x} \quad (73.2)$$

The argument of the negative exponential is known as the optical density at this wavelength. The gas burden, χx , along the optical path is thus given by:

$$\chi x = \frac{\log\left(I(0, \lambda)/I(x, \lambda)\right)}{\sigma(\lambda)} \quad (73.3)$$

and, since $\sigma(\lambda)$ can be measured in the laboratory, one now has a measurement of the gas concentration.

The advantage of absorption techniques is that they require minimal disruption to the observed system. This is of benefit in ambient monitoring where, for example, a long-path measurement can be set up over many hundreds of meters without problems of safety or power. Equally, in emissions monitoring, it is advantageous to be able to measure gas concentrations *in situ* in the flue. Long-path techniques can also be applied in point samplers through the use of a multipass cell (e.g., a White cell [8]). The response time would then be limited by the volume of the cell in relation to the sample throughput.

Because of instrumental offsets and interference from other species, measurement of transmission at a single frequency is unlikely to give an accurate estimate of the gas concentration. More commonly, absorption is measured at several frequencies. Standard techniques include:

- Differential Optical Absorption Spectroscopy (DOAS). A broadband source is used in conjunction with a high-resolution spectroscope tuned around distinctive absorption features of the target gas. The difference between online and offline absorption then gives the gas concentration. If the measured spectrum is digitized, it can be fitted to the target spectrum, allowing some correction for interferent species. In a related analog technique, “Correlation Spectrometry,” several online and offline signals are taken simultaneously from a spectrometer. Regressing the signal against a known absorption spectrum using a spectral mask gives the target gas burden.
- Fourier Transform Infrared (FTIR). The output from the gas cell is put into an interferometer. The Fourier transform of the output signal as a function of phase lag is then the absorption spectrum. Fitting programs can be applied to estimate the mix of pollutants responsible for this spectrum.
- Non-Dispersive Infrared (NDIR). Optical filters are applied to limit the input spectrum to a window where interference effects from other gases are small. No further spectral separation (“dispersion”) is then applied. Gross absorption by the target gas is measured and can be calibrated by switching gas cells into the light path.
- TLDA (Tunable Laser Diode Absorption Spectroscopy). This uses a very narrow-band source (viz. a tunable diode laser) and a broad-band receptor. The frequency of the source will typically be oscillated close to an absorption line of the target gas; the first harmonic of the signal is then proportional to the integrated concentration along the light path.

Emission Techniques

The converse of looking for the absorption of light of a given frequency by the target gas is to excite molecules of the gas and then examine the light emitted as they return to their ground state. The signal is passed through a narrow-band filter and measured with a photomultiplier tube. There are several standard techniques, including:

- Flame photometry. A flame (typically of H₂) is burned in the sample gas. The heat breaks up and ionizes the target molecules, which then relax to their ground state. Since one is now looking at fragments of the molecule rather than the molecule itself, the technique is not completely specific. Its advantage is that it tends to be very fast, being ultimately limited by the timescale for the ions to pass through the flame. A related technique, FID (Flame Ionization Detection), although not strictly spectroscopic, measures the conductivity of the flame that arises from such ionization.
- Chemiluminescence. A reactive gas is added to the sample gas. Light from the excited products of the reaction is detected.
- UV fluorescence. The sample gas is excited with UV light and the subsequent fluorescence measured. A related technique, PID (Photoionization Detection), is to measure the ionization current arising from such UV irradiation. This then detects all species whose first ionization potential is less than the photon energy of the lamp. The technique is extremely fast [9].

Particulate Sampling

Sampling of particulate matter in air gives rise to a different set of considerations from the sampling of trace gases. Note that:

- Spectroscopic methods are unlikely to be effective. The interaction of light with small particles is caused by Rayleigh or Mie scattering [10] and tends not to show very specific behavior as a function of particle composition.
- The aerodynamic behavior of a particle is a strong function of its size. Particles of diameter less than 10 μm (PM₁₀) tend to travel with the air flow. Since, moreover, their Brownian diffusivity

is very small, they exhibit very slow deposition [11]. At less than 5 μm , such particles may be inhaled deeply into the lungs; as such, they are known as “respirable aerosol.”

- Particles of diameter greater than 10 μm exhibit significant inertial and gravitational effects. They can thus deposit through impaction as the air flows around small obstacles. For particles larger than 50 μm , sedimentation becomes dominant.

The sampling method must thus be tuned to the range of particle sizes that one wants to monitor. For a general review, see the book by Vincent [12].

Slow Ambient Monitoring

The initial discussion focuses on systems with sampling times of 1 day and upward. These would typically be used for background monitoring.

Diffusion Tubes

A diffusion tube is the classic inexpensive, slow-response instrument that can be deployed in large numbers to quantify spatial variations of ambient pollutants. Typically, it consists of a sealed perspex tube with a removable cap and an active substrate at the closed end. It is deployed in the field with the open end downward and, after the prescribed exposure time (typically 7 days) it is returned to the laboratory for analysis. The system was originally developed as a personal monitor of NO_2 exposure [13] but has since been widely used for ambient urban surveys.

Assuming that the substrate is a perfect trap for the target gas, the diffusive flux of gas into the tube is given by $DA\bar{c}/L$, where D is the diffusivity of the target species, A the internal cross-sectional area of the tube, and L the length of the tube. So long as the diffusivity remains constant over the period of measurement, the total deposition to the substrate is therefore a measure of the mean concentration over the period of exposure. Theoretically, D should vary with temperature and there may also be some circulation within the tube arising from wind across its mouth. A typical commercially available model has $L = 71$ mm and an i.d. of 12 mm, so such circulation is suppressed. Studies have shown acceptable correlation between samples from diffusion tubes and long-term means from adjacent point samplers [14].

The system employed for NO_2 is a substrate of triethanolamine deposited on a stainless steel mesh. The sample is dissolved in orthophosphoric acid and the nitrite detected colorimetrically using the Greiss/Saltzman technique. Systems are also available for SO_2 , benzene, xylene, toluene, fluoride, chloride, bromide, cyanide, and nitrate. A list of participating laboratories in the U.K. can be obtained from NETCen.

Drechsel Bottles

The classic bubbler (a Drechsel bottle) consists of a Pyrex® bottle containing a solution through which filtered sample gas is bubbled. Capture of the sample gas can be enhanced by passing it through a sintered plug, so that bubble size is reduced. For the detection of SO_2 , a solution of hydrogen peroxide is used so that:

In polluted areas, the H^+ ions are then detected by titration, it being assumed that all the acidity comes from atmospheric SO_2 . In cleaner, rural areas, this is insufficiently sensitive (NH_3 emissions from livestock can give apparently negative SO_2 concentrations!) and the sulfate ions are measured using ion chromatography. Sampling times are typically 24 h for a sensitivity of a few ppb.

As implemented in the U.K. national surveys of smoke and SO_2 , eight such bottles are mounted in a case with a separate pump and flowmeter. At some preset time each day, the airflow is switched from one bottle to the next; at the end of the week, the operator then visits, replaces all the bottles, and returns the old ones to the laboratory for analysis. Depending on the time of the visit relative to the switching

time, the sample on the day of the visit can be spread over two bottles. In this system, the air is first drawn through a separate filter (Whatman Grade 1) for each day of measurement. This captures particulate in the range 5 to 25 μm diameter; the blackness of the stain is measured photometrically to provide a 24-h sample of “black smoke.”

The system is simple, inexpensive (current list prices are less than \$3000), and requires minimal operator training. It was therefore possible to install many hundreds of such sites and run them for a considerable period. In central London, for example, such systems were first installed in 1933. Annual mean SO_2 concentrations were then found to be around $400 \mu\text{g m}^{-3}$; 60 years later, this has dropped to less than $40 \mu\text{g m}^{-3}$. Clearly, there has been considerable improvement. Such measurements have now been considerably scaled down, with 252 sites currently active in the U.K. [5].

In practice, the real cost of such a system is the manpower and the site. These are small if the system is sited in a municipal building and operated by existing staff. At a remote site, however, a secure cabin with power must be provided and it must be visited weekly. The practical difficulties of identifying, securing, and maintaining a site should never be underestimated when designing a monitoring network.

Deposition Gages [15]

Traditionally in the U.K., measurements of atmospheric dust have been made using the passive British Standard dust deposition gage, while measurements of “smoke” have been made using the active filter system described in the previous section. The standard dust deposition gage consists essentially of a bowl of diameter 300 mm and depth 225 mm mounted 1.2 m above the ground; the sample is washed into a bottle beneath the gage, from where it is filtered, dried, and weighed. After having been in use for the better part of a century, the collection efficiency of the standard gage was tested and found to be, in fact, rather poor. In very light winds, 50% of particulate at 100 μm and 80% at 200 μm might be captured, but these efficiencies fall off very rapidly with increasing wind speed.

More recent work has shown that a gage shaped like an upside-down Frisbee® has a far superior capture performance. With the addition of a foam substrate, collection efficiencies in excess of 80% in light winds, even for particle diameters as small as 50 μm , can be achieved and these efficiencies remain good at moderate wind speeds. Such gages are now commercially available.

Active Aerosol Sampling

Measurement of particulate matter of aerodynamic diameter less than 100 μm in air requires an active sampling system.

A conventional high-volume sampler for total suspended particulate (TSP) consists of a filter and a powerful blower. The system is mounted in a housing with a pitched roof, the air being drawn in under the eaves (i.e., at a height of about 1.1 m). Air sampling rates are in excess of $1 \text{ m}^3 \text{ min}^{-1}$. The filter can be changed and weighed, or otherwise analyzed, after 24 h.

Size discrimination is introduced into such samplers by requiring the air to follow a tortuous path. Small particles then follow the streamlines, while large particles are deposited. As a first stage, the high-volume sampler may have an inlet impaction chamber, which only allows the PM10 fraction to be captured in the filter.

In a more sophisticated system, the filter can be replaced with a cascade impactor. This consists of a stack of plates with successively smaller perforations. The holes are staggered so that air passing through one hole impacts on the following plate. As the perforation size diminishes, the air speed increases and the size of particle that can escape diminishes. By covering each plate with a removable membrane, the particulate captured in each size fraction can be analyzed and, in principle, weighed. See [Figure 73.8](#).

Low-flow systems ($1 \text{ m}^3 \text{ h}^{-1}$) are also available, which permit measurement of PM10 or PM 2.5. Inlet heads, certified by the EPA, are available for various cutoff diameters. Reference 16 quotes capture efficiencies for such devices as a function of particle size.

Active or passive aerosol sampling systems are marketed by, among others, Charles Austin Pumps, Graseby-Andersen, and Casella.

FIGURE 73.8 Cascade impactor with a 10 μm inlet head operating at a rural site in eastern England.

Fast Ambient Monitoring

The alternative to a mechanically based, slow-response sampler that must be visited regularly is an automatic, fast-response system, self-calibrating if possible, which is logged on-site and may be interrogated remotely. Routine visits are then minimized, while visits can be made urgently if there is an alarm. Instruments currently available for various common gases are listed below. Most of these systems are designed to be bench- or rack-mountable, weighing typically in the range of 15 to 30 kg. Auto-calibration versions are available for most of them. Most manufacturers also supply appropriate logging systems with user-friendly software. The quoted measurement range is from the lower detectable limit (LDL, typically 2σ) to the maximum concentration. (The full range is not necessarily achievable on a single range setting.) The response time is typically the rise time to 95% of final value; with some instruments, there may also be a significant lag time. Prices were quoted in the U.K. in August 1996; prices of individual models are not quoted since any useful comparison would depend on detailed specifications in relation to the needs of the individual user. Quoted prices of nominally similar instruments show a surprisingly wide spread: it is worth shopping around.

TABLE 73.2 Selection of Manufacturers of Point Samplers with Their Appropriate Model Numbers

Manufacturer	SO ₂	NO _x	O ₃	CO	CO ₂
Dasibi	4108	2100	1008	3008 ^a	
Horiba	APSA-360	APNA-360	APOA-360	APMA-360 ^b	
Monitor Labs	ML9850	ML9841A	ML9810	ML9830 ^a	ML9820 ^a
Signal-Ambitech	Ambirak	Ambirak	Ambirak	Ambirak ^c	
Thermo-Unicam	43C	42C	49C	48C ^a	41 ^a

^a Rotating wheel containing CO (or CO₂) and N₂ gas cells is used to modulate the signal.

^b Modulation is achieved by alternating between sample and reference gas in the absorption chamber.

^c Photoacoustic detection. Modulated change in pressure due to IR absorption in sample relative to reference cell is measured.

SO₂

Most ambient monitors for SO₂ now use UV fluorescence; when irradiated, SO₂ molecules re-emit light in the range 220 to 240 nm. The measured light intensity is then proportional to the SO₂ concentration. Currently available systems have response times of order 1 to 4 min, LDL of order 0.5 to 1 ppb, and maximum ranges of 1 to 100 ppm. Prices start at around \$9000. Most manufacturers also supply a converter that allows H₂S to be measured as a separate channel.

NO_x

Most ambient monitors for NO_x now employ chemiluminescence. Ozone generated within the instrument is mixed with the sample air. NO in the sample then reacts very rapidly to form NO₂, with the emission of IR radiation (peaking at 1200 nm). This is a first-order reaction. IR emission is therefore proportional to the NO concentration. Total NO_x can be measured by first passing the sample air over a catalytic converter to reduce any NO₂ present to NO. By alternating this conversion, or through the use of a dual channel system, NO₂ concentrations may be found by difference. Inevitably, the measurement of NO₂ will be noisier than that of NO or NO_x separately. Currently available systems have response times of order 1 to 4 min, LDL of order 0.5 to 1 ppb, and maximum ranges of 10 to 100 ppm. Prices start at around \$9000. Most manufacturers also supply a converter that allows NH₃ to be measured as a separate channel.

O₃

Most ambient monitors for O₃ now use modulated UV absorption. O₃ has a broad absorption spectrum in the UV, with a peak around 254 nm. Practical instruments alternate the gas in the absorption cell between sample air and a de-ozone reference gas; from the Beer-Lambert law, the log ratio of the signal must then be proportional to the O₃ concentration. Currently available systems have response times of order 20 s to 2 min, LDL of order 0.5 to 2 ppm, and maximum ranges of 1 to 200 ppm. Prices start at around \$7000.

CO and CO₂

The standard method of measuring ambient CO or CO₂ is to use modulated IR absorption (NDIR); modulation of the signal allows detector offsets to be removed. Currently available systems have response times of order 15 s to 2 min, LDL of order 0.05 to 0.1 ppm for CO and <2 ppm for CO₂, and maximum ranges of 10² to 10⁴ ppm. Prices start at around \$9000.

Table 73.2 provides a selective listing of manufacturers of point samplers.

Hydrocarbons

The instruments available for the detection of ambient hydrocarbons tend to be somewhat more diverse than for the gases listed above. The most widely used technique is flame ionization detection (FID). A hydrogen flame is burned in the sample gas between two electrodes and the flame conductivity measured.

This tends to be proportional to the concentration of $\cdot\text{CH}$ ions in the flame, although the calibration varies between hydrocarbon species. Most commercial instruments allow CH_4 to be measured separately by first passing the sample gas across an oxidation catalyst. Non-methane hydrocarbons (NMHC) are thereby removed from the sample; they can be estimated by difference from the total hydrocarbon (THC) channel. In principle, a FID is very fast, with some commercial instruments having response times as short as 1 s. There is, however, a tradeoff between sensitivity and response time, a sampling time of several minutes being required to give an LDL of 20 ppb.

Most of the manufacturers listed in Table 73.2 supply FIDs for ambient monitoring. Dasibi offers an instrument (Model 302) that combines an FID with a gas chromatograph, thereby giving good speciation. Photovac manufactures a hand-held FID (MicroFID), which is designed to be intrinsically safe and intended for, for example, workplace monitoring or leak detection. Prices for the standard instruments start at about \$12500.

An alternative technique for hydrocarbons is photoionization detection (PID). This is nonspecific, with the detector also responding to inorganic gases of low ionization potential (e.g., NH_3). It is, however, very fast (with response times from 0.2 s for an LDL of 10 ppb) and the instruments can be made to be economical, lightweight, and intrinsically safe. A typical application might be as a hand-held leak detector in a chemical plant, or as a personal monitor of toxic solvents. Instruments are marketed by Casella, Photovac, and RAE Systems.

Wet Chemiluminescence

In addition to the above dry systems, wet chemiluminescence systems for NO_x and O_3 are available from Unisearch Associates. In these instruments, sample air is drawn over a wick containing a proprietary solution that reacts with the target gas. Light emitted in the reaction is monitored. The system is fast (response time ≤ 0.5 s), sensitive (LDL ≤ 0.1 ppb), and lightweight. It is, however, somewhat more expensive than the dry systems.

Aerosols

Measuring atmospheric aerosol concentrations at ambient levels in real time is more demanding than measuring trace gases because the pollutant is concentrated into a relatively small number of tiny particles, inaccessible to spectroscopic examination. Methods based on the scattering of laser light are available (e.g., Grimm, Model No. 1.104), although they must be calibrated to the specific aerosol being sampled. Direct gravimetric methods are also employed, based either on beta-absorption or on an oscillating filter. The sensitivity required for such a measurement can be appreciated if one considers a sampler drawing 3 L min^{-1} that is intended to measure aerosol concentrations over a sampling period of 6 min. A detection limit of $5 \mu\text{g m}^{-3}$ then requires that the sample mass be measured to a precision of 90 ng.

In the beta-absorption technique (e.g., Horiba, Model APDA-360), the sample air is drawn through a filter exposed to beta-radiation. As atmospheric aerosol is deposited on the filter, its transparency to the radiation gradually diminishes. Differentiating the transmitted signal with respect to time gives an aerosol concentration at close to real time. Commercial instruments have an automatic system for regularly changing filters, which are then available for subsequent chemical analysis.

In the TEOM (Tapered Element Oscillating Microbalance; Rupprecht and Patashnick, Model No. 1400a) system, the filter is balanced on a hollow tube through which the sample air is drawn. The tube is clamped at its base and induced to vibrate at a frequency that depends on the mass of the filter. Again, the differential of the filter mass with respect to time provides the aerosol concentration.

Whichever system is employed, care must be taken in the choice of inlet port so that the desired fraction of ambient particulate is sampled. Typically, a PM10 sampling head would be employed.

Remote Monitoring

While point samples of air pollution can be very valuable, they are limited both in their position, which is normally near ground level, and in representing a single point rather than a broader spatial sample. A variety of optical techniques are available that permit more general measurement of pollution in the atmosphere.

Long-Path Measurements

With the use of a broadband source and a retroreflector, spectroscopic analysis of the returned light can provide spatially averaged measurements of a wide range of pollutants. Two commonly used systems are Hawk (from Siemens Environmental Systems) and OPSIS.

For ambient monitoring, OPSIS applies DOAS to an absorption spectrum ranging between the UV and the near-IR. The spectrum is digitized by scanning the output from the spectrometer and sophisticated fitting routines are then applied to detect target species in the presence of other absorbers and scatterers. Standard systems are available for monitoring three (NO_2 , SO_2 , O_3) or five (+ toluene, benzene) species, with the three-species system costing from about \$80,000. Modules can be added for a range of trace gases. The system can also be used for emissions monitoring. An absorption band in the IR can then be used and the calibration must be optimized to the optical density of the particular flue.

Hawk employs a broadband source and an oscillating interference filter. Since the spacing of the lines of the filter normal to the light path varies with the cosine of the angle of incidence, the positions of the absorption lines must also oscillate. The system is tuned to lie close to an absorption line of a target gas; the differential signal then measures the gas concentration. A given instrument is thus limited to one, or at most a few closely related analytes; the system is particularly good for alkanes. Instrument costs start at about \$16000, but there is no fixed price since costs depend on the complexities of the spectrum of the desired target species.

Overhead Burden

If one is interested in concentrations well away from the ground, a retroreflector may be impractical. In this case, spectral measurements of sunlight scattered from the sky can provide us with an estimate of the total overhead burden of a pollutant. "Cospecs" (Correlation Spectrometers) have been available since the early 1970s for the measurement of SO_2 or NO_2 burden. These are most valuable in conjunction with mobile surveys of elevated emissions, since they allow the operator to know when he is beneath the plume. With very careful calibration, and a knowledge of the wind speed, they may also be used to estimate the pollutant flux. The instrument has no absolute zero level and so has difficulty distinguishing very broad plumes. They are still made to order by Barringer Research.

The classic measurement of overhead pollutant burden is that of stratospheric O_3 using the Dobson spectrophotometer. This measures the difference in irradiance at two wavelengths 20 nm apart close to the peak of UV absorption by O_3 ; other things being equal, this difference is proportional to the overhead burden of O_3 . The system was used to detect the ozone hole over Antarctica [17]. The detection method has remained unchanged since the original instruments of 60 years ago, although the optics have been refined and the valve electronics have now been replaced with solid-state. The continuity of method was important in giving confidence in the surprising observation of the ozone hole in the mid-1980s. Instruments are available from Ealing Electro-Optics.

Lidar

Lidar (Light Detection And Ranging) is the optical equivalent of radar [8,18]. A pulse of laser light is directed into the atmosphere. Backscattered light is collected by a telescope and directed to a photomultiplier tube. The strength of the return signal corresponding to a given range $R = ct/2$ is given by the Lidar equation:

$$V(R) = \frac{CW}{R^2} \sigma_b n(r) \exp \left\{ -2 \int_0^R (\sigma(\lambda) \chi(r) - \sigma_e n(r)) dr \right\} \quad (73.5)$$

where C is a system constant, W the pulse energy, $n(R)$ the density of scatterers, σ_b and σ_e , respectively, the backscatter and extinction cross-sections for scattering, and $\sigma(\lambda)$ the absorption cross-section from a tracer gas of concentration χ . If the extinction is small, scanning the laser beam through an elevated plume allows a cross-section of the scatterer density to be built up. The range resolution of this cross-section

depends on the frequency at which the signal is digitized; a 60-MHz digitizer gives a range resolution of 2.5 m. The time resolution of the measurement depends on the pulse repetition rate of the laser. At 30 Hz, a 2-s scan would normally give adequate lateral spatial resolution. *A priori* calibration for particulate density requires knowledge of σ_b , which in turn depends on the particle size and refractive index. In practice, an independent gravimetric measurement must be made at some point in the scanned area.

Alternatively, shots can be alternated between two nearby wavelengths having very different values of $\sigma(\lambda)$. Neglecting variations in the other terms, the Lidar equation can be rearranged to give:

$$\chi(R) = \frac{1}{2(\sigma(\lambda_1) - \sigma(\lambda_2))} \frac{\partial}{\partial R} \log \left(\frac{V_2(R)}{V_1(R)} \right) \quad (73.6)$$

Since the differential absorption $\sigma(\lambda_1) - \sigma(\lambda_2)$ can be measured in the laboratory, one now has a remote, range-resolved measurement of the tracer gas. This technique is known as DIAL (Differential Absorption Lidar) [8] and has been applied to a wide range of atmospheric pollutants (SO₂, NO₂, O₃, CH₄, hydrocarbons, Hg, etc.). Its particular strength is in identifying and quantifying fugitive emissions, for example, CH₄ from cattle or leaks in refinery plant [19]. Because of the greater subtlety of the measurement, it does not in general have the spatial or temporal resolution of a simple backscatter Lidar. For a given DIAL system at a given range, the product of spatial, temporal, and concentration resolution is approximately fixed; optimal performance in one is at the cost of worse performance in the others. If the signal is rather weak, there is a temptation to average measurements over a period greater than the timescale for a significant change in the target gas concentration. Great care should be taken in this case since the nonlinearity of Equation 73.6 can then lead to very serious distortions [20].

DIAL services are available from, for example, the National Physical Laboratory (NPL) and Siemens Environmental Systems in the U.K. Elight in Berlin supplies complete DIAL systems.

Emissions Monitoring

Industrial plants are, in general, authorized to release effluent to the atmosphere on the condition that such emissions are monitored reliably enough to satisfy the regulator that authorized limits have not been exceeded. This has increasingly led to the continuous monitoring of prescribed substances, with measurements being automatically displayed and archived. Aside from satisfying regulatory conditions, such monitoring can also be of value to the operator in controlling his plant. Note that any measured value of pollutant concentration must be converted to standard conditions of temperature, pressure, humidity, and excess O₂ before comparison with a regulatory standard.

Isokinetic Sampling of Aerosol

The gold standard for the measurement of aerosol emissions is to take a sample of the effluent and weigh the particulate therein. This is done by introducing a sample line into the flue, pumping the gas through a filter, and measuring the mass gained per metered volume of flue gas. It is essential that the gas speed at the sample inlet is the same as the flow velocity in the flue; if it is too fast (or slow), large particulate will be under (or over) sampled. To ensure a representative sample, such measurements must be made at several diameters downstream of any bends or confluences in the flue. It is also necessary to take several samples (4 or 8) over the cross-section of the flue. Even taking every precaution, the precision of the method may be as poor as 20% of the mean value. In practice, the nominal calibration against continuous monitors can be found to be *very much* worse than this from trial to trial.

Since each sample can take 30 min, this procedure clearly does not give a real-time measurement of particulate load. In poorly designed plants, there may also be severe practical difficulties in gaining access to the flue with heavy, powered sampling equipment at a sufficient height for the flow to be uniform. Nevertheless, this is the only direct gravimetric method of measuring particulate concentration in a flue. For this reason, regular (at least annual) such measurements would be required for the calibration of any continuous monitors.

Aerosol Sampling: *In situ* Methods

In situ methods are particularly attractive for emissions measurements because the pollutant is measured directly without any possibility of loss or transformation in the path from flue to instrument.

The most obvious way of continuously measuring the dust load in a flue is to pass a beam of light across the flue and measure the obscuration. It can be assumed that the transmission obeys the Beer-Lambert law and that the optical density is proportional to the particulate load. Practical instruments, of course, require a degree of sophistication to allow for instrumental offsets. It will not generally be possible to turn off the plant at regular intervals to check the instrument zero! Typically, the light source will be modulated and a modulated signal measured. Purge air is normally blown over transmitter and receptor windows (and the retroreflector if used) in order to keep the light path clear. The sensitivity of the system will nevertheless drift with time (and will change with the composition of particulate), so regular gravimetric calibration is essential.

Such cross-duct monitors are simple and robust, and they provide a measurement across the full width of the flue. They are limited to optical densities in the approximate range 0.01 to 2.5. Systems are available from Codel, Land Combustion, Grimm, United Sciences, and others.

For very narrow ducts, or for very low particle densities, a more sensitive technique must be chosen. As with ambient particulate monitoring, it is possible to use sideways scattering from a light beam. The transmission and reception optics are now set up so that there is no direct path between the two. Light scattered from particles in the flue can, however, be detected. This gives a true zero level in the absence of particulate, and a signal proportional to particle density. Care must be taken to ensure that the light path is representative of the particle distribution in the flue. By switching the light path, it might be possible to route it through a filter of known optical density, thereby permitting online calibration. Such systems are available from Erwin-Sick and from United Sciences.

An alternative technique is the triboelectric monitor. In this device, a metal rod is inserted across the flow. Particles striking the rod transfer static charge to it. The leakage current (or, better, the rms component thereof) is thus proportional to the particle flux along the duct. This method is fast, simple, and robust; it is little affected by the accumulation of dirt on the probe and is insensitive to the presence of steam (which would, of course, preclude optical measurements of particle density). In very wet flows, there are possible problems with leakage across the insulated base of the probe; these can be overcome with the use of purge air or extended insulation. It should be noted that, with this device, calibration is required not only for gravimetric particle density but also for the flow speed in the duct. If this speed varies significantly, the implicit particle density will be in error. Systems are available from PCME.

Gas Sampling: Spectroscopic Methods

The cross-beam technique can be applied to *in situ* sampling for pollutant gases. Practical devices are usually based on nondispersive absorption of IR or UV. DOAS can also be used. Sophisticated instrumental design is necessary to ensure:

- Minimal interference from other species present in the effluent. In combustion gases, for example, high concentrations of H₂O, CO₂, and acid gases may be present. Measurement of CO in the IR involves the use of an absorption window at a wavelength of about 4.7 μm between the absorption bands of CO₂ and H₂O.
- Minimal interference from IR emissions from the hot flue gases. Typically, a modulated system would be used.
- Insensitivity to instrumental drifts (dirty windows, misaligned optics, aging of source and detector). This can be achieved with dual light-path systems, where only one path is sensitive to the target gas. The differential signal then gives a robust measurement of concentration in the flue. This can be calibrated online by switching in cells containing a known concentration of the target gas.

[Table 73.3](#) provides a selected listing of manufacturers of cross-duct emission systems.

TABLE 73.3 Selection of Manufacturers of Cross-duct Emission Systems

Supplier	Technique	Gases
Codel	NDIR	Multigas, CO, SO ₂ , NO/NO _x , HCl, H ₂ O, hydrocarbons, NO ₂ , CO ₂ , NH ₃ , VOCs
Erwin-Sick ^a	DOAS (UV)	SO ₂ , NO, NO ₂ , NH ₃
Land Combustion	NDIR	CO
Monitor Labs ^a	NDIR	CO, CO ₂ , H ₂ O
	Modulated UV	NO, SO ₂
OP SIS	DOAS	Many

^a In these systems, the beam is enclosed within an optical probe inserted into the duct. Sample gas diffuses in through a ceramic filter. Besides protecting the optics, this permits calibration by injecting reference gases into the measurement cavity.

Gas Sampling: Extractive Techniques

If flue gases are to be sampled by an extractive technique, great care must be taken in delivering the sample from the flue to the monitor. Most of the techniques used for extractive emissions monitoring are the same as those for ambient gas monitoring; in many cases, even the same instruments might be used. Since process gases tend to be hotter, wetter, dustier, and more acidic than ambient air, there will often be a need to change the condition of the sample so that it is acceptable to the monitor. The aim of sampling technology is to deliver an acceptable sample to the instrument at a target gas concentration that bears a known relation to the gas concentration in the flue [21].

In general, the sample can be conditioned by dilution, by filtering, by cooling, or by drying. The techniques chosen will depend on the gas being measured and on the instrument being used. At its simplest, conditioning may amount to the sample gas being diluted with several hundred times its volume of clean air. Normal ambient monitors could then be used, but separate measurements would have to be made of O₂ and H₂O in order to express the measured concentration in standard form.

To avoid clogging of the sample line, it is usual to filter the sample as soon as practically possible. To avoid condensation, the normal practice is to keep the line heated. If, however, the instrument cannot tolerate flue gas temperatures, cooling will be necessary at some stage. If this is done without dilution, water will condense out and subsequent measurements will be on a dry gas basis. In itself, this is advantageous, but any acid gases will remain with the water and be lost. Alternatively, the sample can be dried by passing it through a permeation drier. Such driers cannot tolerate acid gases. SO₂, for example, must therefore be measured on a wet gas basis, with temperature and condensation being controlled by appropriate dilution.

Considerable skill is involved in designing and implementing continuous extractive emissions monitoring systems. Instruments are available for hydrocarbons and for the conventional range of stack gases from Bernath Atomic (THC), Horiba, Land Combustion, Monitor Labs, Servomex, Signal-Ambitech, and Thermo-Unicam.

Table 73.4 provides the addresses of the various manufacturers of air pollution measurement instrumentation, and Table 73.5 provides Web site addresses for Table 73.4.

Defining Terms

Aerosol: Particulate matter so finely divided in a gas that it remains in suspension. The aerodynamic diameter of an aerosol particle is conventionally defined as the diameter of a sphere of density 1 g cm⁻³ which would have the same sedimentation velocity.

Burden: The integrated concentration of an analyte along a defined path.

Concentration: The mass or volume of an analyte in a unit sample volume. The volume may need to be defined in terms of temperature, pressure, humidity etc.

Deposition: The transfer of material from the atmosphere to a surface.

Monitoring: A routine series of measurements made for control purposes.

Protocol: A written list of instructions for obtaining a reliable measurement.

73.3 Water Quality Measurement

Kathleen M. Leonard

Maintaining and verifying water quality is important in many environmental applications. The most obvious is in drinking water applications; but industrial and municipal wastewater, natural surface/groundwater, industrial process waters, and closed-loop control systems all require a certain range or maximum concentration of species to operate properly. Therefore, the development of instrumentation for monitoring and detecting these contaminants is a highly competitive area. Of course, the chemical species of interest depend on the ultimate use of the water, but this chapter section deals with some of the water quality sensors and instrumentation being currently used.

Table 73.6 provides a list of the most commonly monitored chemical species in the area of water quality. The third column categorizes the parameters in the general categories of drinking water, wastewater (municipal), industrial, stormwater, and ambient water quality. The "ultimate reference" source for accepted methods of determining chemical concentrations in water is known as the *Standard Method for the Examination of Water and Wastewater* [1]. This book has been updated regularly since 1905 and contains the current techniques recommended by Water Environment Federation (WEF) and the U.S. Environmental Protection Agency (EPA).

The next chapter subsection introduces the theory behind the some of the major types of water quality sensors, including electrical, optical, and chemical separation. Since each technique has its own particular water quality applications, a brief discussion of advantages and disadvantages is included. This section is limited to commercially available instruments commonly used both inside and outside the laboratory,

TABLE 73.6 Common Chemical Species Monitored in Water Quality

Chemical Parameter	Chemical Symbol	Primary Use ^a
Ammonium	NH ₄	DW, WW
Arsenic	As	DW
Barium	Ba	DW
Bicarbonate	HCO ₃ ⁻	DW, WW
Cadmium	Cd	DW, WW
Calcium	Ca ²⁺	DW
Carbonate	CO ₃ ²⁻	DW
Chlorinated Hydrocarbons	Various herbicides and pesticides	DW, SW
Chloride	Cl ⁻	DW, SW
Fluoride	F ⁻	DW
Chromium	Cr	DW
Dissolved Oxygen	O ₂	WQ
Hydrogen (pH)	H ⁺	DW, WW, WQ
Iron	Fe	DW
Lead	Pb	DW
Magnesium	Mg ²⁺	DW
Mercury	Hg	DW
Nitrate	NO ₃ ⁻	DW, WW, SW
Nitrogen	N	DW, WW
Petrochemicals	Various	
Phosphates	PO ₄ ³⁻	WW, SW, WQ
Potassium	K ⁺	WW
Selenium	Se	DW
Silver	Ag	DW
Sodium	Na ⁺	DW
Sulfate	SO ₄ ²⁻	DW, WW
Gross Measures		
Alkalinity	As CaCO ₃	DW
Biochemical Oxygen Demand	BOD	WW, WQ
Conductivity		
Chemical Oxygen Demand	COD	WW, WQ
Hardness	As CaCO ₃	DW
Particle counts		WW, WQ
pH	H ⁺	DW, WW, WQ
Total Organic Carbon	TOC	SW, WW, WQ
Other Parameters		
Color		
Dissolved Solids	In ppm	SW, DW
Turbidity	In NTU	DW, WQ
Microbiological contaminants	Counts/100 mL	DW, WW, WQ
Radiological contaminants	In curies	DW

^a DW: Drinking water, WW: Waste water, SW: Storm water, WQ: Water Quality.

although emphasis is placed on field (i.e., portable) instruments. Future trends will be addressed in the conclusion section.

Theory

Electrical Methods of Analysis

There are various electric mechanisms employed for determining water quality concentrations. For example, in the area of electrochemical sensors, there are potentiometric, amperometric, and conductometric devices [2]. The pH sensor for determining hydrogen ion concentration is probably the most widely used instrument in this category.

Potentiometric Sensors.

This type of sensor is based on the relationship of the electrochemical cell and the chemical activity of a sample, based on the general form of the Nernst equation:

$$E_{\text{cell}} = E^0 - \left(RT/nF \right) \ln \left\{ \left(\text{red} \right) / \left(\text{ox} \right) \right\} \quad (73.7)$$

for the general reaction: $\text{ox} + ne^- \leftrightarrow \text{red}$. ox and red indicate the oxidized and reduced species [3]. The term RT/F has a value of 0.059. E^0 is the standard cell potential and E_{cell} is the adjusted cell potential. In short, the activities of the oxidized and reduced species determine the potential of the electrode. If the relationship of the reacting species is known, it is used to measure concentration of that species in another solution. In most electrochemical instruments, it is important to maintain a reference electrode whose potential remains constant for all cell conditions or one that can be easily calibrated for other species. These sensors are commonly known as ion-selective electrodes (ISE) in environmental applications (also known as ion-sensitive field-effect transistors or ISFET). They are all based on the activity level of a specific ion within a solution. The key to the ISE is the use of an ion-specific membrane with channel size proportional to the concentration of the ion. It is necessary to maintain a reference potential to ensure that the “ion concentration will be directly related to the substrate potential [4].” Specific electrodes can be based on a gas electrode, metal electrode, oxidation–reduction electrode, membrane electrode, glass, liquid membrane, crystalline membrane, or electrode with metal contacting a slightly soluble salt [5]. Examples of this type of sensor and instrumentation for gross measurements include pH sensors, dissolved oxygen, hardness, and dissolved solids.

Commercially available ion-selective electrodes include sensors for ammonia, chlorides, cyanide, iodide, fluoride, nitrates, potassium, and sodium. The instruments labeled as multiparameter water quality monitors, such as that available from Solomat, are usually composed of one meter with separate probes for each measurement parameter. However, some of these multiparameter monitors have been upgraded with a multichannel probe that contains the separate probes within a single housing.

A membrane probe in popular usage is the dissolved oxygen probe based on the principle of polarography. It consists of a gas-permeable membrane over a silver anode and a platinum cathode within a cavity full of electrolyte (usually KCl). [Figure 73.9](#) shows the placement of the anode and electrode in a typical polarographic membrane probe. Since the oxygen will be reduced at the cathode, a current is induced. The amount of oxygen can then be correlated to the current when a potential is applied to the anode and cathode.

The pH instrument is one of the most commonly used potentiometric sensors in water quality applications. It is based on a glass electrode that develops a potential related to hydrogen ion activity of the solution. Since this probe was initially developed in the early part of the 1900s, there are numerous probes and meters on the market. Small, battery-operated, hand-held units are excellent choices for fieldwork. However, for more precise applications, advanced (i.e., expensive) laboratory-grade instruments are also available. Most pH probes require standardization and may have other upkeep requirements after prolonged usage.

Amperometric Sensors.

The amperometric classification of electrical sensors is based on the measurement of current through a working electrode. An empirical relationship can be used to enhance the performance of these electrodes. An example of such a probe is an electrode for chlorine, consisting of a silver anode and platinum cathode within an electrolyte reservoir. A chemically specific membrane allows only the ions of interest within the probe cavity near the cathode. Reduction occurs at the cathode and then the silver anode reacts with the electrolyte and, through oxidation, positively charged ions produce a current.

Conductometric Sensors.

The conductometric sensors are based on measurements of concentration of a sample due to modulation in conductivity. For example, conductivity is usually measured with a direct reading of electrical conductivity in water, which is then correlated with the number of ions present. The probe usually

FIGURE 73.9 Simplified diagram of dissolved oxygen sensor based on polarography. The oxygen-permeable membrane surrounds the anode and cathode to deter other chemical species from entering the electrolytic solution.

consists of two voltage electrodes (+ and -) and two current electrodes (also + and -) supported by some type of housing. The newer instruments have a temperature compensation option and data storage. Most will also provide a reading of total dissolved solids. Conductometric sensors are also available for resistivity, salinity, and temperature measurements.

The most commonly available dissolved oxygen (DO) sensors are galvanic electrodes with replaceable membranes. The current is proportional to the DO concentration under steady-state conditions [1]. One of the drawbacks of this type of probe has been the need for periodic calibration, either in air or a saturated medium. Some of the newer products are self-calibrating, thus eliminating this error source. There are many companies that sell these products and the prices range from modest (\$300) to high, depending on extras. If the application will be messy, (e.g., wastewater), the added expense for the deluxe model, such as a self-cleaning probe may be realized very quickly. A company that has been producing DO instruments for many years is YSI. It has a “deluxe” model with microprocessor control and RS232 interface for continuous reading.

Optical Sensors

This category involves any type of measurement system that relies on an optical property to measure a chemical concentration, including reflection, colorimetry, fluorescence, or absorption of light. The general equation relating wavelength of light (λ) to the energy of a photon (E) is given by the Planck equation:

$$E = hc/\lambda \tag{73.8}$$

where h is Planck’s constant (6.626×10^{-34} J s) and c is the velocity of light (3.0×10^8 m s⁻¹). Some of these mechanisms are included in the category of “gross optical measurements.” This category includes any method that uses reflection/refraction of light beams, colorimetry, or absorption of light. For example, in order to determine the efficiency of a water treatment system due to deteriorating filter capacity or to optimize coagulant dosages, a particle counting method is used. This type of measurement can give not only quantity, but also size ranges. This method is helpful in guarding against the intrusion of cryptosporidium cysts and guardia in a drinking water facility.

Nephelometry.

In this method, light is directed to the sample and the light reflected at right angles to the beam is measured (Tyndall effect). This type of analysis is the accepted method for quantifying turbidity (cloudiness) since the intensity of light scattered by a water sample can be compared to the scattering of a standard (usually Formazin polymer) under similar conditions. The units measured are known as nephelometric turbidity units (NTUs), which are approximately comparable to the older “candle” units. A turbidimeter consists of a light source and a photoelectric sensor that measures the light scattered at 90° from the source.

Absorbance Methods.

Certain chemical species exhibit natural light absorbance patterns over a range of wavelengths. These include nitrates/nitrites, heavy metals, unsaturated organics, and aromatics. This approach is valid even in multicontaminant solutions, since no two substances have exactly the same absorbance pattern. Several commercially available instruments take this technology to water quality applications with online capabilities. For example, in the water/wastewater area, there are flow-through monitors that measure a broad range of wavelengths of ultraviolet light simultaneously. This pattern is checked against a “signature” for the contaminant of interest and both the presence and concentration are verified.

Some contaminants do not have a natural absorbance, so a “conditioning” step is required in order to use this method. This usually involves the addition of a secondary chemical, or indicator, that will absorb in the presence of the contaminant. This is commonly known as induced light absorbance. Ammonia, phosphates, and chlorine absorbance probes are available with this conditioning step.

There are several advantages to using absorbance, including low maintenance, especially when compared to ISEs, high reliability, and automatic compensation for turbidity (which can cause havoc in other systems). One of the major drawbacks of the available models is the need to buy a separate unit for each contaminant, at a comparatively higher cost than ISE.

Colorimetry.

This simple method works by correlating the color of a solution with the concentration of a specific chemical. The theory is that light absorption (A), which is the amount of light intensity (I/I_0) absorbed, as is related to concentration based on Beer’s Law [5]:

$$A = \log\left(I/I_0\right) = k^n C \quad (73.9)$$

where k^n is the constant for a particular solution and C is the concentration of the solution. Beer’s law is valid for most water quality ranges of concentration, but it can be verified using dilutions of a specific contaminant. The first and still simplest colorimetric methods involve the use of color-comparator tubes (or Nessler tubes) for comparing a range of standards to water samples. However, this method is susceptible to large discrepancies due to human error in selecting variations of tints of a color. An instrument that improves upon the accuracy of colorimetry is a photoelectric colorimeter. A light source is directed through a filter (making it monochromatic), then passed through the sample cell and on to the photoelectric detector. The obvious advantage over the comparator is the elimination of the human factor for identifying variations in color. Another adaptation is the spectrophotometer, which employs a diffraction grating to select the wavelength for a wide variety of uses. It is a very versatile instrument since both the incoming and outgoing wavelengths are selectable. Newer models incorporate computer chips for automatic programming and data storage.

Colorimetric tests include single analyte meters for chlorine and DO, and direct readout multianalyte photometers for many parameters. For example, the DPD colorimetric method is commonly used to measure total chlorine concentrations in water and wastewater. However, it must be used with caution, since turbidity, other organic contaminants, monochloramine, etc. will cause interference.

Fluorimetry.

This method utilizes the fluorescence, either natural or induced, of a compound. Fluorescent chemicals absorb radiation of a specific wavelength and emit at another. Fluorescent tracers are commonly used in water quality studies to determine direction of flow for both surface and groundwater systems. Fluorescent tracers include Rhodamine B, Fluorescein, and Pontacyl Pink B. The detection instrument is known as a fluorimeter, which range from moderate cost for a stationery (single chemical) wavelength model (<\$4000) to high cost for a unit with variable wavelength and detection capabilities.

Remote Fiber-Optic Spectroscopy.

In the area of *in situ* chemical analysis, remote fiber spectroscopy (RFS) shows much promise for a variety of monitoring applications. RFS is a fiber-optic application of existing spectroscopic techniques that can be applied to the monitoring of chemical species in remote locations. In this method, light of an appropriate frequency is launched into a single optical fiber or fiber bundle. The light is guided to the region of interest through the fiber by the mechanism of total internal reflection. An optical sensor (optrode) designed for a specific chemical or chemical group is positioned at either the distal end of the fiber, or a length along the fiber. The altered signal is returned through the same fiber to the spectrometer for signal decoupling and analysis. The major advantages to fiber-optic chemical sensors (FOCS) include their small diameter, *in situ* nature, resistance to harsh environments, and imperviousness to electric interference. These properties make FOCS ideal for many environmental applications.

The distinguishing feature of most RFS systems is the type of sensor employed. There are basically two approaches to the sensor, either intrinsic or extrinsic. The intrinsic method utilizes the fiber itself as the active element, for example, using change in index of refractions from the fiber to the media as the parameter being measured. The extrinsic method uses the fiber optic only as light pipe, and usually involves incorporating a chemical onto the fiber as the active element. Most of the related literature for fiber-optic chemical sensors (FOCS) deals with design and advantages of various types of optrodes, that exploit either absorbance, surface enhanced Raman scattering, or fluorescence. Although FOCS have been mentioned in literature for the past decade, there has been little success in developing a multicon-taminant sensor for practical applications.

The direct fluorescence approach (measuring the natural fluorescence of the media) is an attractive technique for applications where aromatic chemicals are to be monitored. However, since many chemicals that act as contaminants are nonfluorophores, a fluorescent intermediate can be incorporated in the FOCS. Ideally, the intermediate should be sensitive to either a group of chemicals or a specific compound, and exhibit a spectral response that could be exploited to identify the compound.

As mentioned previously, the standard pH instrumentation is based on a glass pH electrode; however, optical methods have obvious advantages in corrosive conditions and fluctuating temperatures [6]. Optical-based pH sensors are generally based on the changes in the absorbance or fluorescence of an indicator dye that has been immobilized on a fiber optic. Recently, pH sensors based on the immobilization of fluorescein dye in a sol-gel matrix have been developed. Sol-gel chemistry is a method of producing a porous glass matrix at a low temperature using a hydrolysis of an alkoxide (usually TEO). An example of such a probe is a pH probe based on fluorescein dye in a sol-gel matrix [7].

Optical sensors for O₂ and dissolved oxygen, which are based on fluorescence or phosphorescence quenching, have the advantage of size, nonconsumption of oxygen, and resistance to interference due to flow rates or sample stirring over traditional dissolved oxygen electrodes. The major limitations is finding an indicator dye with a strong sensitivity to oxygen quenching. There are many such studies being performed; however, most are still in the research stage. For example, polycyclic aromatic hydrocarbons such as pyrene and long-wave absorbing dyes have been investigated due to their ability to be quenched by oxygen [6]. A fiber optics-based sensor that is on the market detects VOCs, such as carbon tetrachloride, TCE, and BTX in water systems (FiberChem). A similar application is a fluorescence-based system for measuring petroleum products in the groundwater.

Other Sensors

Infrared Spectrophotometry.

Most organic chemical compounds exhibit absorption in the infrared. This attribute can be used to determine atomic groupings based on quantum mechanics [5]. An example is a unit that measures total organic content (TOC) using UV-promoted persulfate oxidation and nondispersive infrared detection. This methodology allows for online TOC monitoring. Correlations can be made to convert values of TOC to biochemical oxygen demand (BOD) and chemical oxygen demand (COD) for particular samples. Drawbacks to this method include pretreatment to remove inorganic carbon and the high cost of instrumentation.

Respirometry.

The standard method to calculate BOD₅ is to measure oxygen consumption (based on DO concentration) over a 5-day period. However, there are other respirometers based on extremely small differences in DO or CO₂ concentrations using external gas sensors. This method is great for respirometry rates of animals, biodegradable contaminants, and sediment oxygen demand studies.

Chemical Separation Techniques

Separation techniques are based on the phase partitioning of molecules within a mixture. Gas chromatography refers to a mobile phase of a vapor, while liquid chromatography refers, of course, to a liquid mobile phase. There are several commonly used types such as gas-liquid chromatography, high-performance liquid chromatography (HPLC), and ion chromatographs. An excellent reference book for these methods is *Chemistry for Environmental Engineering* [5]. The advantages of these instruments are the ability to detect components in complex mixtures and high sensitivity. Chromatography instruments have long been considered standard in environmental laboratories, but the size of the instruments has been a drawback for field applications. However, size constraints are being challenged with the availability of equipment with size reductions of over 90%.

Mass Spectrometry.

In environmental applications, these are usually used in conjunction with gas chromatography and are referred to as GC/MS. The attraction of these instruments is the ability to detect a variety of compounds and also determine the mass fragmentation patterns of a complex organic structure [1]. The MS essentially ionizes the substances with an electron beam. The ions are then accelerated through a series of lenses according to their mass-to-charge ratios. The charged fragments are detected by an electron multiplier, which results in a mass spectra for the particular compound. In addition to the old-fashioned lab-scale GC/MS, there are portable units now commercially available that can be taken into the field for on-site environmental characterizations. These are very useful for ambient air toxics analysis, process diagnostics, and “real-time” groundwater plume movement. However, a newer technique of capillary electrophoresis (CE) has been gaining in popularity over capillary GC since it requires less solvent and can be extremely sensitive.

Atomic Absorption Spectrometry.

Since metals have their own characteristic absorption wavelengths, they are usually measured by the atomic absorption method where a light beam is directed into a sample being aspirated onto a flame. The resulting light is then sent to a monochromator with a detector that measures the amount of light absorbed by the flame. This method exhibits high sensitivity and is applicable to all of the commonly found metals in water. The drawback of this type of instrument is that it is not portable and is more of a laboratory method.

Instrumentation and Applications

Table 73.7 lists some of the instruments that are commercially available for specific water applications. This is not an exhaustive list of all types and manufacturers, but is indicative of the chemical parameters

TABLE 73.7 Instruments for Remote Water Quality Analysis

Product Name	Water Quality Parameters	Company
Biological Analyzers: portable HMB-IV-S	Bacteria and fungi	H & S Enterprises
Ion-Selective Electrodes: Single Parameter and Combination Types		
DO 201	Dissolved oxygen with automatic cleaning and calibration	HF Scientific, Inc
D63/5440D	Dissolved oxygen	Great Lakes Instruments

and types of instruments that are useful for field use. For example, the chemical separations category is very sparse in the table; although there are numerous laboratory instruments, very few are useful in the field.

Many of the manufacturers provide helpful technical information on theory and applications for their products. For example, Hach Company has many excellent publications for a variety of water/wastewater applications. They sell and develop instruments that vary from inexpensive kits (e.g., for colorimetry) to spectrophotometers with computer compatibility. Additionally, due to the broad range of diversity in the water quality area, there are many small companies that produce instruments for specific applications. [Table 73.8](#) provides contact information for each of the companies listed in [Table 73.7](#). Another excellent source of information is the annual listing of industrial manufacturers by Water Environment Federation.

Data Evaluation

In the past, the better instruments may have had a self-storing data system, usually in the form of paper graph or a retrievable magnetic tape. Although this allowed for continuous sampling, it was not without problems. The ease of obtaining data, *in situ* data gathering, and digital data acquisition are all attributes that are attractive in environmental applications. New technology has made these wishes a reality. For example, radio telemetry is a wireless technology to link remote sensors to dedicated computers or Supervisory Control and Data Acquisition (SCADA) systems. This capability allows for truly automated data acquisition and real-time uplinks. Other systems can be hardwired to computers (usually via RS 232 boards) or through modems to a remote acquisition site.

Trends in Water Quality Measurements

Analytical Chemistry publishes a biennial review dealing with recent literature in the area of water analysis [8]. These review articles, while not in-depth on a single topic, are quite extensive in topic matter and really illuminate trends in environmental sensing. For example, in a recent review, the area of *in situ* analysis contains a significant amount of coverage. Since many water quality applications would benefit from *in situ*, real-time data, it will be an area of research and development growth for the next 5 years.

Defining Terms

A	light absorption
c	velocity of light ($3.0 \times 10^8 \text{ m s}^{-1}$)
C	concentration of the solution
E	energy of a photon
E_{cell}	cell potential adjusted
E^0	standard cell potential
F	Faraday's constant (96,500 C/equivalent)
I	light intensity
I_0	initial light intensity
k^n	constant for a particular solution
h	Planck's constant ($6.626 \times 10^{-34} \text{ J s}$)
n	number of moles
ox	oxidized species
R	ideal gas law constant ($8.31 \text{ J mol}^{-1} \text{ K}^{-1}$)
red	reduced species
T	absolute temperature
λ	wavelength of light

73.4 Satellite Imaging and Sensing

Jacqueline Le Moigne and Robert F. Crompt

What Can Be Seen from Satellite Imagery

Satellite imaging and sensing is the process by which the electromagnetic energy reflected or emitted from the Earth (or any other planetary) surface is captured by a sensor located on a spaceborne platform. The Sun as well as all terrestrial objects can be sources of energy. Visible light, radio waves, heat, ultraviolet and X-rays are all examples of electromagnetic energy. Since electromagnetic energy travels in a sinusoidal fashion, it follows the principles of wave theory, and electromagnetic waves are categorized by their wavelength within the electromagnetic spectrum. Although it is continuous, different portions of the electromagnetic spectrum are usually identified and referred to as (from shorter to longer wavelengths): cosmic rays, γ -rays, X-rays, ultraviolet, visible ([0.4 μm , 0.7 μm]), near-infrared (near-IR), mid-infrared (mid-IR), thermal infrared (above 3 μm), microwave ([1 mm, 1 m]), and television/radio wavelengths (above 1 m). Figure 73.10 shows the electromagnetic spectrum and these subdivisions.

General Sensor Principles

Sensors are often categorized as “passive” or “active.” All energy observed by “passive” satellite sensors originates either from the Sun or from planetary surface features, while “active” sensors, such as radar systems, utilize their own source of energy to capture or image specific targets.

Passive and Active Sensors.

All objects give off radiation at all wavelengths, but the emitted energy varies with the wavelength and with the temperature of the object. A “blackbody” is an ideal object that absorbs and reemits all incident energy, without reflecting any. If one assumes that the Sun and the Earth behave like blackbodies, then according to the Stefan-Boltzmann law, their total radiant exitance is proportional to the fourth power of their temperature. The maximum of this exitance, called dominant wavelength, can be computed by Wien’s Displacement law (see References 1 to 4 for more details on these two laws). These dominant wavelengths are 9.7 μm for the Earth (in the infrared portion of the spectrum) and 0.5 μm for the Sun (in the green visible portion of the spectrum). It implies that the energy emitted by the Earth is best observed by sensors that operate in the thermal infrared and microwave portions of the electromagnetic spectrum, while Sun energy that has been reflected by the Earth predominates in the visible, near-IR, and mid-IR portions of the spectrum. Most passive satellite sensing systems operate in the visible, infrared, or microwave portions of the spectrum. Since electromagnetic energy follows the rules of particle theory, it can be shown that the longer the wavelength, the lower the energy content of the radiation. Thus, if a given sensing system is trying to capture long wavelength energy (such as microwave), it must view large areas of the Earth to obtain detectable signals. This obviously is easier to achieve at very high altitudes — thus the utility of spaceborne remote sensing systems.

The most common active satellite sensor is radar (acronym for “radio detection and ranging”), which operates in the microwave portion of the electromagnetic spectrum. The radar system transmits pulses of microwave energy in given directions, and then records the reflected signal received by its antenna. Radar systems were initially employed by the military as a reconnaissance system because their main advantage was to operate day or night and in almost any weather condition. They are very important in satellite

FIGURE 73.10 Electromagnetic spectrum.

remote sensing because microwave radiations are hardly affected by atmospheric “screens” such as light rain, clouds, and smoke. The time it takes for the radar signal to return to the satellite is also measured by instruments such as altimeters which are very useful in determining surface height measurements.

Polar Orbiting and Geostationary Earth Sensing Satellites.

Satellite remote sensing systems are also characterized by the different Earth orbiting trajectories of a given spacecraft. These two modes are usually referred as “polar orbiting” and “geostationary” (or “geosynchronous”) satellites. A polar orbit passes near the Earth’s North and South poles. Landsat, SPOT, and NOAA are near-polar satellites; their orbits are almost polar, passing above the two poles and crossing the equator at a small angle from normal (e.g., 8.2° for Landsat-4 and -5). If the orbital period of a polar orbiting satellite keeps pace with the Sun’s westward progression compared to the Earth rotation, these satellites are also called “sun-synchronous.” This implies that a sun-synchronous satellite always crosses the equator at the same local sun time. This time is usually very carefully chosen, depending on the application of the sensing system and the type of features that will be observed with such a system. It is often a tradeoff between several Earth science disciplines such as atmospheric and land science. Atmospheric scientists prefer observations later in the morning to allow for cloud formation, whereas the researchers performing land studies prefer earlier morning observations to minimize cloud cover.

A geostationary satellite has the same angular velocity as the Earth so its relative position is fixed with respect to the Earth. Examples of geostationary satellites are the GOES (“Geostationary Operational Environmental Satellite”) series of satellites that orbit at a constant relative position above the equator.

Sensor Characteristics

Spectral Response Patterns.

The design of new satellite instruments is based on the principle that targets of interest can be identified based on their spectral characteristics. For example, different Earth surface features, such as vegetation or water, present very distinctive reflectance or emittance curves that are a function of the energy wavelength. These curves are often called the “spectral signatures” of the objects being observed. Although these curves are very representative of each feature and can help identify them, they do not correspond to unique and absolute responses. Because of different reasons, such as atmospheric interactions, temporal or location variations, the response curves of a given object observed under different conditions might vary. For this reason, these curves are often called “spectral response patterns” instead of “spectral signatures.” [Figure 73.11](#) shows an example of such reflectance patterns for several features: fir tree, clear lake water, barley, and granite.

Atmospheric Interactions.

Earth satellite sensors are designed to take into consideration the fact that all observed radiation must pass at least once through the atmosphere; therefore, the energy interactions of the atmosphere must be considered during the design phase. The distance through which the radiation passes through the atmosphere is called “path length.” The effect of the atmosphere depends on the extent of the path length and on the magnitude of the energy signal. The two main atmospheric effects are known as “scattering” and “absorption.”

Scattering is the unpredictable redirection of radiation by particles suspended in the atmosphere. The type and the amount of scattering mainly depend on the size of the particles but also on the wavelength of the radiation and the atmospheric path length. If these particles are smaller than the radiation wavelength, this effect is known as “Rayleigh scatter.” This scattering especially affects the shorter visible wavelengths of the sunlight (i.e., blue visible wavelength) and it explains why the sky appears blue to the human eye. In the evening, when the path length is longer, the effect of the Rayleigh scatter is only visible on the longer red wavelengths of the sunlight and the sky appears red or orange. If the particles are about the size of the radiation wavelength, the scatter is known as “Mie scatter”; this scattering effect is often due to water vapor and dust. When the atmospheric particles are larger than the radiation wavelengths, a “nonselective scatter” occurs; all visible wavelengths radiations are scattered equally and this type of scattering explains why clouds appear white.

FIGURE 73.11 Examples of spectral response patterns for four different types of features, fir tree, clear water, barley (example of crop), and granite (example of rock). White areas show the portions of the spectrum corresponding to the 7 channels of Landsat-Thematic Mapper (TM-4&5).

Atmospheric absorption occurs in specific wavelengths at which gases such as water vapor, carbon dioxide, and ozone absorb the energy of solar radiations instead of transmitting it. “Atmospheric windows” are defined as the intervals of the electromagnetic spectrum outside these wavelengths, and Earth remote sensors usually concentrate their observations within the atmospheric windows. As an example, white areas of Figure 73.11 show the portions of the spectrum (i.e., the “channels” or “bands”) from visible to mid-IR used by the Landsat-Thematic Mapper (TM).

Spectral, Radiometric, Spatial, and Temporal Resolutions.

Although the spectral response patterns are not absolute, they play an important role in the design of new sensors. When a new sensor is being designed, the type of features to observe and the accuracy with which they will be mapped define which wavelengths are of interest, the widths of the wavelength intervals to be used, what is the accuracy to be achieved in these bandwidths, and what is the “smallest” or “faintest” feature that might be detected by the sensor. Following the examples of Figure 73.11, the best wavelength interval to distinguish between vegetation and granite will be the [1.55 μm, 1.75 μm] wavelength interval. The above sensor requirements correspond to the “resolutions” of the sensor by which it is usually identified — spectral, radiometric, spatial, and temporal resolutions. The term “resolution” is usually employed to define the smallest unit of measurement or granularity that can be recorded in the observed data. The spectral resolution of a sensor is defined by the bandwidths utilized in the electromagnetic spectrum. The radiometric resolution defines the number of “bits” that are used to record a given energy corresponding to a given wavelength. The spatial resolution corresponds to the area covered on the Earth’s surface to compute one measurement (or one picture element, “pixel”) of the sensor. The temporal resolution (or frequency of observation), defined by the orbit of the satellite and the scanning of the sensor, describes how often a given Earth location is covered by the sensor.

Signal-to-Noise Ratio.

Sensors are also characterized by their signal-to-noise ratio (SNR) (i.e., the noise level relative to the strength of the signal). In this case, the “noise” usually refers to variations of intensity that are detected by the sensor and that are not caused by actual variations in feature brightness. If the noise level is very high compared to the signal level, the data will not provide an accurate representation of the observed features. At a given wavelength λ , SNR is a function of the detector quality, the spatial resolution of the sensor, as well as its spectral resolution (see Reference 1 for a detailed formula). To maintain or improve the signal-to-noise ratio and therefore improve the radiometric resolution of the sensor, a tradeoff must be made between spatial and spectral resolutions; in particular, improving spatial resolution will decrease the spectral resolution. Of course, other factors such as atmospheric interactions will also affect the SNR.

Multispectral and Hyperspectral Sensors.

The remote sensing industry is experiencing a rapid increase in the number of spectral bands of each sensor. The first Landsat sensors (Landsat-1 and 2) were designed with four bands in the visible and near-IR portions of the spectrum. Landsat-4 and 5 were refined with seven bands from visible to thermal-IR. Then, Landsat-6 and 7 were planned with an additional panchromatic band, which is highly sensitive over the visible part of the spectrum. In general, most Earth remote sensors are *multispectral*; that is, they utilize several bands to capture the energy emitted or reflected from Earth features. The addition of panchromatic imagery, which usually has a much better spatial resolution than multispectral imagery in the visible part of the spectrum, provides higher quality detail information. Multispectral and panchromatic data, usually acquired simultaneously, are co-registered and can be easily merged to obtain high spatial and spectral resolution. Co-registered multispectral-panchromatic imagery is available from sensors such as the Indian satellite sensor, IRS-1, and the French sensor, SPOT.

Ideally, if a sensor had an infinite number of spectral channels (or bands), each observed area on the ground (or pixel) could be represented by a continuous spectrum and then identified from a database of known spectral response patterns. Adding more bands and making each of them narrower is the first step toward this ideal sensor. But, as previously explained in the previous section, due to technology limitations, it was very difficult until recently to increase the number of bands without decreasing the SNR. Due to recent advances in solid state detector technology, it is now possible to increase significantly the number of bands without decreasing the SNR, thus seeing the rise of new types of sensors, called *hyperspectral*. Although the boundary between multispectral and hyperspectral sensors is sometimes defined as low as 10 bands, hyperspectral imaging usually refers to the simultaneous detection in hundreds to thousands of spectral channels. The aim of hyperspectral sensors is to provide unique identification (or “spectral fingerprints”) capabilities for resolvable spectral objects. Potential applications include agricultural yield monitoring, urban planning, land use mapping, mining and mineral deposits, disaster relief/assessment, tactical military operations, and forest fire protection management. The NASA Airborne Visible InfraRed Imaging Spectrometer (AVIRIS) simultaneously collects spectral information from visible to infrared ranges (from 0.4 μm to 2.5 μm) in 224 contiguous spectral bands. Each band has an approximate bandwidth of 10 nm (or 0.01 μm), with a spatial resolution of about 20 m. The instrument flies aboard a NASA ER-2 airplane at approximately 20 km above sea level. The science objectives of the AVIRIS project are mainly directed toward understanding processes related to the global environment and climate change.

Super-Resolution.

When data is collected from a satellite sensor, each sample of information represents an area on the ground that might correspond to several features with different spectral responses and the final information represents a “mixture” of several disparate information. When a sensor does periodic imaging over the same area, the direction of observation slightly changes, and even when successive data are correctly registered (i.e., in a perfect correspondence), two respective samples might represent two slightly different areas on the ground. Super-resolution is an area of research that aims at combining such

information from different directions but taken under similar lighting conditions in the goal of improving spatial and spectral resolutions. As an example, some recent work [5] utilizes a Bayesian method for generating sub-pixel resolution composites from multiple images with different alignments. Software products have also been proposed by some commercial systems, such as ERDAS-Imagine and ENVI, to help in the unmixing of spectral bands (see Reference 6 for more detail).

Direct Readout Data

Examples of different spectral and spatial resolutions are given in [Table 73.9](#) with a summary of current Earth remote sensing systems that operate from visible to thermal-IR wavelengths. Table 73.9 provides information about their bandwidths and their spatial resolutions. The table also indicates if the data from these sensors can be acquired by direct readout. Sensors can transmit data in two modes. The first mode, called “direct readout,” transmits data as soon as it “sees” it, and any receiving station within that satellite footprint can receive this data. In the second mode, the sensor records whatever it sees for playback at a later time, and specialized receiving stations (or “ground stations”) are required to receive this data since it is transmitted at higher rates than direct readout. The data received by these ground stations can cover a larger extent. Historically, the cost of acquiring and processing Earth remotely sensed data has limited satellite data collection to a small number of expensive ground stations around the world, operated by the owners of the satellites. Direct readout sensors were mostly confined to meteorological applications that required timely data such as weather forecasting, severe weather identification and tracking, and disaster prediction and assessment. But this situation is changing; due to new technology, costs have been greatly reduced, and direct readout data that was initially expensive and beyond the reach of the nontraditional user, is now generating a growing interest. A small industry has evolved to design, install, and upgrade ground stations around the world that acquire direct readout data.

Typical Attributes Measured from Space

This section does not intend to be an exhaustive up-to-date description of all Earth and space applications of satellite imaging and sensing, but rather it presents a few representative applications and their associated satellite sensors. The References section as well as the World Wide Web (WWW) offer more extensive references to other applications and sensors.

Earth Science Applications.

Over the past few decades, a number of international global change research programs have been initiated whose goals are to understand the relation between human activities and the global Earth systems processes and trends. Mission To Planet Earth (MTPE [7]) is a multi-agency program, whose goal is to achieve this kind of understanding, especially through improved satellite observations. As part of NASA’s Mission to Planet Earth program, the Earth Observing System (EOS [8]) will launch, over the next 2 decades, several platforms of sensors aimed at ecology, oceanography, geology, snow, ice, hydrology, cloud, and atmospheric studies. Each platform will carry one or several instruments, thus globally covering a wide range of spectral, spatial, and temporal resolutions. Europe and Japan have similar programs, such as the ADEOS (ADvanced Earth Observation Satellite [9]), developed by the Japanese space agency, NASDA, in collaboration with France and the U.S. ADEOS, launched in 1996, flew for 9 months before it failed, and included remote sensing instruments for observing the Earth’s atmosphere, land surfaces, and oceans. Other examples of such programs are the ERS and ENVISAT satellites from ESA (European Space Agency) and the Indian satellites, IRS. ERS-1 and 2 were launched in 1991 and 1995, respectively, and ENVISAT will be launched in 1999. All these satellites carry on the same platform different instruments making simultaneous observations. The first satellite in the IRS series was launched in 1988, and in 9 years, India has designed and launched six remote sensing satellites. For more information on the IRS series, see Reference 10.

In all the above programs, studies concentrate on global processes occurring in the atmosphere (especially lower parts of the atmosphere), on the Earth surface (terrestrial studies), and in the oceans (hydrospheric studies). Results of all these studies will contribute to international programs such as the

FIGURE 73.12 Simplified diagram of the different layers of the atmosphere.

World Climate Research Programme, the International Geosphere-Biosphere Programme, and the International Human Dimensions of Global Environmental Change Programme.

Several of these instruments show application promise for regional and local community interests, in helping farmers to monitor and control their agricultural productivity (weather, disease control), in early warning and in rescue efforts in case of severe storms (e.g., hurricanes), and in predicting the spread of diseases based on vegetation data combined with socio-economic data.

Examples of Atmospheric Studies.

One of the key issues in climate research is to understand global atmospheric changes and how human activity affects the composition and chemistry of the Earth's atmosphere. To create accurate models, a large number of multiyear global studies must be conducted.

The atmosphere is divided into several layers. From the Earth's surface up to interplanetary space, which starts at about 1000 km, these layers are called troposphere, stratosphere, mesosphere, thermosphere, and exosphere. [Figure 73.12](#) shows a simplified diagram of the different atmospheric layers. Each of these layers is characterized by differences in chemical composition that produce variations in temperature. The two lower layers, troposphere (up to 10 km) and stratosphere (10 to 50 km above the Earth), are particularly important since 99% of the water vapor in the atmosphere is included in the troposphere, and 90% of the ozone of the atmosphere is included in the stratosphere. All weather phenomena occur within the troposphere, with some turbulence sometimes extending to the lower stratosphere. The concentration of ozone, which should stay mainly concentrated in the stratosphere, is being studied in both the troposphere and stratosphere.

Ozone is a relatively unstable molecule made up of three oxygen atoms. Depending on the altitude where it is found, ozone is referred to as "good" or "bad" ozone. The largest concentration of ozone is located in the stratosphere, at an altitude between 20 km and 30 km, and plays a major role in the evolution and the protection of life on Earth. Since it absorbs most of the harmful ultraviolet radiation from the Sun, stratospheric ozone protects life on Earth. When found closer to the Earth's surface, ozone

may be harmful to lung tissue and plants. Recent studies have shown that the proportions of ozone in the air are increasing compared to decreasing amounts of protective ozone. However, studies still need to determine if these changes are due to human activity or if they are part of regular natural cycles.

The mission of the Total Ozone Mapping Spectrometer (TOMS) is to provide global measurements of total column ozone as well as of sulfur dioxide on a daily basis. The TOMS instrument measures the reflectivity of the atmosphere in six near-UV wavelengths (see Table 73.9) and provides differential UV absorption and surface reflectivity data. From these measurements, total ozone is computed by searching precomputed albedo tables, which depend on solar zenith angle, view angle, latitude, surface reflectance, and surface pressure; a lower amount of radiation measured by TOMS corresponds to higher concentrations of ozone. Maps of volcanic eruptions are a byproduct of TOMS sulfur dioxide measurements. The first TOMS instrument was flown on Nimbus 7 in 1978; successive ones were launched on a Russian Meteor spacecraft in 1991, on an Earth Probe satellite in 1994, and on the Japanese ADEOS satellite in 1996. See References 11 to 16 for more information on TOMS and ozone measurements.

The TOMS measurements are also being compared to the ozone measurements provided by the NOAA (National Oceanic and Atmospheric Administration) series of the Television Infrared Observing Satellite (TIROS) Operational Vertical Sounder (TOVS) data. The TOVS sounding unit consists of three instruments, including the High-Resolution Infrared Sounder-2 (HIRS-2) whose channels are shown in Table 73.9. TOVS-type instruments have been flying since 1978. These instruments provide information about the structure of the atmosphere, vertical temperature and moisture profiles, as well as cloud amounts and heights. Through analysis of this data, the TOVS Pathfinder data set is created and contains 74 layers of measurements on attributes such as temperature, water vapor, ozone level, precipitation, cloud coverage, etc. taken at various atmospheric pressure levels (e.g., 1000 mb, 850 mb, etc.). A full global coverage of TOVS data is produced twice daily, and a 16-year global data set for climate studies is being gathered [17].

Another satellite that obtains atmospheric data is the Upper Atmosphere Research Satellite (UARS). UARS was launched in 1991 and performs a comprehensive study of the stratosphere and furnishes important new data on the mesosphere and the thermosphere. UARS operates 585 km above the Earth in a near circular orbit inclined 57° to the equator. This orbit permits UARS sensors to provide global coverage of the stratosphere and mesosphere and measurements are made approximately every 36 days. The ten UARS chemistry and dynamics sensors are making measurements of temperature, pressure, wind velocity, and gas species concentrations. All these simultaneous measurements will help define the role of the upper atmosphere in our climate and its variability.

The Tropical Rainfall Measuring Mission (TRMM, [18]) is a joint project between the United States and Japan. The goal of this project is to measure precipitation at tropical latitudes and to provide accurate mapping of tropical rainfall. The mission consists of three instruments: a precipitation radar, a multi-channel microwave radiometer, and a visible-infrared scanner. The data provided by TRMM will be very important to verify and develop climate models.

The French space agency, CNES, has also developed the POLDER (POLarization and Directionality of the Earth's Reflectances) instrument, which flew on ADEOS. This is the first French/Japanese cooperative project in the area of Earth observation. A second, identical instrument is to be flown on ADEOS-2, successor to ADEOS, in 1999. POLDER is a wide field-of-view imaging radiometer that will provide global, systematic measurements of spectral, directional, and polarized characteristics of the solar radiation reflected by the Earth/atmosphere system, as well as aerosols, land and sea surfaces, and water vapor measurements.

NOAA's AVHRR (Advanced Very High Resolution Radiometer [19]) is very useful to study biomass burning in the tropics, and the interactions of smoke particles with clouds. More generally, information from the five AVHRR channels (see Table 73.9) is integrated into clouds and climate models.

Weather images are an everyday occurrence televised all over the world. Several weather satellites are operated by several countries. In the U.S., NASA and NOAA are operating the GOES series of geostationary satellites, which provide global weather data every 30 min since 1974, positioned at 36,000 km

above the Earth. GOES image and sounder data are also used for climate studies. In Europe, the Meteosat weather satellites are developed and launched by ESA, and financed and owned by Eumetsat, an international organization of 17 European weather services. Meteosat-1 was launched in 1977, followed by five others in 1981, 1989, 1991, and 1993. Three of them are currently in service, each equipped with an imaging radiometer. Table 73.9 shows the spectral ranges of operations of these two series of geostationary satellites. Several channels in the visible, water vapor, and thermal-IR spectral bands provide important information about cloud coverage, storm formation and evolution, as well as Earth radiation.

Examples of Terrestrial Studies.

Land Cover Applications. There are two basic types of data considered most important for global change research [20]; the data for documenting and monitoring global change, and the data for discovering the dynamical interplay among the various elements that define our environment. Previous studies show that global studies of land transformations require extrapolation among several scales (spatial, radiometric, and temporal). This extrapolation is especially important to control the minimum detectable change, whether spatial, spectral, or temporal. This accuracy in change detection, which is based on the properties of the sensing systems [21], can be especially essential in distinguishing between nature- and human-induced changes.

Getting accurate quantitative information about the distribution and the areal extent of the Earth's vegetation formations is a basic requirement in understanding the dynamics of the major ecosystems. Among all land transformations most critical to study for global change research, the assessment of tropical forests is one of the most important [22-25]. The tropical forest biome forms 7% of the Earth land surface, and its extensive loss could have a major impact on the future of the Earth (habitat fragmentation, species extinction, soil degradation, global climatic modifications, etc.). Previous studies have shown that in the last 2 decades, 50% of the areal extent of tropical forests might have been lost to deforestation [23]. At present, there is a wide range of estimates of the areal extent of tropical forests and of their rates of deforestation. Therefore, there is a great need to produce accurate and up-to-date measurements concerning the Tropical Forest worldwide. A range of different sensors must be utilized for such applications.

Other examples of land cover applications include agriculture and crop forecasting, water urban planning, rangeland monitoring, mineral and oil exploration, cartography, flood monitoring, disease control, real estate tax monitoring, detection of illegal crops, etc. In many of these applications, the combination of remote sensing data and Geographic Information Systems (GISs; see References 26 and 27) show great promise in helping the decision-making process.

Most instruments utilized to observe land features are on-board low Earth orbit satellites and are multispectral sensors with two or three bands in the visible part of the spectrum and at least one band in the infrared [6].

The Landsat series of satellites is the oldest land monitoring satellite system. Initiated in 1967, the Earth Resource Technology Satellites (ERTS) program was planning a series of six satellites to perform a broad-scale, repetitive survey of the Earth's land areas. After the launch in 1972 of the first ERTS-1, the ERTS program was renamed "Landsat." As of 1997, five Landsat satellites have been launched, each one carrying two instruments. The payload of Landsat-1 and -2 included a Return Beam Vidicon (RBV) camera and a Multispectral Scanner (MSS), while Landsat-4 and -5 still use the MSS and the Thematic Mapper (TM). The first RBV system consisted of three television-like cameras with a ground resolution of 80 m, each looking respectively at the green, red, and near-infrared portions of the spectrum. On Landsat-3, the RBV was 30 m panchromatic. MSS quickly became of primary interest due mainly to its capability of producing multispectral data in a digital format. The four MSS spectral bands are shown in Table 73.9, and the spatial resolution of MSS data is about 80 m. Very early on, the utility of MSS data was recognized for such applications as agriculture, mapping, forest monitoring, geology, as well as water resource analysis. The same MSS system was kept on Landsat-4 and -5, but the RBV system was replaced by the TM system. Like MSS, TM is a multispectral scanner, but includes spatial, spectral, and radiometric improvements over MSS. With seven bands instead of four (see Table 73.9), TM covers a larger portion

of the visible wavelengths, and includes two mid-IR and one thermal-IR bands. Data are quantized over 256 levels (8 bits) instead of the 64 levels for MSS, and the spatial resolution of a TM pixel is about 30 m. TM data is usually chosen to perform classification of land-cover features, man-made or natural. In vegetation and change detection applications, leaf segmentation is studied with TM visible channel data, while cell structure can be seen in near-IR, and leaf water content is found in the mid-IR channel data. The two mid-IR bands (5 and 7) are also useful for geologic applications. All the Landsat satellites are placed in low Earth orbit (at an altitude of about 900 km for Landsat-1 to -3 and 705 km for Landsat-4 and -5) and in a near-polar, sun-synchronous orbit. Landsat-4 and -5 cross the equator at 9:45 a.m. to hopefully take advantage of cloud-free imagery. Landsat-4 and -5 have a 16-day repeat cycle and their orbits are 8 days out of phase. Landsat-6 failed to achieve orbit in 1993; Landsat-7 is planned to be launched in 1998 and includes an improved TM instrument, the Enhanced Thematic Mapper (ETM), which will also include a panchromatic band at a spatial resolution of 15 m. For a more in-depth description of Landsat systems, see References 1, 29, and 30; for more applications and analysis of Landsat data, see Reference 30.

As previously mentioned, NOAA's AVHRR is primarily used for atmospheric applications but is also utilized for land surface applications. Having a near-polar, sun-synchronous orbit (at 833 km above the Earth's surface), the AVHRR instrument provides global data with a 1.1-km spatial resolution at nadir, and includes five bands, with daily or twice-daily (for thermal-IR) coverage. Since 1978, AVHRR data are available at full resolution (called Local Area Coverage (LAC)) or subsampled to 4 km (known as Global Area Coverage (GAC)). Because of its high temporal resolution, the AVHRR instrument is very useful in applications such as flood, storm, or fire monitoring, as well as volcanic eruption. Because of its global area coverage, AVHRR is also often utilized for studying geologic or physiographic features, vegetation conditions and trends at a global, continental or regional level, snow cover mapping, soil moisture analysis, and sand storms and volcanic eruptions worldwide. A popular parameter extracted from AVHRR data is the Normalized Difference Vegetation Index (NDVI), computed from GAC data as: $NDVI = (\text{Channel 2} - \text{Channel 1}) / (\text{Channel 1} + \text{Channel 2})$. GAC data is processed daily and composited on a weekly basis to produce a global map showing vegetation vigor. An example of NDVI applications is the monitoring of the Sahara desert extent. AVHRR data are also used for sea surface temperature.

The first *Système Pour l'Observation de la Terre* (SPOT), designed by CNES, was launched in 1986. SPOT-2 and SPOT-3 were launched, respectively, in 1990 and 1993. The SPOT satellites fly in a near-polar, sun-synchronous low Earth orbit at an altitude of 832 km and cross the equator at 10:30 a.m. SPOT's repeat cycle is 26 days, but due to its off-nadir viewing capability (viewing angle up to 27°), SPOT has a "revisiting" capability with which the same area can be seen up to five times every 26 days. This off-nadir viewing capability also enables some stereo imaging possibilities. The SPOT payload includes two identical high-resolution-visible (HRV) imaging instruments that can be employed in panchromatic or multispectral modes, with pointing capabilities. Spectral coverage of these two modes is given in Table 73.9. The panchromatic mode is 10 m spatial resolution, while multispectral data have a 20 m spatial resolution. Whereas Landsat is a scanning mirror-type instrument, SPOT employs a push-broom system with a linear array of detectors simultaneously acquiring all data pixels in one image line, which minimizes geometric errors. SPOT data are very useful for applications involving small features. Due to its increased spatial resolution, revisit and pointing capabilities, simultaneous panchromatic and multispectral data, and stereo data capabilities, SPOT opens a new range of applications, such as topographic mapping, studies of earthflows (e.g., land, rock, and mudslides), urban management, and military applications. SPOT-4 is planned for launch in 1998, and SPOT-5 in 2002. Among the planned improvements, a mid-IR channel will be added to SPOT-4, which will also carry a new AVHRR-type instrument, the European Vegetation instrument.

Since 1988, India has launched a series of five satellites, the IRS series. These satellites were designed in support of India's agriculture and exploration businesses, and they seem to be successful in this challenge of bringing remote sensing to the users (see Reference 10). For land applications, IRS-1A, -1B, and -1C all carry the LISS instrument, which is a multispectral scanner very similar to Landsat-TM. LISS-2 acquires imagery in four bands similar to bands 1 to 4 of Landsat-TM (from visible to near-IR)

at the spatial resolution of 36.5m (see Table 73.9 for wavelengths description). LISS-3, carried on IRS-1C, also acquires imagery in four bands, but the visible blue band has been suppressed and replaced by a mid-IR band similar to TM/band 5. Due to their similarity to Landsat data, IRS/LISS-2 data could be used as complements or replacements to Landsat data if needed until Landsat-7 is launched. IRS-1C also carries a 5-m panchromatic instrument whose data are co-registered with LISS-2 data. For more details on IRS data, see References 10 or 27.

Other instruments are also available. JERS-1, designed by Japan, was launched in 1992, and its payload includes both an SAR instrument and an optical-imaging system; see Table 73.9 for its spectral channels from visible to mid-IR wavelengths, with spatial resolutions of 18 m and 24 m. MOMS, the German Modular Optoelectronic Multispectral Scanner, has been flying as a research instrument on U.S. Space Shuttle missions, and has a spatial resolution ranging from 4.5 m to 13.5 m; see Reference 27 for more details on these different instruments.

Among the first EOS instruments to be launched is the Moderate Resolution Imaging Spectrometer (MODIS). MODIS is being developed to provide global monitoring of the atmosphere, terrestrial ecosystem, and oceans, and to detect climate change. MODIS will cover the visible to infrared portions of the spectrum with 36 channels at spatial resolutions of 250 m to 1 km. Many interesting land studies will be performed by fusing together AVHRR, Landsat, and MODIS data.

The fusion of several of these types of data is becoming a very important issue [26]. Already, sensors such as SPOT or LISS-3 present the advantage of acquiring co-registered panchromatic and multispectral data. It would be of great interest to combine data from sensors with different spectral and spatial resolutions, as well as different viewpoints. The combination of coarse-resolution viewing satellites for large area surveys and finer resolution sensors for more detailed studies would offer the multilevel information necessary to assess accurately the areal extent of features of interest (e.g., tropical forests). The fusion of multispectral data with SAR data would provide information on ground cover reflectance with the shape, roughness, and moisture content information from SAR. Of course, multidata fusion requires very accurate registration of the data, as will be described in Section 2.4.

Geologic Studies. Other examples of terrestrial studies are the mapping of geologic features, such as geologic faults and earthquake sites, or volcanic eruptions. Although many geologic features lie beneath the surface of the Earth, remote sensing (aerial or satellite) provides a valuable tool to perform geologic mapping, landforms and structures analysis, as well as mineral exploration. This is due to the fact that topography and soil properties provide clues to underlying rocks and structural deformations. Landsat and SPOT gather data about the effects of subsurface geologic phenomena on the surface. These data are especially useful to recognize some specific landforms (such as volcanoes), to depict topographic features, discriminate some geologic facies and rock unit distribution patterns and more generally provide regional overviews of surface geology. In mineral exploration, rock or soil alteration can be detected by spaceborne sensors and may indicate the presence of mineral deposits or oil reservoirs. Other types of sensors that are very useful for geologic applications are radar sensors, such as the two radar systems, SIR-C and X-SAR, carried on the Space Shuttle Endeavour in 1994. These sensors captured in real-time the eruption of a volcano in Russia and an earthquake in Japan [31]. For more information on geologic applications, see References 2 and 32.

Geophysics Studies. Other satellites, such as the LAEGOS-1 and -2, have proved very useful in geophysics for the study of the Earth's gravity field, tectonic plate motion, polar motion, and tides. LAGEOS sensors are reflector orbs covered with laser beams. For more information on these studies, see References 33 and 34.

Examples of Ocean Studies.

Oceans cover 75% of the Earth's surface and contain most of the energy of the planet. Although their role in climate evolution is very important, it is still poorly understood. By understanding chemical, physical, and biological processes in oceans, scientists will be able to model the interactions between oceans and the atmosphere and determine how these interactions affect Earth temperature, weather, and climate.

An example of interaction between oceans and the atmosphere is illustrated by the phenomenon known as El Niño/Southern Oscillation, which occurs in the tropical Pacific Ocean, usually around Christmas time. El Niño is due to a mass of warm water, usually located off Australia which moves eastward toward equatorial South America. El Niño develops every few years (observed on average every 4 years to a maximum of 7 years), and alters the weather in Australia, Africa, South Asia, and the tropical parts of the Americas. By understanding how winds and waves move in the tropical Pacific, scientists have been able to predict the El Niño phenomenon up to 1 year in advance. Similar phenomena are being studied in the Atlantic Ocean, where patterns seem to move much more slowly.

Besides being used to create global models, and in storm and weather forecasting, ocean data are also very important for day-to-day applications such as ship routing, oil production, and ocean fishing.

Ocean Color. Ocean color data are critical for the study of global biogeochemistry and to determine the ocean's role in the global carbon cycle and the exchange of other critical elements and gases between the atmosphere and the ocean [35,36]. It is thought that marine plants remove carbon from the atmosphere at a rate equivalent to terrestrial plants, but knowledge of interannual variability is very poor. For most oceans, the color observed by satellite in the visible part of the spectrum varies with the concentration of chlorophyll and other plant pigments present in the water. Subtle changes in ocean color usually indicate that various types and quantities of microscopic marine plants (i.e., phytoplankton are present in the water); the more phytoplankton present, the greater the concentration of plant pigments and the greener the water.

The recently launched (October 1997) Sea-viewing Wide Field-of-view Sensor (SeaWiFS), which is a part of MTPE, provides quantitative data on global ocean bio-optical properties to the earth science community. SeaWiFS is a follow-on sensor to the Coastal Zone Color Scanner (CZCS), which ceased operations in 1986. See Table 73.9 for a channel description of these two sensors; notice that all channels are concentrated in the [0.4,0.7] interval of the electromagnetic spectrum.

Other sensors for ocean color are the imaging spectrometer for ocean color applications MOS-IRS, launched on the Indian Remote Sensing Satellite IRS-P3 in March 1996, and the imaging spectrometer MOS-PRIRODA, launched aboard the Russian multisensor remote sensing module PRIRODA and docked to space station MIR in April 1996.

Ocean Dynamics. By studying ocean circulation and sea levels trends, scientists will be able to create global maps of ocean currents and of sea surface topography. Since sea surface height and sea level variations are related to sea surface temperatures, the monitoring of mean sea levels enables the gathering of evidence that can measure global warming or El Niño-type events. For example, conditions related to El Niño may result in a change in sea surface height of 18 cm or greater [37].

TOPEX/Poseidon (T/P) is an important collaboration between U.S./NASA and France/CNES. T/P uses radar altimetry to provide 10-day maps of the height of most of the ice-free oceans' surface. Circling the world every 112 min, the satellite gathers data for 3 to 5 years, and could be operational for 10 years. The T/P satellite was launched in August 1992 on an Ariane rocket. TOPEX measures the height of the ocean surface, as well as changes in global mean sea level. From these altimetry data, global maps of ocean topography are created, from which speed and direction of ocean currents are computed worldwide. Changes in mean sea level are monitored and currently are viewed mostly as related to natural ocean variability and not climate change. Climate change must be studied over a much longer time series of altimeter data. T/P also enables study of tides, waves geophysics, and ocean surface winds.

Sea winds are also being studied with scatterometers such as the NASA Scatterometer (NSCAT) and the soon to be launched EOS Scatterometer, SearWinds. These high-frequency radar instruments measure the reflected signals from the ocean surface to detect wind speed and direction.

ERS-1 is another satellite utilized to measure ocean dynamics. ERS-1 was launched in 1991 on a sun-synchronous, near-polar low-Earth orbit at an altitude of 780 km. ERS-1 orbits the Earth in 100 min and covers the entire planet in 3 days. Its payload consists of two specialized radars and one infrared sensor. The Active Microwave instrument, consisting of a synthetic aperture radar and wind scatterometer, produces extremely detailed images of 100 km swath of the Earth's surface, with a spatial resolution of

20 m. The radar altimeter provides accurate range to sea surface and wave heights, and the along-track scanning radiometer constructs detailed pictures of the thermal structure of the seas and oceans from surface temperature measurements at an accuracy of less than 0.5°C. ERS-1 images are also utilized for land applications where the instruments need to “look through” the cloud cover.

The study of sea ice with passive and active microwave sensors is also very important and additional reading in this topic can be found in References 14 and 38.

A Few Examples of Space Science Applications.

Astronomical satellites have been developed to observe far distant objects that are usually beyond the range of ground-based instruments. They explore phenomena in the solar system, and beyond. Satellite observation of astronomical objects is also less sensitive to atmospheric interactions and can achieve higher accuracy than ground-based measurements. This section will give a brief description of the most important space science satellites.

The first astronomical satellite to be put into synchronous orbit was the International Ultraviolet Explorer (IUE) laboratory. IUE was launched in 1978 under a joint program involving NASA, ESA, and the United Kingdom. In more than 15 years of service, IUE gathered observations on more than 10,000 celestial objects. A program for coordinating its observations with those of the ROSAT satellite has been carried out under the title RIASS (Rosat-IUE All-Sky Survey). ROSAT, the Roentgen Satellite, is a joint collaboration between Germany, the U.S., and the U.K., and was launched in 1990. It is an X-ray observatory that carries two instruments, the X-ray telescope and the wide field camera.

The Infrared Astronomical Satellite, IRAS, is a joint project of the U.S., the U.K., and the Netherlands. The IRAS mission was intended to provide a survey of infrared point sources (from 12 to 100 μm), but has also produced very high-quality image data. MSX (the Mid-Course Space Experiment), ISO (the Infrared Space Observatory), and SIRTf (the Space InfraRed Telescope Facility) are other examples of recently or soon-to-be launched sensors that provide an even finer resolution.

Hipparcos (High Precision Parallax Collecting Satellite) is an astronomy satellite launched in August 1989, with the purpose of determining the astrometric parameters of stars with unprecedented precision. After a life of 4 years, Hipparcos has produced two catalogs. The Hipparcos Catalogue provides position, parallax, and proper motion measurements with accuracy of 2 milliarcsec at 9 mag for over 120,000 stars. The Tycho Catalogue is the result of somewhat less precise astrometric measurements for some 1 million stars.

COBE, the Cosmic Origin Background Explorer developed by NASA, was launched in 1989. Designed to measure the diffuse infrared and microwave radiation from the early universe, it carried three instruments: a Far Infrared Absolute Spectrophotometer (FIRAS), a Differential Microwave Radiometer (DMR), and a Diffuse Infrared Background Experiment (DIRBE). The first full-sky coverage was completed in 1990.

The Hubble Space Telescope (HST) is one of the most well-known astronomical satellites. It was built as a joint NASA/ESA project, and was launched in 1990 as a long-term space-based observatory. The heart of the system is a large reflector telescope 2.4 m in diameter. All the instruments on-board the HST use the light gathered by the reflector telescope. Current HST instruments are the Wide/Field Planetary Camera 2 (WFPC2), the Space Telescope Imaging Spectrograph (STIS), the Near-Infrared and Imaging Spectrograph (NICMOS), and the Faint Object Camera, FOC, provided by ESA. These different instruments can observe astronomical objects from UV to IR wavelengths. In 1993, the HST was serviced to correct a preliminary fault affecting the mirror with a corrective optical apparatus named COSTAR. Despite the preliminary mirror fault, and even more after correction, the HST has achieved much better results than those from observatories on Earth. Since it is located above the Earth's atmosphere (at 600 km), the HST produces highly detailed images of the stars and can detect objects beyond the range of ground-based instruments. Observations with the HST are scheduled as a space-based observatory according to worldwide astronomers' proposals.

ASCA, the Advanced Satellite for Cosmology and Astrophysics, is the product of a Japan/U.S. collaboration. Launched in 1993, this X-ray astronomy mission was still operational in 1997, and carries four large-area X-ray telescopes with arc minute resolution. ASCA data are being archived and can be searched

and retrieved online at the High Energy Astrophysics Science Archive Research Center, HEASARC. GRO (Gamma Ray Observatory), and AXAF (the Advanced X-ray Astrophysics Facility) are other examples of space sensors which operate in this spectrum range.

Management and Interpretation of Satellite Data

Satellite sensors gather the electromagnetic energy reflected or emitted from Earth (or any other planetary) surface features. This energy is then converted into a digital representation that is visualized by a user and interpreted either visually or with a computer. This section summarizes some preliminary ideas on how the digital representation is formed and the basic types of data processing necessary before any further interpretation of the data. For more details on the processing of remote sensing data, see References 39 to 42.

Fundamental Data Levels

After transmission from the satellites, raw data are usually processed, calibrated, archived, and distributed by a ground-based data system. Most of NASA satellite data products are classified in the following data levels [7]:

- *Level 0 data* are the reconstructed raw instrument data at full resolution.
- *Level 1A data* are reconstructed, time-reference raw data, with ancillary information including radiometric and geometric coefficients.
- *Level 1B data* are corrected Level 1A data (in sensor units).
- *Level 2 data* are derived geophysical products from Level 1 data, at the same resolution and location; for example, atmospheric temperature profiles, gas concentrations, or winds variables.
- *Level 3 data* correspond to the same geophysical information as Level 2, but mapped onto a uniform space-time grid.
- *Level 4 data* are model output or results from analysis of lower-level data.

Image Restoration

Ideally, the scene as viewed and recorded by a sensor would be an exact rendering of the features within the sensor's viewing extent, represented as a spectral curve indicating the amount of energy reflecting/radiating for each point in a scene for a range of given wavelengths. From an engineering standpoint, this is impossible, however, because each image is discretized into a finite number of pixels. Variability defines nature, so each pixel will map into a region of the scene that contains a number of features, each producing its own unique spectral curve. The spectral signature recorded for a pixel is a function of these features and their relative sizes within the region covered by the pixel. The spectral response itself is also discretized into a finite number of bandwidths, where each bandwidth covers a small continuous band of the spectrum. The sensor records for each pixel the amount of energy observed for each band. This number itself, referred to as a Digital Number (DN), must be represented in a finite amount of computer memory, such as 8 bits, meaning that each band records activity as a whole number ranging from 0 to 255.

In practice, a number of events outside human control affect the quality of the observation, such as atmospheric scattering, variations in sun angle, high albedo, and instrument errors. Depending on the application, it may be desirable to correct for the presence of thin clouds within an image. The process of image restoration attempts to control and correct for these conditions [42].

Electromechanical effects due to the instrument itself can be discovered due to their periodic nature (such as caused by the repeated motion of a push-broom, or the revolving of a mirror, or the physical process of gathering calibration points). A Fourier transform applied to an image from a sensor undergoing periodic interference exhibits strong noise spikes. A filter can then be used to remove the offending data. Unfortunately, this also removes any good data that happens to fall at the same frequency, although normally this is but a small portion of the data. Data outages and instrument recorder failures appear as streaks in the image parallel with the scanline, and can be discovered by comparing the respective readings of the pixels in the surrounding scanlines of the image.

To account for the atmospheric effects of Rayleigh and aerosol scattering, an estimate of the portion of the signal that is due to the atmosphere is computed and subtracted from the recorded value. The reflectance of water in the near-infrared region of the spectrum should be effectively zero, so the value to subtract for the near-IR band corresponds to the reading of the sensor observed over clear open water. To compute values to be subtracted for each of the other spectral components, a histogram should be formed for each band of a number of sample readings over clear open water. The lowest reading in each band is then used as an estimate of the value to subtract from each pixel to account for the atmospheric effect. In addition, information derived from TOVS, balloon readings, or the atmospheric correction software 5S can be useful in dealing with atmospheric effects.

Data Compression

Data compression is one of the most important tools to overcome the problems of data transmission, storage, and dissemination [43]. Data compression methods are usually classified as either lossless or lossy. With a lossless data compression scheme, the original data can be reconstructed exactly without any loss; in a lossy compression scheme, original data are reconstructed with a degree of error. For transmission from the satellite to the ground station, a lossless data compression must be utilized. For browsing purposes, lossy compression enables quick searches through large amounts of data. A compression scheme is also characterized by its compression ratio, that is, the factor by which the amount of information which represents the data is reduced through compression. For earth science data, lossless compression schemes provide compression ratios up to 2 or 3, while lossy techniques can reduce the amount of information by a factor of 20 or more without degrading the visual quality of the data.

Among the lossless compression methods, the Joint Photographic Experts Group, JPEG, developed a lossless compression method that is based on a predictor, an entropy encoder for prediction error, and an entropy code specifier. Another lossless compression scheme is the Rice algorithm, which can adapt to data of any entropy range. It is based on a preprocessor that spatially decorrelates the data, followed by a variable length encoder. This algorithm gives some of the best compression ratios among all lossless methods, and has been implemented on VLSI chips at NASA.

JPEG has also developed a lossy method based on the Discrete Cosine Transform (DCT). Other methods such as vector quantization or wavelet compression provide either lossless or lossy compressions. In a vector quantization technique, a dictionary of representative vectors, also called a codebook, and all data are encoded relative to the codebook. In this method, the one-time encoding step is computationally expensive but the decoding step at the user end is fast and efficient. Vector quantization is also utilized in a progressive scheme for “quick look”/browsing purposes. In a subband/wavelet compression method, signals are decomposed using quadrature mirror or wavelet filters [44]. Most energy is contained in the low-frequency subbands and high compression ratios can be obtained by compressing the high-frequency information.

For more information or references on data compression techniques, see Reference 43.

Image Registration

In studying how the global environment is changing, programs such as Mission to Planet Earth [7] or the New Millennium program [45] involve the comparison, fusion, and integration of multiple types of remotely sensed data at various temporal, radiometric, and spatial resolutions. Results of this integration can be utilized for global change analysis, as well as for the validation of new instruments or of new data analysis. The first step in this integration of multiple data is registration, either relative image-to-image registration or absolute geo-registration, to a map or a fixed coordinate system. Another case of image registration is co-registration of multiple bands of one sensor. When the detectors of each spectral band have different spatial locations on the satellite’s focal plane, there could be misregistration between each band’s raw image [46,47].

Currently, the most common approach to image registration is to extract a few outstanding characteristics of the data, which are called *control points* (CPs), *tie-points*, or *reference points*. The CPs in both images (or image and map) are matched by pair and used to compute the parameters of a geometric

transformation. Most available systems follow this registration approach; and because automated procedures do not always offer the needed reliability and accuracy, current systems assume some interactive choice of the CPs. But such a point selection represents a repetitive, labor- and time-intensive task that becomes prohibitive for large amounts of data. Also, since the interactive choice of control points in satellite images is sometimes difficult, too few points, inaccurate points, or ill-distributed points might be chosen, thus leading to large registration errors. A previous study [48] showed that even a small error in registration can have a large impact on the accuracy of global change measurements. For example, when looking at simulated 250 m spatial resolution MODIS (Moderate Resolution Imaging Spectrometer) data, a 1-pixel misregistration can produce 50% error in the computation of the Normalized Difference Vegetation Index (NDVI). So, for reasons of speed and accuracy, automatic registration is an important requirement to ease the workload, speed up the processing, and improve the accuracy in locating a sufficient number of well-distributed accurate tie-points.

Automatic image registration methods can be classified into two types: those that follow a human approach, by first extracting control points, and those that take a more global approach. Among the first methods, the most common features utilized as control points are the centers of gravity of regions — with or without region attributes such as areas, perimeters, ellipticity criteria, affine-invariant moments, and inter-regions distances. More recently, features extracted from a wavelet decomposition have also been utilized, such as maxima and minima of wavelet coefficients, high-interest points, or local curvature discontinuities. A few methods utilize Delaunay triangulation methods to progressively increase the number of accurate control points. For the methods that do not match individual pairs of control points, the transformation is either found by correlation or by optimization, in the spatial or in the frequency domain. When in the spatial domain, correlation or optimization is performed either in the original data or on edge gradient data. Other methods propose a global image matching of edge segments or vectors linking feature points. Some recent research has also focused on the use of wavelets for global image registration. More complete surveys of image registration methods can be found in References 47, 49, and 50.

Dimension Reduction

The first step in analyzing multichannel data is to reduce the dimension of the data space. It is particularly important when the analysis method requires a training step, for example, supervised classification (see next section). The main issue in this case has often been referred as “the Curse of Dimensionality” [52]. If the original data has a large number of bands (e.g., for hyperspectral data), theoretical studies have shown that a very large training set should be utilized; but using a large training set deteriorates the estimation of the kernel density. To solve this problem, various dimension reduction schemes enable to perform classification in a smaller-dimensional subspace. Since the information contained in multiple channels is often redundant, it is possible to decorrelate spectrally the channels and reduce the number of channels to be analyzed without losing any information. Principal Component Analysis (PCA) and Projection Pursuit are the most common techniques for dimensionality reduction. For more information on these methods, refer to References 39 through 42.

Data Mining

One objective of the NASA-initiated Mission to Planet Earth is to gather sufficient data to enable scientists to study the Earth as a dynamic system, resulting in a better understanding of the interactions between humans, the atmosphere, and the biosphere [8]. The episodic nature of most interesting events would cause them to be missed if the data were not being gathered continuously. Comprehensive data sets allow scientists to construct and evaluate complex models of many Earth-related processes. But currently, due to computation and time constraints, only a small percentage of the data gathered by remote sensing is actually viewed by an individual user. Data-gathering missions tend to be multidisciplinary, so different aspects of the data sets are pertinent to different researchers.

Data mining can be defined as the process by which data content is automatically extracted from satellite data, enabling a scientist to query the data holdings based on high-level features present within

an image [51]. Given the projected large volumes of data, it is not feasible to rely solely on conventional data management paradigms. Standard methods of segmenting images are inadequate as standalone techniques for image recognition, regardless of the speeds of processing, because there are no general methods for automatically assigning meaningful semantics to any homogeneous regions that are isolated. Metadata derived directly from the image header are not rich enough to enable robust querying of a database in most instances, but limit a user to retrieving all images at a given latitude/longitude during some time period, for example, regardless of the image quality or the unique features existing due to some unexpected set of circumstances. New approaches based on techniques such as image classification (described in the next section) are now feasible, due to the phenomenal increases in computing speed, the availability of massively parallel architectures, and the breakthroughs in signal processing.

An example of data mining is the browsing of 15 years of TOVS data with two complete coverages per day, which would require looking through 10,958 scenes per attribute. Of the several products generated, the scientists are primarily interested in browsing those with some given resolution. After locating a browse product that seems to indicate an interesting structure or phenomenon, a scientist might then retrieve this data temporally, or any supporting data set for further analysis. Scientists using the TOVS data sets desire a more intelligent form of querying so they can quickly and easily find relevant data sets that are pertinent to their research. Certain TOVS observations are more “interesting” than others, and the definition of “interesting” is a combination of objective fact and subjective opinion. Data mining is applicable here to aid in evolving a retrieval heuristic based on an individual scientist’s definition of “interestingness.” In one approach, the scientist could prepare a representative set of images that are labeled as positive or negative instances of “interesting,” and a machine learning system (e.g., neural network, genetic algorithm) could perhaps be trained to classify the remaining images in the TOVS data set according to this definition. In a second approach, the scientists could be asked to identify explicitly structural features within the images that make them interesting, and image processing routines could then be applied to detect images with these features. Over time, a scientist could provide feedback to the heuristic classifier to improve its performance. Both approaches require that the underlying representation language (structures, bin size, spatial and temporal relationships) be robust and flexible enough to permit an appropriate level of expression.

Classification

Image classification is the task of developing a statistical model that labels every potential point in some multidimensional space. A *parametric classifier* assumes that data are described by some underlying parameterized probability density function (PDF). A training set of representative data from the domain is then used to supply appropriate values. For example, if a Gaussian or normal distribution is assumed, then the means, standard deviations, and joint-covariance matrix can be computed from the training data. A *nonparametric* or *unsupervised classifier* is typically used when there is insufficient knowledge about the type of underlying PDF for the domain. Self-organizing classifier models, such as certain kinds of neural networks, are also considered nonparametric classifiers when they make no *a priori* assumptions about any PDF.

In a *statistical* or *supervised classifier*, knowledge about the distribution of the data is utilized to assign a label to an unclassified pixel. Using “ground-reference data,” a training set of known points is created. A prototype vector can then be calculated as the mean of all samples for each of the classes. Assuming a Gaussian distribution in each of the channel readings for a given class, the standard deviation for each class is computed based on the sample. Then, the lowest distance from the given feature prototypes to an unclassified point determines the class of this incoming point. As simple and elegant as this approach might appear, in actuality its utility is limited. Features are not so discernible from a random labeling of an image. Thus, although this algorithm is inaccurate, it is consistent in its mislabelings. The algorithm’s deterministic nature and underlying use of a continuous function combine to produce predictable behavior. In general, this algorithm labels all points similarly if they fall within the same neighborhood in the feature space.

Other parametric classifiers follow the *Maximum Likelihood Decision Rule*, which allows the construction of discriminant functions for the purposes of pattern classification. For more details on this technique, refer to Reference 53.

The classifiers discussed above are, by definition, required to assign an unclassified pixel to the one nearest class. No measurement of the distance to that class or proximity to other classes is recorded, and no information on the confidence of the labeling is provided. *Fuzzy classifiers*, on the other hand, are not obligated to pigeonhole a pixel into a single class. Instead, the pixel is assigned a degree of membership for each possible class. Intuitively, and indeed for mathematical tractability, the pixel's memberships must sum to one, and the degree of membership for a given class must be between 0 and 1, inclusively. Two examples of fuzzy classifiers are given below. The *Fuzzy Nearest Neighbor* nonparametric classifier places an unclassified vector in the dominant class of its k -closest training vectors. If no class has an outright majority, then distances to the nearby vectors for each class which tied are summed and the unclassified vector is placed in the class with the minimum sum. The *Fuzzy Decision Tree Classifier* utilizes a decision tree as the data structure that encapsulates knowledge of what to do given a set of conditions. See Reference 51 for more information on this method. Although this algorithm is conceptually simple, it is only recently that it has become computationally feasible due to the need to search the tree for each unclassified pixel to locate the nearest path. The search algorithm can also be sped up by running the algorithm on a parallel architecture such as a Single Instruction Multiple Data (SIMD) machine.

Many researchers have investigated the use of *neural networks* for automatically extracting metadata from images [54]. Many different neural network models have been considered, but with respect to performance accuracy, the backpropagation training technique has shown to be the best classifier [55]. The *backpropagation algorithm* is the most common method for training a neural network, and is the backbone of much of the current resurgence of research into neural nets [56]. With respect to pattern recognition, backpropagation can be considered to be a nonparametric technique for estimation of a posteriori probabilities.

Accuracy Assessment

A measurement derived solely from satellite imagery is of questionable use unless the technique employed for computing that measurement on those data has been validated. A technique that appears to work accurately on satellite imagery over some given location at some given time may perform abysmally on data from the same sensor at another location, or for the same location at another time. The reasons for this are many: through the course of a year, the sun angle changes causing different lighting conditions; from pass to pass, the viewing angle of the instrument can be different; with seasonal changes, surface reflectance varies due to weather conditions and the alteration of land cover as crops appear in different stages; atmospheric conditions fluctuate; and the sensor and spacecraft themselves age and possibly perform differently.

The key factor in any accuracy assessment of remote sensing data is the method and source used for determining what the satellite sensor is actually viewing. This ground reference data is gathered independent of the remote sensing data itself. There are several sources that can be construed as ground reference data, and each source has its own degree of accuracy. The most obvious is an actual site visit to the area of interest. What is observed, also known as "ground truth," is recorded and compared to the digital rendition of the same spatial extent. This approach usually has a high degree of accuracy, but it is often prohibitively expensive. Depending on the time between the on-site ground reference gathering and the imaging of the area, the validity of the ground reference data may be lessened due to anthropomorphic or natural influences. The shorter the life of the feature being measured, the more difficult it is to find or gather meaningful time-critical ground reference data. If ground reference data is not available, it may be possible to perform photointerpretation with some degree of success. This itself depends on the knowledge of the photointerpreter, and the availability and suitability of a display device for viewing the image data and recording the photointerpreter's assessment. Another approach is to compare the digital image with other sources of ground reference data such as air photos or appropriate reference maps, provided the

feature of interest is detectable using those sources. The degree of correspondence between the ground reference data and the measurement derived from the sensor data can then be compared for accuracy. In the worst case, the lack of adequate/accurate ground reference data requires using an unsupervised clustering approach that is usually less accurate but much cheaper to produce.

The Future in Satellite Imaging and Sensing

Success of future earth and space science missions depends on increasing the availability of data to the scientific community who will be interpreting space-based observations, and on favoring interdisciplinary research for the analysis and the use of this data. One of the main challenges in the future of satellite imaging and sensing will be to handle, archive, and store all of these data in a way that can be easily accessible and retrieved by anyone who needs to use them. Systems such as the EOS Data and Information System (EOSDIS) [57,58], will require that over 1 terabyte per day be collected and processed into several levels of science data products within several hours after observation. After 15 years, the estimated amount of collected, processed, analyzed, and stored data will equal about 11,000 terabytes. Also at NASA, efforts are underway to design an advanced information system, based on an object-oriented database, with the express purpose of developing, incorporating, and evaluating state-of-the-art techniques for handling EOS-era scientific data challenges [59].

Another challenge will be to analyze this tremendous amount of data, and to find out new ways to fuse, integrate, and visualize this data. In particular, research in fast computational capabilities, such as field programmable gate arrays (FPGAs), will be of great importance.

On the other hand, the wide distribution of satellite data to the general public will be facilitated by regional distribution systems such as the Regional Application Centers, RACs [60,61], whose goal is to provide local users, such as industry, agriculturalists, urban planners, regional communities, with local and “on-time” information about regional applications.

Satellite imaging and sensing is a field with a history of more than 2 decades, but is still in full expansion. The future in satellite imaging and sensing will see developments in several areas. The next millennium will see an explosion of commercial satellite systems and the profusion of satellite data, which will have economic and sociopolitical implications. As of this writing, over 30 commercial Earth sensing satellites are either being planned or being built. MTPE and EOS will generate unprecedented amounts of diverse resolution data. The future will also see the development of locally directed satellite systems, in answer to specific applications for specific areas of the planet. Telecommunications will also be a large part of the space market. In space, after the large success of the Mars Pathfinder mission, exploration of distant planets will see a flourishing of distant satellite systems providing unprecedented amounts of data to analyze regarding other planets’ surface features, atmospheric, and magnetic properties. The understanding of other planets will also enable scientists to learn more about the Earth comparatively to other planets such as Mars, and to build a comprehensive data set to aid in planning future missions. The Mars Global Surveyor is an example of such a mission; it will map the entire planet Mars by taking high-resolution pictures of the surface. The future might see a 10-year NASA program that will send pairs of Surveyor-like orbiters and Pathfinder-like landers to Mars every 26 months. In order to gather novel and interesting data, this type of mission will need an increasing amount of on-board processing that will perform mission planning, image processing and understanding, as well as data compression and fusion. The design of systems including on-board processing will require new computational capabilities, such as reconfigurable hardware and parallel processors, as well as new developments in intelligent systems. In the near future, satellite imaging and sensing is a field that will produce unprecedented information about the Earth, its environment, and our solar system.

Acknowledgments

The authors would like to thank William J. Campbell for his support and for his useful comments upon reviewing our paper, Bob Mahoney for providing the spectral libraries used to generate Figure 73.11,

and all the anonymous or nonanonymous authors of Web pages that we consulted during the research part of this endeavor. In particular, the online remote sensing tutorial by N.M. Short, edited by J. Robinson at the URL <http://code935.gsfc.nasa.gov/Tutorial/TofC/Coverpage.html>, and the list of selected links on remote sensing compiled by U. Malmberg and found at the URL <http://www.ssc.se/rst/rss/index.html> were very useful.

74.1 Introduction

This chapter reviews the origins, principles, and designs of instrumentation used in biopotential measurements, in particular for the electrocardiogram (ECG), the electroencephalogram (EEG), the electromyogram (EMG), and the electrooculogram (EOG). These biopotentials represent the activity of the respective organs: the heart, brain, muscle, and eyes. The biopotentials are acquired with the help of specialized electrodes that interface to the organ or the body and transduce low-noise, artifact-free signals. The basic design of a biopotential amplifier consists of an instrumentation amplifier. The amplifier should possess several characteristics, including high amplification, input impedance, and the ability to reject electrical interference, all of which are needed for the measurement of these biopotentials. Ancillary useful circuits are filters for attenuating electric interference, electrical isolation, and defibrillation shock protection. Practical considerations in biopotential measurement involve electrode placement and skin preparation, shielding from interference, and other good measurement practices.

FIGURE 74.1 Sample waveforms: (a) ECG, normal sinus rhythm; (b) EEG, normal patient with open eyes; (c) EMG, flexion of biceps muscles; (d) EOG, movement of eyes from left to right.

74.2 The Origins of Biopotentials

Many organs in the human body, such as the heart, brain, muscles, and eyes, manifest their function through electric activity [1]. The heart, for example, produces a signal called the electrocardiogram or ECG (Figure 74.1a). The brain produces a signal called an electroencephalogram or EEG (Figure 74.1b). The activity of muscles, such as contraction and relaxation, produces an electromyogram or EMG (Figure 74.1c). Eye movement results in a signal called an electrooculogram or EOG (Figure 74.1d), and the retina within the eyes produces the electroretinogram or ERG. Measurements of these and other electric signals from the body can provide vital clues as to normal or pathological functions of the organs. For example, abnormal heart beats or arrhythmias can be readily diagnosed from an ECG. Neurologists interpret EEG signals to identify epileptic seizure events. EMG signals can be helpful in assessing muscle function as well as neuromuscular disorders. EOG signals are used in the diagnosis of disorders of eye movement and balance disorders.

The origins of these biopotentials can be traced to the electric activity at the cellular level [2]. The electric potential across a cell membrane is the result of different ionic concentrations that exist inside and outside the cell. The electrochemical concentration gradient across a semipermeable membrane results in the Nernst potential. The cell membrane separates high concentrations of potassium ion and low concentrations of sodium ions (along with other ions such as calcium in less significant proportions)

FIGURE 74.2 Schematic showing origins of biopotentials: (a) an action potential from a heart cell (recorded using a microelectrode); (b) the electrogram from the heart surface (recorded using an endocardial catheter); and (c) the ECG signal at the chest (recorded using surface electrodes).

inside a cell and just the opposite outside a cell. This difference in ionic concentration across the cell membrane produces the resting potential [3]. Some of the cells in the body are excitable and produce what is called an action potential, which results from a rapid flux of ions across the cell membrane in response to an electric stimulation or transient change in the electric gradient of the cell [4]. The electric excitation of cells generates currents in the surrounding volume conductor manifesting itself as potentials on the body.

Figure 74.2 illustrates the continuum of electrophysiological signals from the (a) heart cells, (b) myocardium (the heart muscle), and (c) the body surface. Each cell in the heart produces a characteristic action potential [4]. The activity of cells in the sinoatrial node of the heart produces an excitation that propagates from the atria to the ventricles through well-defined pathways and eventually throughout the heart; this electric excitation produces a synchronous contraction of the heart muscle [5]. The associated biopotential is the ECG. Electric excitation of a neuron produces an action potential that travels down its dendrites and axon [4]; activity of a massive number of neurons and their interactions within the cortical mantle results in the EEG signal [6]. Excitation of neurons transmitted via a nerve to a neuromuscular junction produces stimulation of muscle fibers. Constitutive elements of muscle fibers are the single motor units, and their electric activity is called a single motor unit potential [7]. The electric activity of large numbers of single motor unit potentials from groups of muscle fibers manifests on the body surface as the EMG. Contraction and relaxation of muscles is accompanied by proportionate EMG signals. The retina of the eye is a multilayered and rather regularly structured organ containing cells called rods and cones, cells that sense light and color. Motion of the eyeballs inside the conductive contents of the skull alters the electric potentials. Placing the electrode in the vicinity of the eyes (on either side of the eyes on the temples or above and below the eyes) picks up the potentials associated with eye movements called EOGs. Thus, it is clear that biopotentials at the cellular level play an integral role in the function of various vital organs.

TABLE 74.1 Biopotentials, Specifications, and Applications

Source	Amplitude (mV)	Bandwidth (Hz)	Sensor (Electrodes)	Measurement Error Source	Selected Applications
ECG	1–5	0.05–100	Ag–AgCl disposable	Motion artifact, 50/60 Hz powerline interference	Diagnosis of ischemia, arrhythmia, conduction defects
EEG	0.001–0.01	0.5–40	Gold-plated or Ag–AgCl reusable	Thermal (Johnson) RF noise, 50/60 Hz	Sleep studies, seizure detection, cortical mapping
EMG	1–10	20–2000	Ag or carbon, stainless steel, needle	50/60 Hz, RF	Muscle function, neuromuscular disease, prosthesis
EOG	0.01–0.1	dc–10	Ag–AgCl	Skin potential motion	Eye position, sleep state, vestibulo-ocular reflex

74.3 Biopotentials

Biopotentials from organs are diverse. Table 74.1 lists some of these biopotentials, their representative clinical applications, and their key measurement indices and associated sensors. Note that all acquisitions are made with the aid of specialized electrodes in which actual design may be customized for specific needs. The most noteworthy features of biopotentials are [1,8]

- Small amplitudes (10 μ V to 10 mV),
- Low frequency range of signals (dc to several hundred hertz)

The most noteworthy problems of such acquisitions are

- Presence of biological interference (from skin, electrodes, motion, etc.),
- Noise from environmental sources (power line, radio frequency, electromagnetic, etc.).

These signal acquisition challenges and problems for each of the biopotentials are considered in greater detail below.

ECG

ECG signals are acquired by placing electrodes directly on the torso, arms, and legs (Figure 74.3a). The activity on the body surface is known to reflect the activity of the heart muscle underneath and in its proximity. A clinically accepted lead system has been devised and is called the 12-lead system [9, 10]. It comprises a combination of electrodes taking measurements from different regions designated limb leads, the precordial leads, and the chest leads. Limb leads derive signals from electrodes on the limbs, and are designated as leads I, II, and III. Precordial leads are designated aVR, aVL, and aVF, and are derived by combining signals from the limb leads. The remaining six leads, V1, V2, ... V6, are chest leads. Together, ECGs from these various leads help define the nature of the activity on a specific part of the heart muscle: for example, ischemia (impaired oxygen supply to the muscle) or infarction (damage to the muscle) on the left side of the chest may be noticeable in lead III.

The ECG signals at the surface of the body are small in amplitude, which make the measurements susceptible to artifacts [11], generated by the relative motion of the electrode and the skin as well as by the activity of the nearby muscles. An important consideration in good ECG signal acquisition is the use of high-quality electrodes [12]. Electrodes made out of silver coated with silver chloride or of sintered Ag–AgCl material, are recommended. An electrolytic gel is used to enhance conduction between the skin and the electrode metal. Artifacts at the electrode–skin contact as well as electromagnetic interference from all sources must be minimized [13]. Since ECG instruments are often used in critical-care environments, they must be electrically isolated for safety [14] and protected from the high voltages generated by defibrillators [15].

FIGURE 74.3 Schematics showing how biopotential signals are recorded from the human body. (a) ECG: 12-lead ECG is recorded using right arm (RA), left arm (LA), left leg (LL), right leg reference (RL), and six chest (C) electrodes. (b) EEG: selected electrode locations from the standard 10-20 EEG lead system with ears used as reference. (c) EMG: recording electrodes on the biceps and triceps with an independent reference. (d) EOG: electrodes above or below (up-down) and the sides of the eyes along with an independent reference.

ECG biopotential amplifiers find use in many monitoring instruments, pacemakers, and defibrillators [16]. ECG signal acquisition is also useful in many clinical applications including diagnosis of arrhythmias, ischemia, or heart failure.

EEG

EEG signals are characterized by their extremely small amplitudes (in the microvolt range). Gold-plated electrodes are placed very securely on the scalp to make a very low resistance contact. A clinically accepted lead system [17], which includes several electrodes placed uniformly around the head, is called the 10-20 lead system (Figure 74.3b). This comprehensive lead system allows localization of diagnostic features, such as seizure spikes, in the vicinity of the electrode [18].

EEG signals are difficult to interpret since they represent the comprehensive activity of billions of neurons transmitted via the brain tissues, fluids, and scalp [18]. Nevertheless, certain features can be interpreted. In the waveform itself, it is possible to see interictal seizure spikes or a full seizure (such as petit mal and grand mal epilepsy) [18]. Analysis of the frequency spectrum of the EEG can reveal changes in the signal power at different frequencies being produced during various stages of sleep, as a result of anesthetic effects, and sometimes as a result of brain injury [17].

Practical problems and challenges associated with EEG signal recordings arise from physiological, environmental, and electronic noise sources. Physiological sources of interference are motion artifact, muscle noise, eye motion or blink artifact, and sometimes even heartbeat signals. Electrical interference arises from the usual sources: 60 Hz power lines, radio frequencies (RF), and electrically or magnetically induced interference. Moreover, the electronic components in the amplifier also contribute noise. Good design and measuring techniques can mitigate the effects of such noise and interference.

EMG

Muscle fibers generate electric activity whenever muscles are active [19]. EMG signals are recorded by placing electrodes close to the muscle group (Figure 74.3c). For example, a pair of electrodes placed on the biceps and another pair placed on the triceps can capture the EMG signals generated when these muscles contract. EMG signals recorded in this manner have been shown to give a rough indication of the force generated by the muscle group [8]. Electrodes used for such applications should be small, securely attached and should provide recordings free of artifacts. Either silver–silver chloride or gold-plated electrodes perform quite well, although inexpensive stainless steel electrodes may also suffice.

Since the frequency range of EMG signals is higher than that of ECG and EEG signals, and since the signals are of comparable or larger amplitudes, the problem of motion artifact and other interference is relatively less severe. Filtering can reduce the artifact and interference: for example, setting the bandwidth to above 20 Hz can greatly reduce the skin potentials and motion artifacts.

Recording activity directly from the muscle fibers themselves can be clinically valuable in identifying neuromuscular disorders [19]. Therefore, invasive electrodes are needed to access the muscle fibers or the neuromuscular junction. Fine-needle electrodes or thin stainless steel wires are inserted or implanted to obtain local recording from the fibers or neuromuscular junctions [7].

EOG

Electric potentials are generated as a result of movement of the eyeballs within the conductive environment of the skull. The generation of EOG signals can be understood by envisaging dipoles (indicating separated positive and negative potential sources) located in the eyeballs. Electrodes placed on either side of the eyes or above and below them pick up the potentials generated by the motion of the eyeball (Figure 74.3d). This potential varies approximately in proportion to the movement of the eyeballs, and hence EOG is sometimes used to study eye positions or disorders of eye movement and balance (a reflex called vestibulo-ocular reflex affects the nystagmus of the eye). Similarly, saccades inherent in eye motion as well as blinking of the eyelids can produce changes in the EOG signal.

This signal is small (10 to 100 μV) and has low frequencies (dc to 10 Hz) [8]. Hence, an amplifier with a high gain and good low frequency response and dc stability is desirable. Additionally, the electrode–gel combination should be such that it produces low levels of junction potential, motion artifacts, and drift in the dc signal [20]. Practical problems associated with dc drift, motion artifacts, and securing

electrodes in the vicinity of the eyes make their long-term use problematic. Nevertheless, EOG signals can be useful clinically in acute studies of human disorders, and therefore careful acquisition of the signal followed by appropriate analysis is used to interpret the EOG potentials.

Other biopotential recording techniques follow similar principles of measurements. The electrode design should be specifically adapted to the source of the signal. A thorough effort is required to minimize the noise and interference by improving electrode design and placement and optimizing the amplifier circuit. Good electrode attachment along with selective filtering at the amplifier can help obtain relatively noise-free recording. The design principles and practical considerations are described below.

74.4 The Principles of Biopotential Measurements

The unifying principles of biopotential recordings involve

- Electrode design and its attachment suited to the application;
- Amplifier circuit design for suitable amplification of the signal and rejection of noise and interference;
- Good measurement practices to mitigate artifacts, noise, and interference.

74.5 Electrodes for Biopotential Recordings

Electrodes for biopotential recordings are designed to obtain the signal of interest selectively while reducing the potential to pick up artifact. The design should be pragmatic to reduce cost and allow for good manufacturing and reliable long-term use. These practical considerations determine whether high-quality but reusable electrodes made of silver or gold or cheaper disposable electrodes are used [20].

Silver–Silver Chloride Electrodes

The classic, high-quality electrode design consists of a highly conductive metal, silver, interfaced to its salt, silver chloride, and connected via an electrolytic gel to the human body [21]. Silver–silver chloride–based electrode design is known to produce the lowest and most stable junction potentials [1, 20]. Junction potentials are the result of the dissimilar electrolytic interfaces, and are a serious source of electrode-based motion artifacts. Therefore, additionally, an electrolytic gel typically based on sodium or potassium chloride is applied to the electrode. A gel concentration in the order of 0.1 M (molar concentration) results in a good conductivity and low junction potential without causing skin irritation.

Reusable silver–silver chloride electrodes (Figure 74.4a) are made of silver disks coated electrolytically by silver chloride [1], or, alternatively, particles of silver and silver chloride are sintered together to form the metallic structure of the electrode. The gel is typically soaked into a foam pad or is applied directly in a pocket produced by the electrode housing. The electrode is secured to the skin by means of nonallergenic adhesive tape. The electrode is connected to the external instrumentation typically via a snap-on connector. Such electrodes are well suited for acute studies or basic research investigations.

Disposable electrodes are made similarly, although the use of silver may be minimized (for example, the snap-on button itself may be silver coated and chlorided). To allow for a secure attachment, a large foam pad attaches the electrode body with adhesive coating on one side (Figure 74.4b). Such electrodes are particularly suited for ambulatory or long term use.

Gold Electrodes

Gold-plated electrodes (Figure 74.4c), which have the advantages of high conductivity and inertness desirable in reusable electrodes, are commonly used in EEG recordings [1]. Small reusable electrodes are designed so that they can be securely attached to the scalp. The electrode body is also shaped to make a recessed space for electrolytic gel, which can be applied through a hole in the electrode body [18]. The electrodes are attached in hair-free areas by use of a strong adhesive such as colloidon or securely attached with elastic bandages or wire mesh. Similar electrodes may also be used for recording EMG, especially

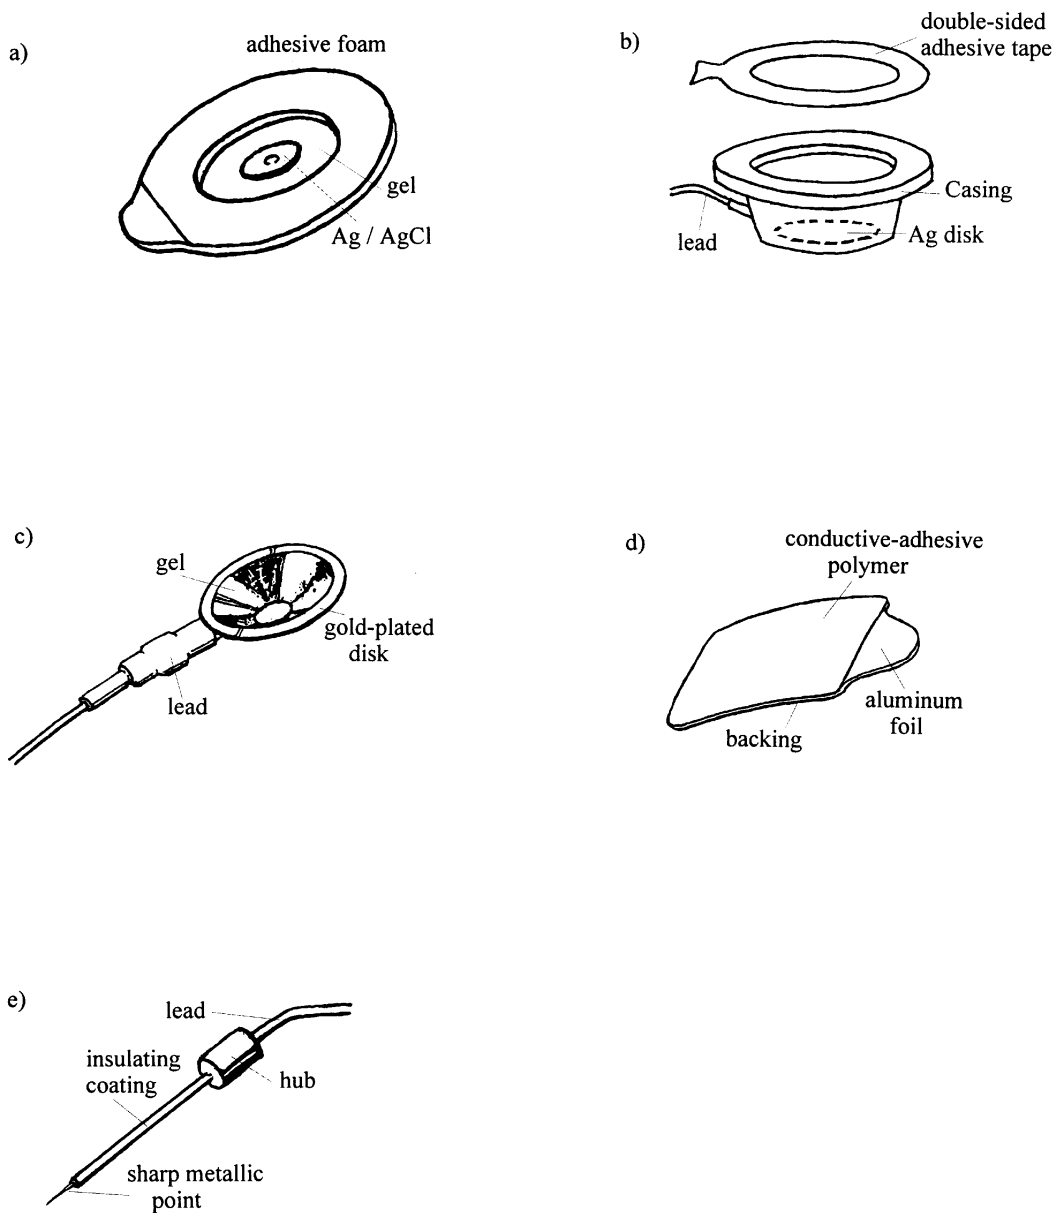

FIGURE 74.4 Examples of electrodes used in biopotential recordings: (a) disposable Ag–AgCl electrode, (b) reusable Ag–AgCl disk electrode, (c) gold disk electrode, (d) disposable conductive polymer electrode, and (e) needle electrode.

when a great deal of motion is expected. Disadvantages of using gold electrodes over silver–silver chloride electrodes include greater expense, higher junction potentials, and greater susceptibility to motion artifacts [20]. On the other hand, gold electrodes maintain low impedance, are inert and reusable, and are good for short-term recordings as long as a highly conductive gel is applied and they are attached securely.

Conductive Polymer Electrodes

It is often convenient to construct an electrode out of a material that is simultaneously conductive and adhesive [20]. Certain polymeric materials have adhesive properties and by attaching monovalent metal ions can be made conductive. The polymer is attached to a metallic backing made of silver or aluminum

foil, which allows electric contact to external instrumentation (Figure 74.4d). This electrode does not need additional adhesive or electrolytic gel and hence can be immediately and conveniently used. The conductive polymeric electrode performs adequately as long as its relatively higher resistivity (over metallic electrodes) and greater likelihood of generating artifacts are acceptable. The higher resistivity of the polymer makes these electrodes unsuitable for low-noise measurement. The polymer does not attach as effectively to the skin as does the conventional adhesive on disposable ECG electrodes built with a foam base and, furthermore, the potentials generated at the electrode–skin interface are more readily disturbed by motion. Nevertheless, when the signal level is high and when restricting the subject movement minimizes artifact, the polymeric electrode offers a relatively inexpensive solution to biopotential recording.

Metal or Carbon Electrodes

Although other metals such as stainless steel or brass electrodes [21] are used rather infrequently now because high-quality noble metal electrodes or low-cost carbon or polymeric electrodes are so readily available, historically these metallic electrodes were used in laboratory or clinical settings because of their sturdy construction and reusability. Electrode gel is applied to the metal electrode which is fastened to the body by means of a rubber band. These electrodes have the potential for producing very high levels of artifact and are bulky and awkward to use, but do offer the advantage of being reusable and tend to be inexpensive. Carbon or carbon-impregnated polymer electrodes are also used occasionally (although they are mainly used as electrical stimulation electrodes) [20]. These electrodes have a much higher resistivity and are noisier and more susceptible to artifacts, but they are inexpensive, flexible, and reusable and are thus chosen for applications such as electric stimulation or impedance plethysmography. For these applications, gel is usually not applied and the electrodes are used in “dry” form for easy attachment and removal.

Needle Electrodes

Needle electrodes (Figure 74.4e) comprise a small class of invasive electrodes, used when it is absolutely essential to record from the organ itself. The most common application is in recording from muscles or muscle fibers [8]. A metallic, typically steel, wire is delivered via a needle inserted at the site of the muscle fiber. The wire is hooked and hence fastens to the muscle fiber, even as the needle is removed. Small signals such as motor unit potentials can be recorded in this manner [7]. For research applications, similar needle or wire electrodes are sometimes connected directly to the heart muscle. Since such electrodes are noninvasive, their use is limited to only highly specialized and supervised clinical or research applications.

74.6 The Biopotential Amplifier

Biopotentials exhibit small amplitudes and low frequencies [22]. Moreover, biopotential measurements are corrupted by environmental and biological sources of interference. Therefore, the essential, although not exhaustive, design considerations include proper amplification and bandwidth, high input impedance, low noise, and stability against temperature and voltage fluctuations. The key design component of all biopotential amplifiers is the instrumentation amplifier [21]. However, each biopotential acquisition instrument has a somewhat differing set of characteristics, necessitating some specialization in the design of the instrumentation amplifier. Table 74.2 summarizes the circuit specialization needed in various biopotential amplifiers, with the ECG amplifier used as the basic design.

The Instrumentation Amplifier

The instrumentation amplifier is a circuit configuration that potentially combines the best features desirable for biopotential measurements [8], namely, high differential gain, low common mode gain,

TABLE 74.2 Distinguishing Features and Design Consideration for Biopotentials

Biopotential	Distinguishing Feature	Exclusive Amplifier Design Consideration	Additional Features Desired
ECG ^a	1 mV signal, 0.05–100 Hz BW ^b	Moderate gain, BW, noise, CMRR, input R	Electrical safety, isolation, defibrillation protection
EEG	Very small signal (microvolts)	High gain, very low noise, filtering	Safety, isolation, low electrode–skin resistance
EMG	Higher BW	Gain and BW of op amps	Postacquisition data processing
EOG	Lower frequencies, small signal	dc and low drift	Electrode–skin junction potential, artifact reduction

^a The ECG signal acquisition is considered as the standard against which the other acquisitions are compared.

^b BW = bandwidth.

FIGURE 74.5 The instrumentation amplifier. This amplifier has a very high input impedance, high CMRR, and a differential gain set by the resistors in the two amplifier stages. The gain of the first stage (amplifiers A1 and A2) is $1 + 2R2/R1$, the second stage (amplifier A3) is $R4/R3$, and the third stage (amplifier A4) is $1 + R7/R6$. The lower corner frequency is $1/(2\pi R5C1)$ and the upper corner frequency is $1/(2\pi R7C2)$. The variable resistor R is adjusted to maximize the CMRR. Electrodes E1 and E2 are the recording electrodes while E3 is the reference or the ground electrode.

high common mode rejection ratio (CMRR), and high input resistance [23]. Figure 74.5 shows the design of the basic instrumentation amplifier. The basic circuit design principles have been described elsewhere [23,25]. The instrumentation amplifier is constructed from operational amplifiers, or op amps, which have many of the desirable features listed above [24]. The front end of the amplifier has two op amps, which consists of two noninverting amplifiers that have been coupled together by a common resistor $R1$. The gain of the first stage is $(1 + 2R2/R1)$. The second stage is a conventional differential amplifier with gain of $-(R4/R3)$. This design results in the desired differential gain distributed over two stages of the amplifier. It also achieves a very high input resistance as a result of the noninverting amplifier front end. It exhibits a very high CMRR as a result of the differential first stage followed by a second-stage differential amplifier. The CMRR is enhanced by adjusting one of the matching resistors and by selecting high CMRR op amps. This instrumentation amplifier is a key design component universal to many biosensor interfaces and almost all biopotential instruments [22].

The ECG Amplifier

The ECG amplifier can readily be designed using the instrumentation amplifier as the principal building block. Active filters with a lower corner frequency of 0.05 Hz and an upper corner frequency of 100 Hz are also typically added [8].

ECG amplifiers are needed in many applications, such as monitoring in cardiac intensive-care units, where safety and protection are of paramount importance. Because the possibility of a direct or low-resistance access to the heart via catheters or intravenous lines exists in such settings, very small electric leakage currents can be fatal. Consequently, leakage from the amplifier is required to be below the safety standard limit of 10 μA [14]. Additionally, safety of the patient is achieved by providing electrical isolation from the power line and the earth ground, which prevents passage of leakage current from the instrument to the patient under normal conditions or under reasonable failure conditions. Electrical isolation is achieved by using transformer or optical coupling components [9], although it is important to remember that any such design should preserve the bandwidth and linearity of the amplifier. ECG amplifiers are also likely to be operated in circumstances where defibrillators might be used; thus, the amplifier circuit must be protected against the high defibrillation voltages and must be augmented by circuit components such as current-limiting resistors, voltage-limiting diodes, and spark gaps [15].

The EEG Amplifier

The distinguishing feature of an EEG amplifier is that it must amplify very small signals [8]. The amplifier gain must be suitably enhanced to deal with microvolt or lower levels of signals. Furthermore, all components of the amplifier must have a very low thermal noise and in particular low electronic (voltage and current) noise at the front end of the amplifier. EEG amplifiers used in clinical applications again must be electrically isolated and protected against high defibrillation voltages, similar to the ECG amplifier.

The EMG Amplifier

EMG amplifiers are often used in the investigation of muscle performance, neuromuscular diseases, and in building certain powered or smart prostheses. In such applications, slightly enhanced amplifier bandwidth suffices. In addition, postprocessing circuits are almost always needed. For example, a rectified and integrated EMG signal has been shown to give a rough indication of the muscle activity, approximately related to the force being generated at the location of the EMG electrode [8].

The EOG Amplifier

The EOG signal is small in amplitude and consists of very low frequencies. Therefore, an EOG amplifier must not only have a high gain, but also a very good low frequency, or even dc, response. This frequency response also makes the amplifier potentially susceptible to shifts in the junction potential at the skin–electrode interface and to drift in the electronic circuit characteristics. In addition to using good electrodes (Ag–AgCl) and gel (high conductivity), some type of active dc or drift cancellation or correction circuit design may be necessary.

74.7 Circuit Enhancements

The basic biopotential amplifier described above, along with the specific design considerations for each biopotential, can yield a signal acquisition of acceptable quality in most laboratory settings. In practice, however, further enhancements are always necessary to achieve acceptable clinical performance in novel applications. These enhancements include circuits for reducing electric interference, filtering noise, reduction of artifacts, electrical isolation of the amplifier, and electrical protection of the circuit against defibrillation shocks [9].

FIGURE 74.6 Circuit enhancements for biopotential measurements. (a) The schematic on the left shows electric interference induced by the displacement current i_d from the power line. This current flows into the ground electrode lead generating common-mode voltage V_c . The driven right leg circuit on the right uses negative feedback into the right leg electrode to reduce the effective common-mode voltage. (b) Amplifier front end filters — T1: RF choke; R0 and C0: RF filter; R1 and C1: high-pass filter; R2 and C2: low-pass filter. (c) Notch filter for power line interference (50 or 60 Hz): twin T notch filter in which notch frequency is governed by R1, R2, R3, C1, C2, and C3, and notch tuning by R4. (d) Baseline restoration circuit: the high-pass filter capacitor C1 is discharged by field effect transistor F when activated manually or automatically by a baseline restoration pulse. (e) Electrical isolation: transformer coupled using the transformer T (top) or optical using the diode D and the photodetector P (bottom). Note that the isolator separates circuit common on the amplifier side from the Earth ground on the output side. (f) Electrical protection circuit: resistance R limits the current, reverse-biased diodes D limit the input voltage, and the spark gap S protects against defibrillation pulse-related breakdown of the isolation transformer T.

Electrical Interference Reduction

Environmental electric interference is always present, especially in urban hospital environments. It is desirable to eliminate interference before it enters the amplifier, for example, by proper shielding of the subject, leads, and the instrument and by grounding the subject and the instrument. Sources of interference include induced signals from power lines and electric wiring; RF from transmitters, electric motors, and other appliances; magnetically induced currents in lead wires; and so on [13]. Interference induced on the body common to the biopotential sensing electrodes is called the common mode interference (as distinguished from the biopotential that is differential to the sensing electrodes). If the induced current is i_d and the resistance to ground is R_0 , then the common mode interference potential is $V_c = i_d R_0$. The common mode interference is principally rejected by a differential or instrumentation amplifier with a high CMRR. Further improvement is possible by use of the “driven right leg circuit.” The right leg lead, by standard convention, is used as the ground or the circuit reference. The driven right leg circuit employs the clever idea of negative feedback of the common mode signal into this lead. The common mode signal is sensed from the first stage of the instrumentation amplifier, amplified and

(b)

(c)

(d)

FIGURE 74.6 (continued)

inverted, and fed back into the right leg lead (Figure 74.6a). At this stage the common mode signal is reduced to $(i_d R_0)/(1 + 2R_2/R_1)$. Thus, the common mode interference is greatly reduced at its source. The driven right leg circuit along with a high CMRR of the amplifier and filtering permit very high quality biopotential measurements.

(e)

FIGURE 74.6 (continued)

Filtering

After following the precautions described above, filtering at the front end of the amplifier and limiting the bandwidth of the biopotential amplifier can further help to reduce the interference (Figure 74.6b). Small inductors or ferrite beads in the lead wires help to block very high frequency electromagnetic interference. Small capacitors between each electrode lead and ground filter the RF interference. Bandwidth limitation can be imposed at each stage of the amplifier. Because dc potentials arising at the electrode–skin interface must be blocked well before the biopotential is amplified greatly (otherwise, the amplifier could saturate), use of high-pass filtering in the early stages of amplification is recommended. Low-pass filtering at several stages of amplification is recommended to attenuate residual RF interference as well as muscle signal interference. Power line interference at 50 or 60 Hz and their harmonics clearly poses the biggest problem in biopotential measurement [11,13]. Sometimes it may be desirable to provide

(f)

FIGURE 74.6 (continued)

a 50 or 60 Hz notch filter to remove the power line interference (Figure 74.6c), an option that is often available with low-level signal (EEG, EOG) measuring instruments. The risk of a distorted biopotential signal arises when a notch filter is used and this may affect diagnosis. Filtering should, therefore, be used selectively.

Artifact Reduction

One principal source of artifact is the potential arising at the electrode–skin interface [11]. Slow changes in the baseline can arise due to changes in the junction potential at this interface and, in some instances, can cause a temporary saturation of the amplifier [9]. This event is detected manually or automatically (by quickly discharging the high-pass capacitor in the amplifier to restore the baseline; Figure 74.6d). Movement of the subject or disturbance of the electrode can produce motion artifacts [11], which can be reduced by filtering the signal, but as suggested above, such filtering, typically high pass, can severely distort the biopotential being measured. Alternatively, computerized processing may be necessary to identify an artifact and delete it from display and processing. Of note, a biopotential source could be the desired one in one case, but an unwanted artifact in another case. For example, EOG signal resulting from blinking of eyes can produce a rather significant artifact in EEG recordings. Similarly, EMG signals become unwanted artifacts in all other non-EMG biopotential measurements. ECG monitoring must especially account for EMG artifact for high-fidelity recording. Another example is the pacemaker pulse. Since a pacemaker pulse can be detected and amplified as a short (about 2 ms) pulse preceding a QRS complex, it can be mistakenly interpreted as a heartbeat by some circuits for automatically determining heart rate. Special circuits must be designed to identify and delete this artifact [9].

Electrical Isolation

Electrical isolation limits the possibility of the passage of any leakage current from the instrument in use to the patient [22]. Conversely, patient safety must be ensured by electrical isolation to reduce the prospect of leakage of current from any other sensor or instrument attached to the patient to the Earth ground of the instrument being tested [8]. Passage of leakage current through the patient could be harmful or even fatal if this current were to leak to the heart via a catheter or intravenous line. Electrical isolation can be done electrically by inserting a transformer in the signal path or optically by introducing an optical coupler (Figure 74.6e). Since the primary and the secondary of the transformer remain electrically isolated, no direct path to ground can exist. One problem with this approach is that the transformer is inherently an ac high-frequency device. Therefore, a suitable solution is to modulate the biopotential signal using a high-frequency carrier preferred by the transformer. An alternative solution is to use optical isolation. The electric signal from the amplifier is first converted to light by a light-emitting diode (LED). This optical signal is modulated in proportion to the electric signal, and transmitted to the detector. A photodetector (photodiode or a phototransistor) then picks up the light, converts it into an electric signal, which is then demodulated to recover the original signal. The optical signal is typically pulse code modulated to circumvent the inherent nonlinearity of the LED–phototransistor combination.

Defibrillation Protection

Biopotential-measuring instruments can encounter very high voltages, such as those from electric defibrillators, that can damage the instrument [9]. For example, electric shocks in the order of 1500 to 5000 V may be produced by an external defibrillator [1]. Other high-voltage sources are electrocautery (used in surgery) and power lines (inadvertent short circuits in the instrument). Therefore, the front end of the biopotential instrument must be designed to withstand these high voltages (Figure 74.6f). Use of resistors in the input leads can limit the current in the lead and the instrument. Protection against high voltages is achieved by the use of diodes or Zener diodes. These components conduct at 0.7 V (diode conduction voltage) or 10 to 15 V (depending on the Zener diode breakdown voltage), thus protecting the sensitive amplifier components. Since it is more likely that protection against higher voltages will be needed, low-pressure gas discharge tubes such as neon lamps are also used. They break down at voltages on the order of 100 V, providing an alternative path to ground for the high voltages. As a final line of protection, the isolation components (optical isolator or transformer) must be protected by a spark gap that activates at several thousand volts. The spark gap ensures that the defibrillation pulse does not breach the isolation.

74.8 Measurement Practices

Biopotential measurements are made feasible, first of all, by good amplifier designs. High-quality biopotential measurements require use of good electrodes and their proper application on the patient, along with good laboratory or clinical practices. These practices are summarized below.

Electrode Use

Various electrodes best suited for each biopotential measurement were described earlier. First, different electrodes by virtue of their design offer distinguishing features: more secure (use of strong but less-irritant adhesives), more conductive (use of noble metals such as silver and gold), less prone to artifact (use of low-junction-potential materials such as Ag–AgCl). Electrode gel can be of considerable importance in maintaining a high-quality interface between the electrode metal and the skin. High conductivity gels, in general, help reduce the junction potentials along with the resistance (they tend, however, to be allergenic or irritating and hence a practical compromise in terms of electrolyte concentration must be found) [20]. Movement of the electrode with respect to the electrode gel and the skin is a potential source of artifact (Figure 74.7a). Such movements can change the electrode junction to skin potentials, producing

FIGURE 74.7 Examples of electric interference in biopotential recordings: (a) ECG signal with baseline changes and motion artifacts, (b) muscle signal interference, (c) electromagnetic interference (60 Hz power line and RF).

motion artifacts [21]. Placement above bony structures where there is less muscle mass can reduce unwanted motion artifact and EMG interference (Figure 74.7b). Electrodes must be securely attached, for example, with stress loops secured away from the electrode site, so that motion artifact can be reduced. In certain instances, the electrodes may be essentially glued to skin, as in the case of EEG measurements.

Skin Preparation

The potentials existing at the skin surface, attributable to potentials at the membranes of cells in the epidermal layers of the skin, can result in a large dc potential (which can be a significant problem in EOG measurements). Any disturbance of the skin by motion, touching, or deformation can cause this potential to change and result in motion artifacts (Figure 74.7a). Sweat glands in the epidermis can also contribute varying extents of skin resistance and skin potential. Such potentials and artifacts can be reduced by abrading the epidermal skin. A mild abrasion by sandpaper or its equivalent can significantly reduce skin resistance and skin potential and thereby reduce artifact [26]. A less traumatic, but somewhat less effective approach, is to use an alcohol swab or similar skin-cleansing solution to wet and clean the skin surface to remove debris, oils, and damaged or dead epidermal cells. Sometimes, as with EEG measurements where very low signals are recorded and very low noise is permitted, skin resistance must be significantly lowered, perhaps to below 2 k Ω [18]. Obviously, reduced motion or muscle activity while measurement is carried out also helps.

Reduction of Environmental Interference

Electromagnetic interference radiated from the power lines, RF interference from machines, induced magnetic field in the leads, and electric currents induced on to the body are all potential sources of environmental interference (Figure 74.7c). Shielding of the amplifier along with the electrode and the lead, and in certain extreme conditions, shielding of the subject (for example, when taking magnetic field measurements from the body) can greatly help reduce the signals picked up by or induced into the

amplifier. The electrode leads can be shielded or at the very least twisted together to reduce induced electromagnetic interference.

The amplifier circuit should also have extensive filtering of unwanted electromagnetic interference. To eliminate RF interference, filter capacitors should be used in the front end of the amplifier as well as at various stages of the amplifier. Very high frequencies can be blocked by the use of a choke or an inductor at the input leads. The effect of electrostatic interference can be minimized or eliminated by grounding the instrument.

Electric interference in the environment induces current into the body, which is then picked up by the biopotential amplifier as a common-mode voltage [27]. The CMRR property of the amplifier is essential for reduction of the common-mode voltage [24]. Finally, the driven right leg design [27], described earlier, can be optionally used to reduce further the common-mode voltage and the effective interference.

74.9 Conclusions

Biopotential acquisition is a well-developed science, and acceptable engineering design solutions do exist. It is apparent that each biopotential source presents its own distinct challenge in terms of electrode interface, amplifier design, pre- or postprocessing, and practical implementation and usage. ECG signals can be best acquired using Ag–AgCl electrodes, although good experimental/clinical practice is needed to reduce biological and environmental interference. Further circuit protection and isolation are necessary in clinical usage. EEG signals are distinguishable by their very low amplitude, and hence EEG electrodes must be securely attached via a very small electrode–skin resistance and the amplifier must exhibit exceptionally low noise. For EMG acquisition, electrodes are needed that can be attached for long periods of time to the muscle groups under study. The EMG signal inevitably needs postprocessing, such as integration, to derive a measure of muscle activity. EOG signals have small amplitudes and are characterized by dc or low frequencies. Skin–electrode potentials and dc drift of the amplifier are, therefore, important considerations.

These biopotential measurement principles are applicable to a variety of conventional as well as emerging applications. For example, although ECG acquisition is used mainly in cardiac monitors, it is also of interest and importance in implantable pacemakers and defibrillators. EEG acquisition is useful in the detection of seizure spikes and study of sleep patterns and it may also be used to identify cortical dysfunction after trauma or stroke. EMG acquisition is used in diagnosing neuromuscular diseases. Interesting attempts have been made to use EMG for controlling prostheses. EOG has been helpful in diagnosing vestibulo-ocular disorders and also has been studied as a way of operating communication devices (pointing) used by quadriplegics. The measurement and instrumentation principles described in this chapter would be applicable, with some modifications, to these emergent applications.

75.1 Introduction

Blood pressure measurements have been part of the basic clinical examination since the earliest days of modern medicine. The origin of blood pressure is the pumping action of the heart, and its value depends on the relationship between cardiac output and peripheral resistance. Therefore, blood pressure is considered as one of the most important physiological variables with which to assess cardiovascular hemodynamics. Venous blood pressure is determined by vascular tone, blood volume, cardiac output, and the force of contraction of the chambers of the right side of the heart. Since venous blood pressure must be obtained invasively, the term *blood pressure* most commonly refers to arterial blood pressure, which is the pressure exerted on the arterial walls when blood flows through the arteries. The highest value of pressure, which occurs when the heart contracts and ejects blood to the arteries, is called the systolic pressure (SP). The diastolic pressure (DP) represents the lowest value occurring between the ejections of blood from the heart. Pulse pressure (PP) is the difference between SP and DP, i.e., $PP = SP - DP$. The period from the end of one heart contraction to the end of the next is called the cardiac cycle. Mean pressure (MP) is the average pressure during a cardiac cycle.

Mathematically, MP can be decided by integrating the blood pressure over time. When only SP and DP are available, MP is often estimated by an empirical formula:

$$MP \approx DP + PP/3 \quad (75.1)$$

Note that this formula can be very inaccurate in some extreme situations. Although SP and DP are most often measured in the clinical setting, MP has particular importance in some situations, because it is the driving force of peripheral perfusion. SP and DP can vary significantly throughout the arterial system whereas MP is almost uniform in normal situations.

The values of blood pressure vary significantly during the course of 24 h according to an individual's activity [1]. Basically, three factors, namely, the diameter of the arteries, the cardiac output, and the state or quantity of blood, are mainly responsible for the blood pressure level. When the tone increases in the muscular arterial walls so that they narrow or become less compliant, the pressure becomes higher than normal. Unfortunately, increased blood pressure does not ensure proper tissue perfusion, and in some instances, such as certain types of shock, blood pressure may seem appropriate when peripheral tissue perfusion has all but stopped. Nevertheless, observation or monitoring of blood pressures affords dynamic tracking of pathology and physiology affecting the cardiovascular system. This system in turn has profound effects on the other organs of the body.

75.2 Measurement Techniques

The basis of any physiological measurement is the biological signal, which is first sensed and transduced or converted from one form of energy to another. The signal is then conditioned, processed, and amplified. Subsequently, it is displayed, recorded, or transmitted (in some ambulatory monitoring situations). Blood pressure sensors often detect mechanical signals, such as blood pressure waves, to convert them into electric signals for further processing or transmission. They work on a variety of principles, for example, resistance, inductance, and capacitance. For accurate and reliable measurements a sensor should have good sensitivity, linearity, and stability [2].

75.3 Indirect Blood Pressure Measurement

Indirect measurement is often called noninvasive measurement because the body is not entered in the process. The upper arm, containing the brachial artery, is the most common site for indirect measurement because of its closeness to the heart and convenience of measurement, although many other sites may have been used, such as forearm or radial artery, finger, etc. Distal sites such as the wrist, although convenient to use, may give much higher systolic pressure than brachial or central sites as a result of the phenomena of impedance mismatch and reflective waves [3]. An occlusive cuff is normally placed over the upper arm and is inflated to a pressure greater than the systolic blood pressure. The cuff is then gradually deflated, while a detector system simultaneously employed determines the point at which the blood flow is restored to the limb. The detector system does not need to be a sophisticated electronic device. It may be as simple as manual palpation of the radial pulse. The most commonly used indirect methods are auscultation and oscillometry, each is described below.

Auscultatory Method

The auscultatory method most commonly employs a mercury column, an occlusive cuff, and a stethoscope. The stethoscope is placed over the blood vessel for auscultation of the Korotkoff sounds, which defines both SP and DP. The Korotkoff sounds are mainly generated by the pulse wave propagating through the brachial artery [4]. The Korotkoff sounds consist of five distinct phases. The onset of Phase I Korotkoff sounds (first appearance of clear, repetitive, tapping sounds) signifies SP and the onset of Phase V Korotkoff sounds (sounds disappear completely) often defines DP [5].

Observers may differ greatly in their interpretation of the Korotkoff sounds. Simple mechanical error can occur in the form of air leaks or obstruction in the cuff, coupling tubing, or Bourdon gage. Mercury can leak from a column gage system. In spite of the errors inherent in such simple systems, more mechanically complex systems have come into use. The impetus for the development of more elaborate detectors has come from the advantage of reproducibility from observer to observer and the convenience of automated operation. Examples of this improved instrumentation include sensors using plethysmographic principles, pulse-wave velocity sensors, and audible as well as ultrasonic microphones [6].

The readings by auscultation do not always correspond to those of intra-arterial pressure. [5]. The differences are more pronounced in certain special occasions such as obesity, pregnancy, arteriosclerosis,

FIGURE 75.1 Indirect blood pressure measurements: oscillometric measurement and auscultatory measurement. (Adapted from Current technologies and advancement in blood pressure measurements — review of accuracy and reliability, *Biomed. Instrum. Technol.*, AAMI, Arlington, VA (publication pending). With permission.)

shock, etc. Experience with the auscultation method has also shown that determination of DP is often more difficult and less reliable than SP. However, the situation is different for the oscillometric method where oscillations caused by the pressure pulse amplitude are interpreted for SP and DP according to empirical rules [7].

Oscillometric Method

In recent years, electronic pressure and pulse monitors based on oscillometry have become popular for their simplicity of use and reliability. The principle of blood pressure measurement using the oscillometric technique is dependent on the transmission of intra-arterial pulsation to the occluding cuff surrounding the limb. An approach using this technique could start with a cuff placed around the upper arm and rapidly inflated to about 30 mmHg above the systolic blood pressure, occluding blood flow in the brachial artery. The pressure in the cuff is measured by a sensor. The pressure is then gradually decreased, often in steps, such as 5 to 8 mmHg. The oscillometric signal is detected and processed at each step of pressure. The cuff pressure can also be deflated linearly in a similar fashion as the conventional auscultatory method.

Figure 75.1 illustrates the principle of oscillometric measurement along with auscultatory measurement. Arterial pressure oscillations are superimposed on the cuff pressure when the blood vessel is no longer fully occluded. Separation of the superimposed oscillations from the cuff pressure is accomplished by filters that extract the corresponding signals. Signal sampling is carried out at a rate determined by the pulse or heart rate [7]. The oscillation amplitudes are most often used with an empirical algorithm to estimate SP and DP. Unlike the Korotkoff sounds, the pressure oscillations are detectable throughout

the whole measurement, even at cuff pressures higher than SP or lower than DP. Since many oscillometric devices use empirically fixed algorithms, variance of measurement can be large across a wide range of blood pressures [8]. Significantly, however, MP is determined by the lowest cuff pressure of maximum oscillations [9] and has been strongly supported by many clinical validations [10, 11].

Self-Measurement

From the growing number of publications on the topic in recent years, it is evident that the interest in self-measurement of blood pressure has increased dramatically. There is also evidence that the management of patients with high blood pressure can be improved if clinic measurements are supplemented by home or ambulatory monitoring. Research has shown that blood pressure readings taken in the clinic can be elevated, by as much as 75 mmHg in SP and 40 mmHg in DP, when taken by a physician. The tendency for blood pressure to increase in certain individuals in the presence of a physician due to stress response is generally known as “white-coat” hypertension [12]. When reasonably priced and easy to use, oscillometric devices became commonly available in the early 1970s, public interest in the self-measurement of blood pressure increased and this has made it possible for greater patient involvement in the detection and management of hypertension [13]. Health care costs may also be reduced by home monitoring. Indeed, a recent study found that costs were almost 30% lower for patients who measured their own blood pressure than those who did not [14]. Measurements taken at patient’s home are more highly correlated to 24-h blood pressure levels than clinic readings are. It has also been shown that most patients are able to monitor their blood pressure and may be more relaxed as well as assured by doing so, particularly when experiencing symptoms [15].

Ambulatory Monitoring

There is great significance for ambulatory monitoring of blood pressure. Over a period of 24 h, blood pressure is subject to numerous situational and periodic fluctuations [1]. The pressure readings have a pronounced diurnal rhythm in an individual, with a decrease of 10 to 20 mmHg during sleep and a prompt increase on getting up and walking in the morning. Readings tend to be higher during working hours and lower at home and they depend on the pattern of activity. After a bout of vigorous exercise or strenuous work, blood pressure may be reduced for several hours. The readings may be raised if the patient is talking during the measurement period. Smoking a cigarette and drinking coffee, especially if they are combined, may both raise the pressure [16]. When assessing the efficacy of antihypertensive drugs, ambulatory blood pressure monitoring can provide considerable information and validation of the drug treatment [17].

Although the technique of noninvasive ambulatory blood pressure monitoring was first described more than three decades ago, it has only recently become accepted as a clinically useful procedure for evaluation of patients with abnormal regulation of blood pressure. It gives the best evaluation for patients who have white-coat hypertension. Technical advances in microelectronics and computer technology have led to the introduction of ambulatory monitors with improved accuracy and reliability, small size, quiet operation, and reasonable low price. They can take and store several hundred readings over a period of 24 h while patients may not be compromised with their normal activities, thus becoming usable for purposes of clinical diagnosis [18]. Theoretically, ambulatory monitoring can provide information about the level and variability covering the full range of blood pressure experienced during day-to-day activities. It is now recognized to be a very useful procedure in clinical practice since blood pressure varies significantly during the course of 24 h, especially useful in detecting white-coat hypertension. However, many studies have found that accuracy of monitoring using current ambulatory monitors is acceptable only when patients are at rest but not during physical activity [19] or under truly ambulatory conditions. Report of error codes during operation in the latter situations is much higher [20].

TABLE 75.1 AHA Acceptable Bladder Dimensions for Arm of Different Sizes^a

Cuff	Bladder Width (cm)	Bladder Length (cm)	Arm Circumference Range at Midpoint (cm)
Newborn	3	6	≤6
Infant	5	15	6–15 ^b
Child	8	21	16–21 ^b
Small adult	10	24	22–26
Adult	13	30	27–34
Large adult	16	38	35–44
Adult thigh	20	42	45–52

^a There is some overlapping of the recommended range for arm circumferences in order to limit the number of cuffs; it is recommended that the larger cuff be used when available.

^b To approximate the bladder width:arm circumference ratio of 0.40 more closely in infants and children, additional cuffs are available.

Adapted from the *Recommendations for Human Blood Pressure Determination by Sphygmomanometers*, Dallas: American Heart Association, 1993. With permission.

Cuff Size

Both the length and width of an occluding cuff are important for accurate and reliable measurement of blood pressure by indirect methods. A too-short or too-narrow cuff results in false high blood pressure readings. Several studies have shown that a cuff of inappropriate size in relation to the patient's arm circumference can cause considerable error in blood pressure measurement [21]. The cuff should also fit around the arm firmly and comfortably. Some manufacturers have designed cuffs with a fastener spaced so that a cuff of appropriate width only fits an arm of appropriate diameter. With this design, the cuff will not stay on the arm during inflation unless it fits accordingly.

According to American Heart Association (AHA) recommendations [5], the width of the cuff should be 40% of the midcircumference of the limb and the length should be twice the recommended width. [Table 75.1](#) presents the AHA cuff sizes covering from neonates to adults.

Recommendations, Standards, and Validation Requirements

The AHA has published six editions of the AHA recommendations for indirect measurement of arterial blood pressure. The most recent edition [5] included the recommendations of the joint national committee on the diagnosis, evaluation, and treatment of hypertension for classifying and defining blood pressure levels for adults (age 18 years and older) [22], as shown in [Table 75.2](#). The “Report of the Second Task Force on Blood Pressure Control in Children” [23] offered classification of hypertension in young age groups from newborns to adolescents, as shown in [Table 75.3](#).

The AHA recommendations provide a systemic step-by-step procedure for measuring blood pressure, including equipment, observer, subject, and technique. It extends considerations of blood pressure recording in special populations such as infants and children, elderly, pregnant and obese subjects, etc. It also provides recommendations of self-measurement or home measurement of blood pressure, as well as ambulatory blood pressure measurement.

The Association for the Advancement of Medical Instrumentation (AAMI) and American National Standard Institute (ANSI) published and revised a national standard [24, 25] for evaluating electronic or automated sphygmomanometers. This standard established labeling requirements, safety and performance requirements, and referee test methods for electronic or automated sphygmomanometers used in indirect measurement of blood pressure. Specific requirements for ambulatory blood pressure monitors were also included. Recently, AAMI/ANSI amended this SP10 standard to include neonatal devices as well [26]. Some of the specific requirements, procedures, and limits were modified to fit neonatal

TABLE 75.2 Recommendations of the Joint National Committee on the Diagnosis, Evaluation, and Treatment of Hypertension for Classifying and Defining Blood Pressure Levels for Adults (age 18 years and older)^a

Category	Systolic Pressure (mm Hg)	Diastolic Pressure (mm Hg)
Normal ^b	<130	<85
High normal	130–139	85–89
Hypertension ^c		
Stage 1 (mild)	140–159	90–99
Stage 2 (moderate)	160–179	100–109
Stage 3 (severe)	180–209	110–119
Stage 4 (very severe)	≥210	120

^a Not taking antihypertensive drugs and not acutely ill. When systolic and diastolic pressures fall into different categories, the higher category should be selected to classify the individual's blood pressure status. For instance, 160/92 mmHg should be classified as stage 2, and 180/120 mmHg should be classified as stage 4. Isolated systolic hypertension is defined as a systolic blood pressure of 140 mmHg or more and a diastolic blood pressure of less than 90 mmHg and staged appropriately (e.g., 170/85 mmHg is defined as stage 2 isolated systolic hypertension). In addition to classifying stages of hypertension on the basis of average blood pressure levels, the clinician should specify presence or absence of target-organ disease and additional risk factors. For example, a patient with diabetes and a blood pressure of 142/94 mmHg plus left ventricular hypertrophy should be classified as having “stage 1 hypertension with target-organ disease (left ventricular hypertrophy) and with another major risk factor (diabetes).” This specificity is important for risk classification and management.

^b Optimal blood pressure with respect to cardiovascular risk is less than 120 mmHg systolic and less than 80 mmHg diastolic. However, unusually low readings should be evaluated for clinical significance.

^c Based on the average of two or more readings taken at each of two or more visits after an initial screening.

Adapted from *The fifth report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNCV)*, *Arch. Intern. Med.*, 153, 154–183, 1993.

applications, such as the maximum cuff pressure, ranges of age and weight, reference standards for validation, minimum sample size of data, etc. The overall system efficacy for both neonatal and adult devices requires that for systolic and diastolic pressures treated separately, the mean difference between the paired measurements of the test system and the reference standard shall be ± 5 mmHg or less, with a standard deviation of 8 mmHg or less.

For manual or nonautomated indirect blood pressure measuring devices, ANSI/AAMI SP9 standard [27] applies.

The British Hypertension Society (BHS) also published and revised a protocol for assessing accuracy and reliability of blood pressure measurement using automatic and semiautomatic devices [28, 29]. Many automatic and semiautomatic devices, including ambulatory devices, have been evaluated according to the BHS protocol. Such evaluation provided a quality-control mechanism for manufacturers and an objective comparison for customers. However, there are many more devices available on the market, which have not been accordingly evaluated. Different from the AAMI SP10 standard in which either indirect or direct blood pressure may be used as a reference standard, the BHS protocol relies exclusively on references of sphygmomanometric blood pressure measurement, and does not recommend comparison with intra-arterial blood pressure values [30]. This could make accurate validation of ambulatory devices difficult because sphygmomanometric measurements during exercise and under ambulatory conditions are not accurate [31].

Significantly, the BHS protocol emphasized the need on special-group validation, such as children, pregnancy, and the elderly for the intended use. It also emphasized the need for validation under special circumstances, such as exercise and posture. The accuracy criteria use a grading system based on the percentages of test instrument measurements differing from the sphygmomanometric measurements by ≤ 5 , ≤ 10 , and ≤ 15 mmHg for systolic and diastolic blood pressure, respectively, as shown in [Table 75.4](#).

TABLE 75.3 Classification of Hypertension in the Young by Age Group^a

Age Group	High Normal	Significant Hypertension	Severe Hypertension
	(90–94th percentile) mmHg	(95–99th percentile) mmHg	(>99th percentile) mmHg
Newborns (SBP)		96–105	≥106
7 d	—	104–109	≥110
8–30 d	—		
Infants (≥2 y)			
SBP	104–111	112–117	≥118
DBP	70–73	74–81	82
Children			
3–5 y			
SBP	108–115	116–123	≥124
DBP	70–75	76–83	≥84
6–9 y			
SBP	114–121	122–129	≥130
DBP	74–77	78–85	≥86
10–12 y			
SBP	122–125	126–133	≥134
DBP	78–81	82–89	≥90
13–15 y			
SBP	130–135	136–143	≥144
DBP	80–85	86–91	≥92
Adolescents (16–18 y)			
SBP	136–141	142–149	≥150
DBP	84–91	92–97	≥98

^a SBP indicates systolic blood pressure; DBP, diastolic blood pressure.

Adapted from the Report of the Second Task Force on Blood Pressure Control in Children — 1987, *Pediatrics*, 79, 1–25, 1987. With permission.

TABLE 75.4 Grading Criteria of the 1993 British Hypertension Society Protocol^{a,b}

Grade	Absolute Difference between Standard and Test Device (mmHg)		
	≤5	≤10	≤15
	Cumulative Percentage of Readings		
A	60	85	95
B	50	75	90
C	40	65	85
D	Worse than C		

^a Grades are derived from percentages of readings within 5, 10, and 15 mmHg. To achieve a grade all three percentages must be equal to or greater than the tabulated values.

^b Grading percentages changed from the 1990 British Hypertension Society protocols due to changes in sequential assessment of blood pressure references.

Manufacturer, Product, Price, Efficacy, and Technology

The annual publication of the *Medical Device Register* is a comprehensive reference work that provides a wealth of detailed information on U.S. and international medical devices, medical device companies, OEM suppliers, and the key personnel in the industry. Blood pressure devices are listed in the sphygmomanometer

directory. Price information of specific models for some providers is also published. For example, A&D Engineering, Inc. listed price from \$51.95 (model UA701) to \$179.95 (model UA-751) for a whole line of sphygmomanometers in the 1997 *Medical Device Register* [32]. Since technology and market can change rapidly, models, features, specifications, and prices may change accordingly. More specific and updated information may be available by contacting the manufacturers or distributors directly.

Table 75.5 lists only a limited number of indirect blood pressure devices from a literature review. Many of the listed blood pressure devices have multiple evaluation studies and only a few study results are presented here. In view of reference standards for comparison, although direct and indirect methods yield similar measurements, they are rarely identical because the direct method measures pressure and the indirect method is more indicative of flow [5]. Egmond et al. [33] evaluated the accuracy and reproducibility of 30 home blood pressure devices in comparison with a direct brachial arterial standard. They found average offsets of all tested devices amounted to -11.7 mmHg for systolic and 1.6 mmHg for diastolic blood pressure, which were close to those of the mercury sphygmomanometer (-14.2 mmHg for systolic and -0.1 mmHg for diastolic pressure), indicating a significant difference between the two assessment standards. When selecting a blood pressure device for a specific application, the evaluation using the reference that is of a common practice in the intended population or environment may be practically more informative, since that reference has been the common basis for decision making in blood pressure diagnosis and treatment.

Different evaluation results for the same brand product can also be due to different versions of a model used for validation, where a later version may have performance improvement over the earlier one [34]. Another source of discrepancies can come from utilizing different study protocols or only partially following the same protocols. It is recommended that the original clinical evaluation report be carefully examined in determining the desired efficacy that may meet the users' requirements. If the devices were FAD approved for marketing in the U.S., one may request a copy of their clinical validation report directly from the manufacturer.

In addition to the fundamental categories such as intended use, efficacy, and acquisition technology, listed in Table 75.5, many other categories are also very important in evaluating, selecting, purchasing, using, and maintaining blood pressure devices. These include but are not limited to the following items: measurement range of each pressure (systolic, diastolic, and mean) for each mode of intended use (i.e., neonates, children, adults); maximum pressure that can be applied by the monitor and cuff for each mode of intended use; cuff size range for the target population of the intended use; cost; measurement and record failure rate; noise and artifact rejection capability; mode of operation (manual, automatic, semiautomatic); data display; recording, charting, reporting, and interfacing; physical size and weight; power consumption; operation manual; service manual; labels and warnings; etc.

Advancement of Indirect Blood Pressure Measurement

Since the introduction of Dinamap™, an automated blood pressure monitor based on the oscillometric principle [9], many variants of oscillometric algorithms were developed. However, the fixed or variable fractions of the maximum oscillations are still the fundamental algorithms of the oscillometry [10, 53, 54]. Typically, mean blood pressure was determined by the lowest cuff pressure with greatest average oscillation [11]. Systolic and diastolic blood pressure were determined by the cuff pressure with the amplitude of oscillation being a fixed fraction of the maximum. Performance of the algorithms may be improved by introducing a greater level of complexity or variables into considerations. The Dinamap™ 1846SX (Critikon, Tampa, FL) oscillometric device offered two measurement modes. The normal mode uses two matching pulse amplitudes at each cuff pressure step to establish an oscillometric envelope or curve. Therefore, measurement time is heart rate dependent. The second mode, which the manufacturer refers to as “stat mode,” is capable of faster determination by disabling the dual pulse-matching algorithm which was designed for artifact rejection. The stat mode does not appear to compromise accuracy in anesthetized patients [55], in which rapid measurement of blood pressure is often more desirable, particularly during induction and management of anesthesia.

^a MC: mercury column; AC: arterial catheter.

^b Data quoted for the standing position; grading was the same as for pooled data of three positions (supine, seated, and standing).

^c Data quoted for the three positions of supine, seated, and standing.

^d Efficacy quoted was determined in adult population.

^e Efficacy quoted was determined in neonate and adult populations, respectively.

^f Semiautomatic; all other listed are automatic.

^g Only partially followed AAMI and BHS protocol and only validated one size (median) of three cuffs (small, median, large).

Adapted from Current technologies and advancement in blood pressure measurements-review of accuracy and reliability, *Biomed. Instrum. Technol.*, AAMI, Arlington, VA (publication pending). With permission.

Another variant of the oscillometric algorithm was developed by Protocol Systems [56]. In addition to using pulse amplitude for primary artifact rejection, it further calculated impulse value, a principal area of pulse waveform, in constructing an oscillometric curve. This curve is smoothed by employing a Kalman filter that also provides an expected mean and acceptable upper and lower bounds of prediction for the principal area of subsequent pulse waveform. Smoothing of the oscillometric curve is accomplished by using the difference between the predicted and calculated area data of pulse waveform for each cuff pressure step. Blood pressures are derived from the final smoothed oscillometric curve.

In more recent study, oscillometric algorithms using an artificial neural network have been reported to produce better estimates of reference blood pressures than the standard oscillometric algorithm [57]. By using neural network training and processing, subtle features and nonlinear relationships of the oscillometric envelope have been modeled. Empiricism of the oscillometric fixed fraction criteria is overcome and variances of measurements are greatly reduced.

Because of its low risk and cost, noninvasive continuous blood pressure monitoring represents another need in critical-care monitoring to supplement invasive arterial catheterization. A significant development in this field is the arterial counterpulsation principle, proposed by Penaz [58], and further developed by two major groups of people [59, 60]. Finapres™, a continuous finger arterial blood pressure monitor was engineered and developed by Ohmeda, Denver, CO. Many clinical evaluation reports of these devices have been published since then.

Recently, a number of other continuous blood pressure monitors have been made commercially available. Examples of these are Cortronic APM770 [61], which monitors pulsation of the brachial artery with a slightly pressurized arm cuff and calibrates it to a continuous pressure waveform; Sentinel ARTRAC 7000 [62], which monitors pulse transit time and correlates that to pressure change; Colin CBM-3000 and JENTOW (Colin Electronics, Komaki, Japan) [63, 64] and Nellcor NCAT N-500 (Nellcor, Hayward, CA) [65], which are tonometric devices monitoring the radial artery pulse waveform by a matrix pressure sensor. All of these monitors require a frequent calibration reference. Except for a few favorable reports with the tonometric method and devices, many reports so far are unfavorable. Nevertheless, noninvasive continuous monitoring represents an important and growing field of biomedical sensor and instrumentation research and development. Continuous monitors, which maintain cuff pressure, must periodically relieve pressure to prevent the risk of venous congestion, edema, swelling, and tissue damage.

75.4 Direct Blood Pressure Measurement

Direct measurement is also called invasive measurement because bodily entry is made. For direct arterial blood pressure measurement an artery is cannulated. The equipment and procedure require proper setup, calibration, operation, and maintenance [66]. Such a system yields blood pressures dependent upon the location of the catheter tip in the vascular system. It is particularly useful for continuous determination of pressure changes at any instant in dynamic circumstances. When massive blood loss is anticipated, powerful cardiovascular medications are suddenly administered, or a patient is induced to general anesthesia, continuous monitoring of blood pressures becomes vital.

Most commonly used sites to make continuous observations are the brachial and radial arteries. The femoral or other sites may be used as points of entry to sample pressures at different locations inside the arterial tree, or even the left ventricle of the heart. Entry through the venous side of the circulation allows checks of pressures in the central veins close to the heart, the right atrium, the right ventricle, and the pulmonary artery. A catheter with a balloon tip carried by blood flow into smaller branches of the pulmonary artery can occlude flow in the artery from the right ventricle so that the tip of the catheter reads the pressure of the left atrium, just downstream. These procedures are very complex and there is always concern of risk of hazard as opposed to benefit [67].

Invasive access to a systemic artery involves considerable handling of a patient. The longer a catheter stays in a vessel, the more likely an associated thrombus will form. The Allen's test can be performed by pressing on one of the two main arteries at the wrist when the fist is clenched, then opening the hand to see if blanching indicates inadequate perfusion by the other artery. However, it has proved an equivocal

predictor of possible ischemia [68]. In the newborn, when the arterial catheter is inserted through an umbilical artery, there is a particular hazard of infection and thrombosis, since thrombosis from the catheter tip in the aorta can occlude the arterial supply to vital abdominal organs. Some of the recognized contraindications and complications include poor collateral flow, severe hemorrhage diathesis, occlusive arterial disease, arterial spasm, and hematoma formation [69].

In spite of well-studied potential problems, direct blood pressure measurement is generally accepted as the gold standard of arterial pressure recording and presents the only satisfactory alternative when conventional cuff techniques are not successful. This also confers the benefit of continuous access to the artery for monitoring gas tension and blood sampling for biochemical tests. It also has the advantage of assessing cyclic variations and beat-to-beat changes of pressure continuously, and permits assessment of short-term variations [70, 71].

Catheter–Tubing–Sensor System

A large variety of vascular catheters exist. Catheter materials have undergone testing to ensure that they have a minimal tendency to form blood clots on their surface. The catheter chosen may be inserted percutaneously over a hollow stylet into the blood vessel. Guide wires can be useful to facilitate longer or larger-diameter catheters into vessels, after the guide wires have been placed through a smaller catheter or needle. Less often, entry to a vessel requires a “cutdown,” a direct exposure of the vessel after a skin incision. Ultrasonic devices may assist locating the vessels not readily apparent at the skin surface.

Although pressure sensors can be located at the catheter tip, this presents a problem for calibration if left in place and a clot forms near the tip of the catheter, damping the pressure signal. Instead, most catheters connect to an external pressure sensor via fluid-filled low-compliance tubing. The signal from the sensor then undergoes transformation for display or recording. The sensor may take one of several forms, from a variable resistance diaphragm to a silicon microchip. A basic system can consist of an intravascular catheter connected to a rigid fluid-filled catheter and tubing which communicates the pressure to an elastic diaphragm, the deflection of which is detected electrically. There is a direct relationship between the deflection of the diaphragm and the voltage. The higher the voltage, the greater the pressure. Continuous low-rate infusion of heparinized saline is carried out to keep the catheter patent or free from coagulation. The advent of disposable sensor kits have greatly simplified the clinical use of intravascular monitoring [72]. With the cost continually being lowered with the development of semiconductor industry, disposable sensors become more and more cost-effective.

Although direct recording is considered the most accurate method, its accuracy may be limited by variations in the kinetic energy of the fluid in the catheter or dynamic frequency response of the measurement system. The hydraulic link between the patient and the sensor is the major source of potential errors and hazard for the monitoring. Damping and degrading the system’s natural frequency, caused by trapped air bubbles, small catheters, various narrow connections, compliant and too long tubing, and too many components connected, are the two characteristic problems with a pressure sensor system. Extreme care should be exercised to eliminate all air bubbles from the fluid to provide adequate dynamic response. The sensor should be zeroed at the level of the heart to eliminate hydrostatic error [73]. A fast flush testing is easy to use for inspection of the dynamic response of the whole system of catheter–tubing–sensor. It can also help direct adjustments for the system to minimize dynamic artifacts [74, 75].

75.5 Reproducibility, Accuracy, and Reliability Issues and Recommendations for Corrective Measures

For each blood pressure assay technique, there is an issue of reproducibility of measurements given approximately similar conditions. Reproducibility quantifies the internal uncertainty of an individual method and instrument, whereas accuracy quantifies the external uncertainty when compared with a reference. [Table 75.6](#) presents estimated uncertainties of reproducibility for three blood pressure–measuring techniques: auscultation, oscillometry, and umbilical arterial catheter [50]. When dealing with

TABLE 75.6 Estimated Uncertainties of Reproducibility for Blood Pressure Measuring Techniques of Auscultation, Oscillometry, and Umbilical Arterial Catheter^a

	Auscultation	Oscillometry ^b	Umbilical Arterial Catheter
Neonate			
Systolic pressure (mmHg)	N/A	3.3	2.2
Diastolic pressure (mmHg)	N/A	3.4	1.8
Adult			
Systolic pressure (mmHg)	2.8	3.2	N/A
Diastolic pressure (mmHg)	2.2	3.5	N/A

^a From Reference 50.

^b Evaluated from SpaceLabs Medical Oscillometric monitor [50].

blood pressure measurement, it is important to bear in mind that even for standard methods, there is a certain amount of nonrepeatable random error. Consequently, taking the average of repeated measurements or multiple readings is always advised before any serious recommendation or management is made.

Table 75.7 presents a review of common problems associated with accuracy and reliability in both indirect and direct blood pressure measurements. Consequences of these problems are analyzed and recommendation of preventive action or alternative solutions are provided. Hazard or safety analyses and review are also very important.

75.6 Blood Pressure Impact, Challenge, and Future

Hypertension is one of the most common and important risk factors of health in industrialized countries [82]. It is the leading cause of death in the U.S. It is treatable by a variety of effective medications. It can cause serious damage to the heart and arteries leading to cardiac infarct, stroke, or renal failure. Significant sudden changes in blood pressure may also precede a major physiological catastrophe such as cardiac arrest. There is now almost universal acceptance that basic physiological parameters such as blood pressure should always be monitored in the clinical setting.

There has been increasing interest in automatic blood pressure monitoring devices in recent years and some clinicians are now advising patients to record their blood pressure at home over a period of up to 3 months before starting antihypertensive medication [83]. Self-monitoring of blood pressure has become very common with the development of microchip technology and oscillometric monitors. The patients no longer have to learn how to listen for Korotkoff sounds. This has also removed bias and observer errors, allowing more accurate measurement than by conventional techniques using a stethoscope and a mercury sphygmomanometer [84].

Special populations have unique blood pressure assessment requirements. Newborns require miniaturized equipment. The act of taking a blood pressure in a newborn may stimulate a series of movements causing motion artifact. The very obese may be hard to fit properly with a cuff at the upper arm, if the upper arm is too conical rather than cylindrical. In pregnancy, auscultatory and oscillometric methods, although useful to follow trends, may correspond poorly with central pressures [85] and even the proper Korotkoff sound (IV or V) to designate as diastolic pressure is uncertain [86].

Observing blood pressures has limitations. It may suggest what is happening with blood volume, but sometimes does not reveal that blood volume has become inadequate until circulatory collapse has occurred. Venous and left atrial pressures are often used in an attempt to clarify blood volume problems but with uncertain results [87]. Similarly, a satisfactory blood pressure does not always indicate adequate tissue perfusion. Some medications that increase blood pressure can do so at the expense of general perfusion. Since blood pressure is measured at specific sites in the arterial tree, if circulation has become nonhomogeneous, such as can happen in arteriosclerosis, the region distal to the arteriosclerosis can be compromised without warning from blood pressure readings sampled at another site. Even mean blood pressure, so useful otherwise, can fail in these circumstances.

TABLE 75.7 Common Issues of Accuracy and Reliability in Blood Pressure Measurement and Recommendations of Preventive Action or Alternative Solution in Both Indirect and Direct Measurements

Source	Problem	Result	Recommendation
Indirect Measurement			
Subject	Obesity, peripheral edema, peripheral vascular disease	Weak Korotkoff sounds and diminished sound transmission may reduce the accuracy and reliability of auscultatory measurement; oscillometric measurement may also be affected	Verify with a second indirect method such as oscillometry; direct blood pressure measurement may be elected to use in severe conditions that indirect measurement does not warrant sufficient accurate and reliable measurement
	Shock, severe peripheral vasoconstriction, diminished peripheral circulation resulting from shunting of blood to central organs; Korotkoff sounds and pulses may be absent even in presence of normal pressure [76]	Any of the indirect methods, including auscultatory, oscillometric and Doppler techniques may not provide accurate and reliable reading; indirect measurement may be impossible or may give misleading results	Direct measurement should be considered
	Arrhythmias, respiratory effect	Pronounced variation in beat-to-beat blood pressure and waveform	Take multiple measurements and average
	Subject shivering, pain, anxiety, discomfort, motion artifact	Shivering and motion artifact may cause either false high or false low reading, whereas pain, anxiety, and discomfort may cause false high reading	Minimize pain, anxiety, and discomfort; reduce shivering and movement
	Physical activity within 5 min of measurement; talking, moving, arm unsupported, back unsupported, legs dangling, and any other isometric activities	False high reading that does not reflect subject's resting blood pressure	Subject should rest at least 5 min in the same position that blood pressure is going to be taken; subject should not talk and involve any isometric activities during measurement; arm should be supported at heart level
	Arm supported at above heart level	Hydrostatic pressure causes false low reading by 0.78 mmHg for each centimeter of offset [77]	Support the arm with midpoint of upper arm at heart level
	Arm supported at below heart level	Hydrostatic pressure causes false high reading by 0.78 mmHg for each centimeter of offset	Support the arm with midpoint of upper arm at heart level
	White-coat hypertension during clinical measurement	Psychological or stress response causes blood pressure temporarily elevated and unrepresentative of subject's true condition	Take multiple self-measurements at home or ambulatory monitoring as desired and provide record to care providers
Operator	"Pseudo-hypertension" with calcified or stiffened arteries	Reduced arterial compliance, often occurring in the elderly, causes cuff blood pressure falsely too high or unable to be measured accurately	Use Osler maneuver for screening; direct method is recommended for those who test positive [78,79]
	Hose kinked	Will cause reading error or operation failure	Rearrange hose to avoid kink
	Cuff used too narrow for arm	Will cause false high reading	Select appropriate cuff size that its width encircles 40% of arm circumference
	Cuff used too wide for arm	May cause false low reading; may not fit on arm	Select appropriate cuff size that its width encircles 40% of arm circumference

TABLE 75.7 (continued) Common Issues of Accuracy and Reliability in Blood Pressure Measurement and Recommendations of Preventive Action or Alternative Solution in Both Indirect and Direct Measurements

Source	Problem	Result	Recommendation
	Cuff wrapped too loosely	Will cause false high reading; may introduce artifact of inter cuff–arm abrasion if placed for long-term monitoring	Cuff should be snugly applied; one should not be able to insert two fingers between the cuff and arm for adult
	Cuff wrapped too tightly	May cause false low reading; will restrict and impair limb circulation if placed for long-term monitoring	Cuff should be snugly but not restrictively applied; one should be able to insert one finger between the cuff and arm for adults
	Cuff pressure inflated too high	Patient discomfort; may induce increase in systolic blood pressure during inflation period, so called “cuff-inflation hypertension” [80]	Inflate cuff pressure to 30 mmHg above palpatory blood pressure
	Cuff pressure inflated too low	Will either miss or have false low systolic pressure reading	Inflate cuff pressure to 30 mmHg above palpatory blood pressure
	Cuff pressure deflated too fast	May degrade the accuracy of the reading	Deflate cuff pressure at 2–4 mmHg per heart beat or 3 mmHg/s
	Cuff pressure deflated too slow	May cause discomfort or forearm congestion	Deflate cuff pressure at 2–4 mmHg per heart beat or 3 mmHg/s
	Repeated cuff pressure measurement too frequently	May cause discomfort and forearm congestion	A sufficient time should elapse (at least 60 s) before the next reading to allow the return of normal circulation
	Miss identifying auscultatory gap between systolic and diastolic pressure	Will cause false low systolic or false high diastolic pressure	Listen to Korotkoff sounds carefully for a wide pressure deflation range or use oscillometric method
	Stethoscope head or sensor not over the brachial artery	Will not hear clear sounds or detect sufficient signal for blood pressure determination	Place the stethoscope head or sensor over the brachial artery at least 1.5 cm above the antecubital fossa
	Noise and artifact created by accidentally touching or bumping the cuff, hose, stethoscope, or sensor	May cause inaccurate reading or failure of reading	Avoid incidence of extraneous noise and artifact
Equipment	Leaky hose, bladder/cuff, or pneumatic components	Will cause inaccurate reading or failure in operation	Require service or replace equipment
	Faulty valves	Will cause inaccurate reading or failure in operation	Require service or replace equipment
	Limited selection for different size of cuffs	Will cause false low or false high reading if cuff is too large or too small, respectively	Manufacturer should provide appropriate label/labeling for the intended use and arm size; blood pressure measurement beyond the intended use of the device should be warned against and prohibited
	Device zero-shifted, out of calibration	Will create systematic bias or uncertainty in blood pressure reading	Require routine calibration and maintenance
Direct Measurement			
Subject	Subject position change (e.g., body position change, bed lowered or elevated, etc.) in relation to pressure sensor	Subject heart level change in relation to pressure sensor will introduce bias of hydrostatic pressure in blood pressure recording	Move the sensor zero port to the heart level and zero the sensor/monitor
	Catheter whip in pulmonary artery, catheter impact in aorta or ventricle	Catheter whip can result in superimposed waves of ± 10 mmHg; catheter impact can cause high-frequency transients to occur in waveform [81]	Catheter whip and catheter impact are difficult to prevent; evaluation of pressure waveform and reading should consider the effect of these events

TABLE 75.7 (continued) Common Issues of Accuracy and Reliability in Blood Pressure Measurement and Recommendations of Preventive Action or Alternative Solution in Both Indirect and Direct Measurements

Source	Problem	Result	Recommendation
Operator	Subject severe shivering, pain, anxiety, discomfort, moving	Severe shivering and moving may cause artifact on blood pressure waveform whereas pain, anxiety, and discomfort may elevate blood pressure	Minimize pain, anxiety, and discomfort, reduce shivering and moving
	Tubing kinked	Will change dynamic response of tubing system and distort pressure waveform	Use short and low compliant tubing, and place tubing appropriately to avoid kink
	Sensor zero port higher than heart level when zeroing	Hydrostatic pressure causes false low pressure measurement by 0.78 mmHg for each centimeter of offset	Move the sensor zero port to heart level and zero the sensor/monitor
	Sensor zero port lower than heart level when zeroing	Hydrostatic pressure causes false high pressure measurement by 0.78 mmHg for each centimeter of offset	Move the sensor zero port to heart level and zero the sensor/monitor
	Air bubbles entrapped in the tubing system	Air bubbles will decrease natural frequency and increase damping coefficient; therefore they damp and distort the waveform, causing high-frequency components to loss in pressure waveform	Eliminate air in both tubing system and flush solution bag; light tapping while fluid is filling the tubing system is an effective method for removing air
	Tubing too long, too thin, and with too many components	All of these will degrade the system dynamic response and result in distorted waveform and erroneous reading	Use tubing of large inner diameter, short length, and reduce the number of components as much as possible
	Connectors not tightly connected	Will decrease natural frequency of tubing system and cause pressure waveform to be distorted	Check loose luer-lock connection and cracked connection; replace cracked components and secure tight connection of all components
	Failure to flush the arterial line adequately after blood draw	May cause the catheter tip partially clotted by the blood and pressure waveform over damped and distorted	Flush the arterial line adequately; may need to replace with a new catheter if dynamic response cannot be improved to meet the minimum requirement
	Failure to zero the sensor/monitor after subject position change in relation to pressure sensor	Subject heart level change in relation to pressure sensor will introduce bias of hydrostatic pressure in blood pressure recording	Move the sensor zero port to the heart level and zero the sensor/monitor
	Failure to provide constant infusion of anticoagulation/saline solution	May cause catheter tip partially clotted by the blood and pressure waveform overdamped and distorted	Check the constant infusion device to have sufficient flow rate; flush the arterial line adequately; may need to replace with a new catheter if dynamic response cannot be improved to meet the minimum requirement
Equipment	Failure to test dynamic response at least once a shift and anytime after blood draw or component change	This leaves the system dynamic performance unknown, which may affect the accuracy of systolic pressure the most, diastolic pressure the second; mean pressure is hardly affected	Routinely perform the fast flush test to evaluate the dynamic response visually according to Gardner's chart of natural frequency vs. damping coefficient [73]
	Not equipped with an appropriate flush device	May not be able to generate quality test waveform to evaluate the adequacy of dynamic response of the catheter-tubing-sensor system	Select appropriate flush device that permits fast flush test for the system dynamic response
	Tubing or component not transparent	Unable to see entrapped air bubbles	Use transparent tubing and components

TABLE 75.7 (continued) Common Issues of Accuracy and Reliability in Blood Pressure Measurement and Recommendations of Preventive Action or Alternative Solution in Both Indirect and Direct Measurements

Source	Problem	Result	Recommendation
	Tubing, sensor, or constant flush device too compliant	Will decrease natural frequency of the system and cause pressure waveform to be distorted	Use only high-quality and low-compliance tubing, sensor, and constant flush device
	Stopcocks not tightly sealed	Will decrease natural frequency of the system and cause pressure waveform to be distorted	Replace with tightly sealed, high-quality stopcocks
	Monitor failure to zero the sensor electronically, sensor zero drift, or pressure amplifier zero drift	Will introduce unknown offset or bias in pressure measurement	Require service or replacement of the equipment
	Natural frequency and damping coefficient of the catheter–tubing–sensor system failure to meet minimum dynamic response requirement	Fidelity of pressure waveform recording suffers and accuracy of systolic and diastolic pressure measurement degrades	Need to optimize the catheter–tubing–sensor system by replacing part or all of the components; use low-compliance pressure sensor, tubing, and all other components; use short and large tubing and reduce the number of components as much as possible
	Blood pressure monitor failure to identify special events such as sensor zeroing, fast flush testing, blood drawing, as well as artifacts	Blood pressure monitor displays false digital reading of blood pressure without warning sign or error message	Health care provider needs to exercise care in viewing the digital results with waveform display; quality control or screening process is needed in dealing with monitoring database

Adapted from Current technologies and advancement in blood pressure measurements—review of accuracy and reliability, *Biomed. Instrum. Technol.*, AAMI, Arlington, VA (publication pending). With permission.

In spite of inherent problems, observation of blood pressure through both old and new technologies retains more than enough usefulness to have remained an essential aspect of patient care. The promise of improved technology to solve problems such as those of motion artifacts, noninvasive continuous monitoring, long-distance telemetry, rapid analysis of accumulated or concurrent data, and assessment of new inaccessible regions of blood flow represent continued challenges for future biomedical research and development.

Recently, exciting research has revealed that comparing pressures taken at the arm and the ankle results in a simple but extremely useful index for assessment of lower extremity vascular disease, with implications for general cardiovascular risk factors [88]. The possibility of obtaining noninvasive blood pressures from arteries in the forehead by stick-on oscillometric patches has also been proved. At least in anesthetized patients, the forehead noninvasive blood pressure corresponded reasonably well with central arterial pressures [89]. Finger blood pressure monitors have found some applications in continuous ambulatory and sleep blood pressure assessments [90]. A technology that is capable of continuously monitoring brachial or even central blood pressure continues to be a clinical demand and future challenge.

76.1 Doppler Measurements

Ultrasound Doppler

The ultrasound Doppler measurements [1, 2] are based on a principle discovered by the Austrian physicist Christian Doppler 1842 [3], who theoretically predicted that a wave, backscattered from a moving object, will be shifted in frequency. The principle was verified by two hornblowers, one aboard a moving train and the other standing still, with the ability to assess the pitch of the sound.

To obtain a Doppler signal from a fluid, the fluid must contain scattering particles, which in the case of blood are the blood cells. The size of a red blood cell is about $2 \times 7 \mu\text{m}$, which means that the scatterers are much smaller than the wavelength of the ultrasound. Hence, a diffuse scattering of the ultrasound will occur (Rayleigh scattering). The scattering from tissues surrounding the heart and vessels usually gives a much larger signal (20 to 40 dB) than that from blood in motion. The velocity of tissue motion is usually much lower than that of blood. This contribution can therefore be suppressed by high-pass filtering. In recent years ultrasound contrast agents (consisting of gas-filled shells) have been introduced to increase the blood flow signal. [Figure 76.1](#) illustrates the ultrasound Doppler principle. An ultrasound beam is sent toward a moving object. The beam hits the object and returns to the receiver with a Doppler-shifted frequency carrying information about the velocity of the object.

The Doppler shift f_d of an ultrasound signal with the nominal frequency f_c is given by

$$f_d = 2f_c \cdot \frac{v}{c} \quad (76.1)$$

where v is the velocity component in the direction of the ultrasound beam and c is the speed of sound in the medium which is in the range of 1500 to 1600 m s^{-1} in soft tissue and usually set to 1540 m s^{-1} . The frequency f_c is in the range of 2 to 10 MHz, which gives a wavelength between 0.15 and 0.77 mm.

FIGURE 76.1 For Doppler ultrasound, the moving object shifts the received frequency.

The peak systolic flow velocity in the heart and larger vessels is normally 0.5 to 1 m s^{-1} , resulting in a Doppler shift in the range of 1.3 to 13 kHz (depending on the ultrasound frequency f_c). The Doppler sound is therefore audible, which is helpful for the investigator in identifying vessels and phenomena of interest.

The most straightforward ultrasound investigation is to use a continuous wave system. The ultrasound beam is focused by a suitable ultrasound transducer geometry and by a lens. By this arrangement a narrow beam can be arranged and the backscattered information can come from any section along the beam.

In order to know from where along the beam the blood flow data are collected, a pulsed Doppler system has to be used. The transducer sends four to eight cycles of the ultrasound signal; a specified time later a gate is opened and the transducer will act as a reviewer. By using a preset time delay between the sending and the reviewing signal only flow information from a certain depth will be collected. The depth is obviously determined by the delay time and the propagation velocity in the tissue. Flow velocity information is obtained by spectral estimation of the Doppler signal.

By multirange gating, blood flow at various points along the ultrasound beam can be measured. By scanning with an ultrasound beam within a sector, a two-dimensional velocity field can be presented. By color coding the information a color Doppler flow image can be obtained. By scanning in one additional orthogonal plane, a three-dimensional flow image can be created.

An important medical application of the ultrasound Doppler is in the study of heart valve flow when one might suspect stenosis or leaking flow in the valves. The pumping ability of the heart can be assessed from the general flow patterns. Regions with arteriosclerotic obstructions can be localized in the peripheral vessels.

Laser Doppler Flowmetry

The Doppler principle is also utilized in blood flow measurements in the microcirculatory bed in which laser Doppler flowmetry measures the blood perfusion. Laser light from a gas or semiconductor laser is launched into an optical fiber which leads the light to the tissue. (Figure 76.2). Photons are reflected, scattered, and absorbed in the tissue matrix and those that hit moving red blood cells become Doppler shifted, whereas those that are reflected in stationary structures are refracted without any change in frequency. A part of the photons returning to the fiber-optic system will be conducted by the pickup fiber to the detector. Shifted and nonshifted photons are mixed at the surface of a square-law photodetector. According to elementary wave mechanics this type of mixing (coherent detection) results in the

FIGURE 76.2 For laser Doppler flowmetry, the moving blood cells shift the received frequency.

sum and difference frequencies. The frequency of the “difference wave” is proportional to the average velocity of the red blood cells. The amplitude of the same signal is proportional to the number of moving scatterers in the tissue volume. A velocity distribution will result in a Doppler spectrum, usually in the range of 30 to 12,000 Hz.

Variants of the method utilizing fiber optics, airborne beams, microscope-based setups, and color-coded imaging scanners are described in the literature. For a review, see Shepherd and Öberg [4].

76.2 Indicator Dilution Methods

Cardiac output measurement is one of the most essential heart performance measures. The rest and exercise flows carry important diagnostic information. The monitoring of cardiac output is very important for the critically ill patient.

The principle is that an indicator is injected upstream in the circulation. Mixing with the circulating blood volume occurs and the indicator concentration is detected downstream. By knowing the added

FIGURE 76.3 Indicator dilution measurements. The flow can be calculated if the amount of indicator and the time course of its concentration are known.

quantity of indicator and the time integral of the detected indicator concentration, the flow can be determined (Figure 76.3).

We can subdivide the indicator dilution methods into dye dilution and thermal dilution methods. See Webster [5] and Bronzino [6].

Dye Dilution Method

To determine the cardiac output (l/min) a known quantity (mass m) of a dye indicator such as Evans Blue is injected into the right heart and a concentration of the indicator $c(t)$ is detected in the pulmonary artery. At the time t an indicator quantity Δm passes the detector at a time interval Δt . If F is the blood flow,

$$\Delta m = F c(t) \Delta t \quad (76.2)$$

or by integration

$$F = \frac{m}{\int c(t) dt} \quad (76.3)$$

Thus, only the amount of indicator added and the time integral of the downstream concentration, assuming good mixing, has to be known to be able to calculate the flow, i.e., the cardiac output.

Thermal Dilution Method

The thermal dilution method is a variant of the indicator dilution method family. A thermal dilution catheter is placed with the injection outlet in the right atrium of the heart and with a temperature sensor in the pulmonary artery (Bronzino [6] and Weissel et al. [7]).

A chilled solution of dextrose in water or saline solution is used for the injection and causes transient decrease in the pulmonary artery temperature $T(t)$. The blood flow (cardiac output) can be calculated from

$$F = \int T(t) dt \rho_b c_b = V(T_b - T_i) \rho_i c_i K \quad (76.4)$$

or

$$F = \frac{V(T_b - T_i)}{\int T(t) dt} (\rho_i c_i / \rho_b c_b) K \quad (76.5)$$

where V is the injected volume, T_b the undisturbed temperature in the pulmonary artery, T_i the temperature of the indicator, ρ_i and ρ_b the density of the indicator and the blood, c_i and c_b the specific heat of the indicator and the blood and K is a correction factor that takes heat transfer along the catheter into account.

The thermodilution technique is the standard technique for the monitoring of cardiac output in critically ill patients.

76.3 Plethysmography

The word *plethysmography* means methods for recording volume changes of an organ or a body part. Depending on the technique used, strain gage, impedance, and optical techniques can be used for the volume determination. See Webster [5] and [Figure 76.4](#).

Strain Gage Plethysmography

The classical strain gage plethysmography is used to study circulation in the lower extremities from changes in the circumference of the legs.

Small-diameter silicone rubber tubes, filled with mercury or other types of conductive liquids, are placed around the circumference of the leg. Changes in the latter can be directly related to electrical impedance changes of the silicone rubber tube. If a cylindrical cross section of the leg is assumed, volume changes should be proportional to the total circumference, times the change in impedance.

The strain gage tubes ([Figure 76.4](#)) are positioned around the lower part of the leg, an inflatable cuff is placed around the upper part (above the knee) and inflated to 40 to 50 mmHg, i.e., above the venous pressure that will cause the outflow of blood to cease. The increased volume of the leg is therefore proportional to the arterial inflow. The latter is determined from the initial slope. Flow is volume increase per time unit.

When the cuff pressure is released, blood will flow out from the leg via the veins. The time course of the volume change will be related to venous function. If there is venous thrombosis, the decline in the volume curve will be slower.

Impedance Plethysmography

Bioelectric impedance measurements have a history dating back to the 1940s. The reason impedance is useful for detection of volume changes is that different tissues in the body have different resistivity. Blood is one of the best conductors among the tissues of the body.

Impedance plethysmography has its most established applications in respiratory monitoring in newborn infants and for detection of venous thrombosis. Less-established applications are cardiac output measurements, peripheral blood flow studies, and body composition assessments.

A constant current with a frequency of 50 to 100 kHz and an amplitude of 0.5 to 4 mA rms is applied via skin electrodes ([Figure 76.4](#)). Influences from skin impedance are eliminated by the use of the four electrode technique.

FIGURE 76.4 For occlusion plethysmography, increased volume stretches the strain gage (top) and decreases the impedance (bottom).

The measurement object can be described with a conduction object with the constant impedance Z_0 in parallel with a time-varying impedance ΔZ . The impedance ΔZ is represented with a column of a conducting media with resistivity ρ and the length L . If the changes in ΔZ are small in comparison to those of Z_0 , the volume changes can be obtained as:

FIGURE 76.5 For photoplethysmography, increased blood decreases received light in (a) transmission mode and (b) reflection mode.

$$\Delta V \approx \rho \frac{L^2}{Z_0^2} \Delta Z \quad (76.6)$$

This technique can be used in the same way as the strain gage plethysmographic method to study circulation in the leg.

For the measurement of cardiac output, Equation 76.6 or a modified formula can be used [8]. The method seems to work rather well in normal persons for relative change, but for patients with cardiac disease the cardiac output estimation might be poor.

Photoelectric Plethysmography

Hertzman and Spealman [9] and Hertzman [10] were the first to use the descriptive term *photoelectric plethysmography* (PPG). The first reports on the successful use of the principle were published in the middle of 1930 by Molitor and Kniazuk [11]. The principle on which PPG is based is simple, although the underlying detailed optical mechanisms remain unknown. A beam of light is directed toward the part of the tissue in which blood flow (or volume) is going to be measured. (Figure 76.5). Reflected, transmitted, and scattered light leaving this volume is collected and focused on a photodetector. A signal modulated by the attenuation or scattering of light in the blood volume can be recorded. Two different components can be derived from the detector. One is pulsatile and synchronous with the heartbeat (the ac component), the other is a constant voltage (the dc component). The physiological significance of the two signals is still under debate, but they reflected the blood volume and the orientation of erythrocytes during the cardiac cycle.

PPG has been used mainly for monitoring blood perfusion in skin, venous reflux conditions, and skin flaps during plastic surgery. Challoner [12], Roberts [13], and Bernstein [14] have reviewed the methodology and applications of PPG.

76.4 Radioisotopes

Kety [15] introduced the principle of tissue clearance of rapidly diffusing inert isotopes for blood flow measurements. An extensive theoretical treatment is given by Zierler [16]. In most applications, lipid-soluble gases like ^{133}Xe and ^{85}Kr have been used. These isotopes rapidly diffuse from blood to tissue and

FIGURE 76.6 For isotope measurement of microcirculatory blood flow, radioactivity decreases with washout.

a rapid equilibration of the isotope concentration within a tissue volume takes place. Figure 76.6 illustrates the measurement principle. Their elimination from a microcirculatory bed is related to the blood flow rate. If the tissue is uniformly and constantly perfused, the activity of the isotope decays monoexponentially with time. The elimination of the isotope can be described by the equation

$$C(t) = C_0 \exp(-kt) \quad (76.7)$$

where $C(t)$ and C_0 are the tissue concentrations at times t and at the onset of the injection C_0 . k is the clearance constant related to the local blood flow by the relation

$$k = \ln 2 / t_{1/2} \quad (76.8)$$

in which $t_{1/2}$ is half the time of decay. Blood flow Q (in $k \cdot s \cdot 100 \text{ ml} \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$) can then be derived from the formula

$$Q = k \cdot s \cdot 100 \quad (76.9)$$

where s denotes the tissue–blood partition coefficient. The indicator is administered via an injection into the tissue volume, or through passive diffusion after deposition on the surface of the tissue volume under study.

The advantage of clearance methods is that they can be applied to the study of all kinds of tissue blood flow problems. One of the disadvantages is that the method does not give a continuous measurement of flow. In addition, the clearance curves are sometimes difficult to interpret. The trauma caused by injection of the isotope into the tissue seriously disturbs the flow, as shown by Holloway [17] and Sejrsen [18]. In spite of these shortcomings, the isotope clearance method has been applied extensively to the study of skin and tissue blood flow in experimental as well as clinical problem areas.

76.5 Thermal Convection Probes

Thermal convection probes have been developed specifically for skin blood flow measurements. Gibbs [19] pioneered the field by describing a probe in the form of a needle. Hensel and Bender [20] and van

FIGURE 76.7 For thermal convection measurement of blood flow, heat dissipation increases with blood flow.

de Staak et al. [21] developed noninvasive variants by designing probes that can be positioned at the surface of the tissue.

All methods measure the rate of removal of heat from the tissue volume under the probe. A relation exists between the blood flow rate and the rate by which heat dissipates from the tissue volume under study. The sensing unit is usually designed around a central metal disk and a concentric outer ring between which a temperature difference is established. (Figure 76.7). The two rings are thermally and electrically isolated from each other and both are in contact with the tissue. The temperature difference between the two rings is a measure of the blood flow under the probe.

A temperature difference of 2 to 3°C is usually established between the inner disk and the outer annulus. The central disk is heated with an electric current and kept at a constant temperature that only by 1 or 2°C exceeds the resting temperature of the tissue under study. Thermal probes have not been extensively used because of their extreme nonlinear properties and the difficulties in their practical use, i.e., the contact pressure sensitivity. Another difficulty is the highly variable thermal characteristics of the skin.

77.1 Ventilation

This section deals mainly with **spirometry**, i.e., with the measurement of volumes and flows associated with respiration. Spirometric tests (which embody useful information about parameters related to pulmonary function) are often used for diagnostic purposes in conjunction with other measurements; [Figure 77.1](#) and [Table 77.1](#) show spirometric quantities of clinical interest [1].

The classification of spirometric instruments may be based on different criteria. For example, one may consider *open-circuit* devices (the subject takes a full inspiration or expiration before connecting to the meter) and *closed-circuit* devices (the subject remains connected to the apparatus during one or several respiratory cycles). Another distinction concerns whether the instrument is a *portable* one and is mainly used for monitoring purposes or is a *diagnostic* one whose purpose is to provide an accurate value that may be compared with a reference value. As for the nature of the physical functions more directly investigated, a subdivision into *volume measurements* and *flow measurements* is important, even though, using some care, it is sometimes possible to shift from one class to the other by time-differentiation or time-integration procedures. Another technique deals with the direct evaluation (as a function of frequency) of the complex impedance of the respiratory system viewed as a suitable network of resistors, capacitors, and inductors. This method has been the subject of considerable investigation in the last two decades, thanks to the advent of computers and to their use in the spectral analysis of signals. This topic will be discussed in the final section.

As a general comment about measurements associated with ventilation, it may be said that there are few other fields in applied science where a correct *operation procedure* is virtually as important as the reliability of the measuring instruments themselves. See, for example a study conducted on nearly 6000 patients affected by some airflow obstruction (Reference 2 and references therein, especially n. 26).

Volume Measurements

In this case, gas volumes associated with the respiratory process are the main target of investigation; the principal instruments that have been used so far in the clinical routine and in research activity are [3]

FIGURE 77.1 Spirometric trace illustrating the definitions of some significant quantities commonly evaluated in spirometry (see also Table 77.1).

TABLE 77.1 Common Spirometric Quantities

Vital capacity	VC
Inspiratory capacity	IC
Inspiratory reserve volume	IRV
Expiratory reserve volume	ERV
Tidal volume	TV
Functional residual capacity	FRC
Residual volume	RV
Total lung capacity	TLC

1. *Spirometer*: An expandable chamber whose volume is monitored during inspiration or expiration. The subject is instructed to blow into a conduit communicating with the chamber; the latter may consist of a bell, a piston, or more often a bellows (as in the once ubiquitous Vitalometer®).
2. *Turbine meter*: Based on the principle that air blown through the inlet produces the rotation of a turbine connected to a revolution counter.
3. *Impedance plethysmograph*: Based on the measurement of resistance (*strain gage plethysmograph*) or of inductance (*inductance plethysmograph*); in both cases, the impedances of an elastic coil wrapped around the subject's chest and one wrapped around the subject's abdomen are monitored during respiration.
4. *Total body plethysmograph*: A kind of sealed telephone booth inside which the subject sits; the pressure inside the box is sensed and converted to volume values.

Flow Measurements (Pneumotachometry)

In this case the airflow through the upper airways is directly measured; in principle, the flow could be evaluated by time differentiating the spirometer records, but this method would suffer from limitations due to nonlinearity effects and to errors related both to poor frequency response and to some hysteresis of the volume meter. The reverse procedure is in fact more common: since they are normally connected to an electronic integrating device, flowmeters can be employed as volume-measuring instruments as well. Calibration is normally performed by discharging a syringe (of known capacity) through the flowmeter; the response of the latter is time integrated to check whether it corresponds to the calibration volume. It is convenient to repeat the calibration procedure a few times, with the syringe discharged each time at a different speed, in order to detect possible effects due to deviations from linearity of the flow sensor.

A useful summary of standard specifications governing the performance of several types of pneumotachometers (PTM) together with a concise description of the more common PTM types can be found in Reference 4. Conventional devices for measuring respiratory flow are

1. *Linear Resistance* PTM (LRPTM): Evaluates the pressure difference generated by the (laminar) airflow across a fixed hydrodynamic resistance. This procedure is based on the Poiseuille equation and is analogous to evaluating current by measuring voltage across a known resistor and using Ohm's law. The resistive element may consist either of a bundle of tubelets (Fleisch-type) or of a wire mesh screen (Lilly-type).
2. *Hot Wire* PTM (HWPTM): A very thin wire heated by an electric current, cooled by the flowing gas; the rate at which heat is conveyed away from the wire depends on the fluid flow; a variant of this instrument uses a heated film in lieu of the heated wire.
3. *Ultrasonic* PTM (UPTM): Based on the principle that the speed of a beam of ultrasounds exchanged between a pair of transducers is increased or decreased as it propagates through the moving air; the variations of the time of flight of the ultrasonic beam is related to the average speed of the flowing air.
4. *Vortex-Shedding* PTM (VSPTM): Basically measures the frequency at which vortices are generated in the wake of a suitably shaped obstacle (the "bluff body") exposed to the flow.

Respiratory Impedance Measurements

In recent years, considerable interest has been devoted to the impedance of the respiratory system, a parameter that contains information about the morphology of our breathing apparatus and plays a role analogous to the impedance of an electrical circuit. **Respiratory impedance** may be obtained by connecting the patient's upper airways to an alternating pressure generator and by evaluating the ratio of the measured pressure to the measured flow; this can be done at several excitation frequencies, using a method that is referred to as the forced oscillation technique.

77.2 Instrumentation: Principles and Description

Measurements of Volume

Spirometer

A widely used spirometer is the bell-type (see [Figure 77.2](#)): the volume of the lungs is monitored by the position of a light cylindrical bell (possibly equipped with counterweights) connected to the patient's mouth. The bell spirometer is rather cumbersome but, thanks to its great reliability, is an ideal tool for calibration purposes as well as for comparing data recorded at different centers. In its turn, the bell spirometer needs periodic calibration at least every 3 months; this may be performed by means of a 3-L syringe equipped with electronic volume readout [5]. The syringe must be accurate to within 25 mL and the spirometer should be able to measure volumes of at least 8 L with an accuracy of at least $\pm 3\%$ or 0.050 L, whichever is greater, with flows between zero and 14 L/s [6].

Turbine Meter

Its operating principle is quite straightforward. The revolutions of the turbine wheel, whose speed is proportional to the flow, are counted by electronic sensors (optoelectronics or Hall effect based) and processed to give volume or flow values. The main limitation of the turbine meter is that low flow values are underestimated since a greater fraction of the air slips past the wheel as the flow rate decreases; it also displays poor frequency response and can be used only in unidirectional flows. Although these features make the device unsuitable for accurate laboratory measurements, it is used extensively to monitor the ventilation of patients in intensive care and in portable instruments, thanks to its overall (sensor and pulse processing) simplicity and low cost.

FIGURE 77.2 Schematic view of the classical bell spirometer.

Inductance Plethysmograph

Like the spirometer, the pneumotachometer, and the total-body plethysmograph, this technique allows for noninvasive monitoring of human ventilation but it does not require a connection to the airways. Two elastic belts with serpentine inductors encircle the torso, the first around the rib cage, the other around the abdomen. Each inductor is part of the resonant tank circuit of a free-running oscillator (resonant frequency from 0.2 to 1 MHz) whose output is optically coupled to the demodulator circuit (for the purpose of electrical isolation of the subject from the equipment, usually operated by the ac power line). Ventilation causes the inductor cross section areas to vary changing their inductances and thus varying the frequency of the two oscillators (FM modulation).

Strain Gage Plethysmograph

Its principle of operation is similar to that of the inductance plethysmograph; in this case, the sensing element consists of a strain gage whose resistance is varied as the gage is stretched and released during respiration.

Total-Body Plethysmograph (Constant-Volume Box)

This is a sealed chamber that allows the measurement of thoracic gas volume (TGV) by exploiting the pressure–volume relation of a fixed quantity of ideal gas. A schematic illustration of the method for a constant-volume plethysmograph is shown in [Figure 77.3](#). The balloon-shaped object represents the subject's respiratory system, the volume of which varies during breathing. In the course of the measurement operation (which lasts only a few seconds), the shutter appearing in [Figure 77.3](#) must remain closed in order that the alveolar pressure may be identified with the pressure measured at the mouth. In the following, the subscript *A* (for alveolar) denotes the gas in the lungs and the subscript *C* denotes the gas in the chamber.

For moderate respiratory acts, the air contained in the lungs at a given time can be treated as an approximately isothermal gas (temperature 37°C, water vapor saturated) while the air in the chamber is more appropriately treated [1] as an adiabatic gas. By differentiating the ideal gas equation for the isothermal air in the lungs,

FIGURE 77.3 The respiratory system of a patient sitting inside an airtight chamber is schematized as an expandable balloon. The quantities of air inside and outside the balloon are separately constant: only their volumes and pressures change as the subject attempts to breathe against the closed shutter.

$$V_A = -P_A \frac{\Delta V_A}{\Delta P_A}$$

while for the adiabatic air in the chamber,

$$\Delta V_C = -V_C \frac{\Delta P_C}{\gamma P_C}$$

where γ is the usual ratio between molar heat capacities: $\gamma = c_p/c_v$.

Since the system is globally closed ($\Delta V_A = -\Delta V_C$), the lung volume V_A is related to the alveolar pressure P_A (which is taken to be the barometric pressure minus the water vapor pressure at 37°C) and to the differential pressures ΔP_C and ΔP_A (respectively equal to the chamber pressure fluctuation and to the alveolar pressure fluctuation) by the formula:

$$V_A = k P_A \frac{\Delta P_C}{\Delta P_A}$$

The coefficient k can be obtained through a calibration procedure that creates sinusoidal volume variations by means of a reciprocating pump. The pressure changes appearing on the right-hand side of the last equation may be measured by sending the outputs of the two sensors of Figure 77.3 to a data acquisition module installed in a host computer, typically a personal computer.

Correcting to Standard Conditions

Measurements of gas volumes make reference to lung BTPS (body temperature and pressure, saturated with water vapor) conditions. Volume measurements (V_A) made at ATP (ambient temperature and pressure) conditions should be corrected to BTPS conditions (V_B).

When bell or bellows spirometers are employed, the following formula [1] is often used:

$$V_B = \frac{310.2 (P_B - P_W)}{(273.2 + t) (P_B - 6.3)} V_A \quad (77.1)$$

where t = inside gas temperature ($^{\circ}\text{C}$), P_B = barometric pressure (kPa); P_W = saturated water vapor pressure (kPa) of the gas. The temperature t of the air inside the spirometer should be measured accurately during each breathing maneuver (Table 3 in Reference 7).

Measurements of Flow

Linear Resistance Pneumotachometer

The standard LRPTM contains the following elements (Figures 77.4a and b):

1. A fixed resistive load;
2. A differential pressure sensor;
3. Electronic instrumentation for processing and displaying the output of the pressure sensors.

The relationship between flow rate and pressure difference should be linear within the range of useful flow rates; the maximum flow value, determined by the onset of turbulence, and the linearity range are given by the manufacturer's specifications.

It is good practice to calibrate the PTM periodically, by connecting it in series with a bell spirometer, and then use it without changing the geometry of the immediately adjacent tubing. In fact, accurate flow rate measurements are possible only if information about the flow–pressure characteristics over the useful flow range is available; furthermore, this information should have been obtained in the same conditions in which the flowmeter will be used [8].

Figure 77.4(a) depicts the Fleisch PTM, whose resistive element consists of a bundle of capillary tubes. The function of the heater is to avoid the condensation of water vapor inside the tubes; the two chambers of the differential pressure sensor are connected at the two ends of the resistive element, whose resistance is lower than 0.1 kPa s/L (1 cm H₂O s/L). Since typical spirometric flows, for quiet breathing and slow maneuvers, are of the order of 1 L/s, they generate pressure differentials of about 1 cm H₂O. Considerably stronger flows, exceeding 10 L/s, may be produced by adults in some maneuvers; in these cases, Fleisch PTMs of larger dimensions should be employed in order to keep the spirometric flow within the linearity regime.

Figure 77.4(b) illustrates the Lilly PTM, whose resistive element consists of a wire mesh and is of the order of 0.05 kPa s/L (0.5 cm H₂O s/L) to which pressure differentials of the same order as the Fleisch are associated. The Lilly PTM is much less exposed than the Fleisch to the risk of nonlinearity at higher flow rates.

The linear resistance PTMs, in conjunction with an appropriate differential pressure transducer, an amplifier, and an analog or, more often, digital integrator, form the most widely used instrument for the combined measurement of flow and volume. In fact, recent recommendations on the standardization of lung function tests are limited to Fleisch and Lilly tachometers only [1].

Hot Wire Pneumotachometer

The HWPTM works on the principle that the cooling rate of a heated wire depends on the speed at which the surrounding fluid is flowing [9-11]. The rate at which thermal energy is lost by the wire may be written as

$$Q = hS(T_w - T) \quad (77.2)$$

where Q is the heat transfer rate; S is the surface area of the wire; T_w is the wire mean temperature; T is the temperature of the fluid surrounding the wire; h is the transfer coefficient between sensor and fluid and is defined by the equation above.

FIGURE 77.4 (a) The Fleisch (capillary) pneumotachograph. (b) The Lilly (wire-mesh screen) pneumotachograph. In both sensors, the task of the heater is to reduce water vapor condensation.

The speed v of the fluid is linked to h by an important empirical relation whose analytical form has withstood the test of time; however, owing to the complexity of the formula and to the number of physical quantities involved in it, it is convenient to make direct reference to Reference 11 where all necessary details can be found.

It is wise to remember, in fact, that from the operational point of view the last word on these instruments is always entrusted to a sound calibration procedure.

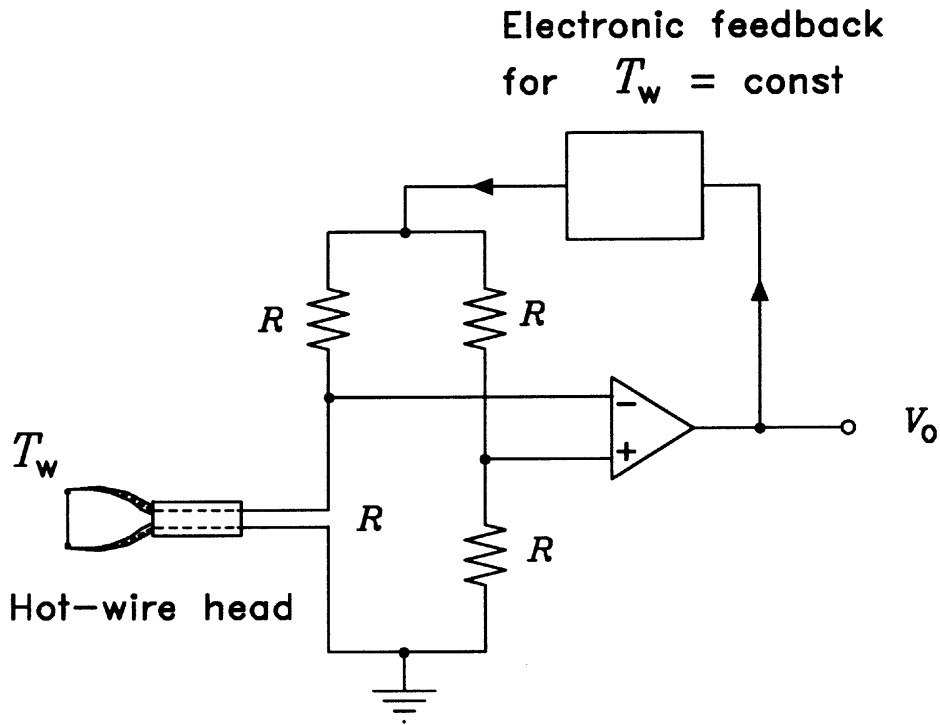

FIGURE 77.5 Block diagram of the constant-temperature hot-wire flowmeter. The electronic feedback system allows one to maintain the sensing wire temperature constant.

For spirometric purposes, it is recommended to use the HWPTM in the *constant temperature* mode of operation, according to the diagram of [Figure 77.5](#).

Using a suitable feedback system the current is adjusted so as to maintain the wire temperature (hence, its resistance) at a constant value through the entire range of velocities allowed by the flowmeter. Once this condition is satisfied, the output voltage value is a measure of the heat transfer rate. The constant-temperature design has several advantages, e.g., the wire is protected against burnout and it is easy to compensate for environment temperature change either by using a temperature-sensitive element in the bridge or by measuring the actual temperature and correcting the results.

Accurate measurements require periodic calibration procedures (for example, using the syringe mentioned in connection with the spirometer) because dirt accumulating on the wire may significantly alter the heat transfer coefficient; it is easy, however, to remove dirt thoroughly from the sensor by manually superheating the wire for a few seconds or by immersing the sensor head into a suitable cleaning liquid. The calibration procedure should be repeated at intervals comparable to those of the LRPTM.

The setup in [Figure 77.5](#) measures only unidirectional flows.

Hot-Film Pneumotachometer

More recently, hot-film PTMs have been developed which can be used in place of the hot wire, the rest of the PTM remaining unchanged. The sensing element is deposited onto a nonconducting support (quartz) by vacuum sputtering, which ensures uniform thickness (about $0.1 \mu\text{m}$) of the sensing element (platinum or nickel). In these sensors, heat can be conducted through the substrate and lost by convection to the ambient gas. The length-to-diameter ratio of the sensor is smaller; consequently, the temperature distribution along the sensor is less uniform. These drawbacks, which are more theoretical than real since calibration is always necessary, are largely compensated for by a lower fragility and sensitivity to particulate contamination.

FIGURE 77.6 Transit time ultrasonic pneumotachograph. Owing to the large Q factor of the resonators, the central resonant frequencies of the two piezoelectric crystals should closely match.

Ultrasonic Pneumotachometer

The basic working principles of UPTMs [10] are (1) sound is sped up or slowed down as it propagates through a moving medium, (2) the back and forth transit time of a sound signal is related to flow velocity and turns out to be largely independent of the acoustic velocity of the medium. UPTMs can be classified according to whether they use *pulsed* or *continuous* ultrasound signals.

In the first case, the transmitter is driven by a short pulse of sine waves; the round-trip transit time of individual pulses or sequences of pulses is measured.

In the second case, a continuous ultrasonic signal is transmitted along a closed path and either the phase shift or the frequency shift is measured. As a specific example, a pulsed transit time UPMT (Figure 77.6) is described.

Two piezoelectric crystal transducers are recessed into the wall of a conduit at an angle ϑ to the flow axis. Provisions are made in order to reduce the level of acoustical and electromagnetic external interferences. Moreover, moderate heating (at about 40°C) prevents water from condensing on their surfaces. The two devices are made to function alternately as transmitter and receiver of a short burst of 50 to 200 kHz sound wave.

With no gas flowing through the conduit, the time required for sound transmission in either direction is the same. When gas is flowing, the two times are, respectively,

$$t_{12} = L / (c + v \cdot \cos \vartheta) \quad t_{21} = L / (c - v \cdot \cos \vartheta)$$

where L is the transmitter–receiver distance and c is the speed of sound.

The gas velocity v turns out to be independent of the actual value of c (which in turn depends on the gas type and on the working conditions and can range from around 200 m s^{-1} to nearly 1000 m s^{-1}); an expression for v is easily obtained from the last equations by assuming $c^2 \gg v^2$

$$v \approx \frac{L}{2 \cos \vartheta} \cdot \frac{\Delta t}{t_a^2} \quad (77.3)$$

where $\Delta t = t_{21} - t_{12}$ and $t_a = (t_{21} + t_{12})/2$.

FIGURE 77.7 A vortex shedding flowmeter equipped with an ultrasound vortex sensor. Vortices generated by the bluff body are sensed by the ultrasonic beam located downstream. In the optical model, the functions of vortex generation and counting are both taken on by an optical fiber.

The flowmeter measures the average flow velocity of the gas along the path of the ultrasound beam.

In using the UPTM it should be remembered that the working frequency is very close to the resonant frequencies of the two crystals which should be closely matched: small differences would cause a strong reduction of the instrument sensitivity owing to the sharpness of the resonance curves.

Vortex-Shedding Pneumotachometer

When the Reynolds number is sufficiently high, vortices of regular periodicity are born downstream of a bluff body located in the fluid flow (see Figure 77.7).

The frequency at which these eddies are generated is a linear function of flow velocity and depends weakly on the dimensionless Strouhal number [12,13]. Different types of VSPTMs use different methods for measuring the vortex frequency; to this end, ultrasonic beams and optical fibers are widely employed.

Ultrasonic: An acoustic beam (Figure 77.7) is sent across the flow by an ultrasound transmitter located on one side of the tube (downstream of the bluff body); an ultrasound receiver is located on the opposite side of the tube. In this case, eddies generated by the bluff body act as modulators of the sound wave intensity. By doubling the setup [13] the ultrasonic VSPTM can also be used for bidirectional flows.

Optical fiber: In this model, an optical fiber is stretched across the tube and acts both as the bluff body and the vortex frequency sensor [14]. The light from an LED enters the fiber at one end, the other end being coupled to a photodiode. The intensity of the light propagating through the fiber is modulated by the mechanical vibrations of the fiber produced by the eddies moving with the fluid and fluctuates in step with the vortex generation frequency.

Both in the ultrasonic and the optical fiber VSPTM, the fluctuating intensity of the beam (respectively, sound and light) is processed to output a flow indication.

The main limitation of all types of VSPTMs is a “blind zone” at low fluid flows corresponding to the absence of vortices at low Reynolds numbers. In compensation, these devices are quite insensitive to the thermodynamic conditions of the gas and to the presence of particulate matter. Similarly to the case of HWPTMs, the last word on VSPTMs is entrusted to a sound calibration procedure.

Measurement of Volume Using a PTM Plus an Integrator

Another kind of plethysmograph can be built by combining a PTM and a digital integrator that calculates volume as follows:

$$V(\tau) = \int_0^{\tau} \dot{v}(t) dt \quad (77.4)$$

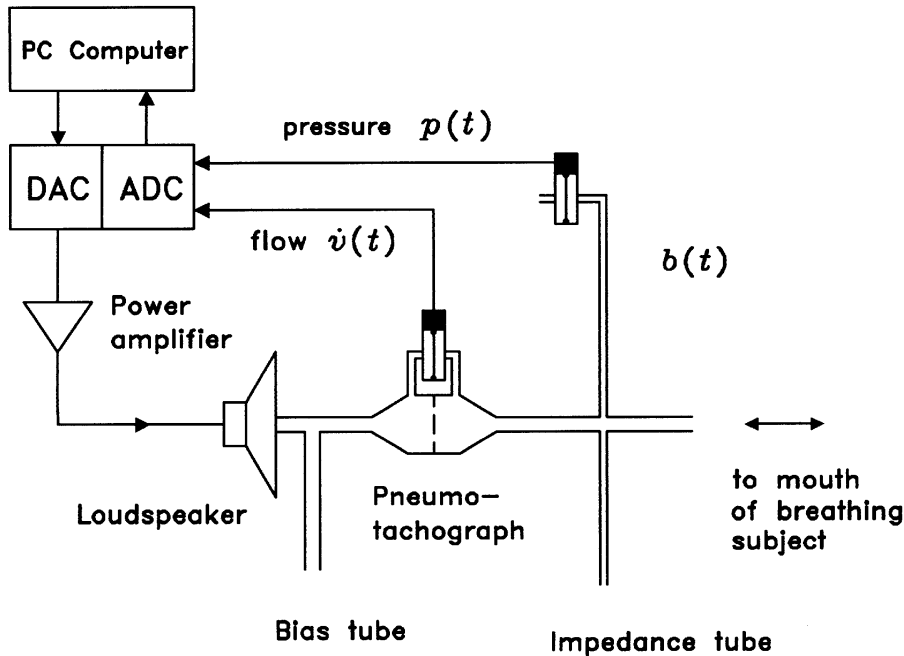

FIGURE 77.8 Experimental setup for the computer-based measurement of respiratory input impedance.

where $\dot{v}(t)$ is the instantaneous flow. The problems exhibited by this kind of instrument are the same as those of the PTM around which it is built, since the process of integration is invariably digital; moreover, correction to BTPS requires considerably more care [1]. Finally, when a heated PTM is employed, correction to BTPS is often done by assuming instantaneous thermalization of the gas within the tachometer (this means that the gas passing through the instrument assumes completely and without delay the same temperature of the tachometer [1]); this assumption may be quite unrealistic, especially in the case of the wire mesh screen type. The correction should thus be different for different types of PTMs.

The Forced Oscillation Technique

The forced oscillation technique (FOT) is a modern tool [15] used to gain information on the structural and mechanical properties of the respiratory system by measuring how the latter responds to an externally imposed excitation. When linearity is assumed, well-known correlation techniques (borrowed from conventional signal analysis) can be exploited to measure the system complex impedance $Z_R(f)$, which is defined as the ratio of complex input pressure difference to complex output flow (i.e., the ratio of amplitudes and the difference of phases) and is equal to the inverse of the system transfer function $H_R(f)$.

Depending on the part of the respiratory system actually investigated, i.e., on the positions where the excitation pressure difference is applied and the flow is measured, different values for $Z_R(f)$ can be obtained:

- *Input impedance:* Both the excitation pressure (measured relatively to the pressure on the body) and flow are measured at the mouth;
- *Transfer impedance:* The excitation pressure is measured at the mouth, whereas flow is measured at the thorax (or vice versa) by means of a body plethysmograph.

An experimental setup for the measurement of respiratory input impedance is shown in [Figure 77.8](#). A suitable software provides

- Generation of a pseudorandom sequence (typically obtained by summing the first 25 harmonics of 2 Hz with random phases) which, after digital-to-analog conversion and proper power amplification, drives a large (20 to 30 cm diameter) loudspeaker;

FIGURE 77.9 The respiratory system modeled in the frequency domain.

- Acquisition of two blocks of pressure and flow samples: 2×4096 data are collected in a 16-s run at a sampling rate of 256 sample/s;
- Processing of data in order to obtain the desired $Z_R(f)$ function in the typical interval 2 to 48 Hz.

The bias tube allows a flow of fresh air to be drawn through the system to minimize rebreathing of expired air. The impedance tube (2 m long, 2 cm diameter) allows spontaneous breathing; moreover, because its electrical equivalent is an inductor, it acts like a shunt for the low-frequency breathing components, thus reducing their level of disturbance on the pressure and flow measurements (noise), without affecting in a significant way the imposed pressure input (signal).

The respiratory apparatus is modeled as a system whose input is a random noise pressure $p(t)$ and whose output is a flow signal $\dot{v}(t)$, both corrupted by a breathing disturbance $b(t)$ uncorrelated to $p(t)$. Any text on random signal analysis [16] may provide useful information on the mathematical quantities employed in this section.

Using the following Fourier transform (FT) quantities:

- $P(f)$ = FT of the random noise pressure input $p(t)$
- $B(f)$ = FT of the subject's breathing noise $b(t)$
- $\dot{V}(f)$ = FT of the linear system output $\dot{v}(t)$

we have (Figure 77.9)

$$\dot{V}(f) = P(f) \cdot 1/Z_R(f) + B(f) \quad (77.5)$$

A valid estimate of $Z_R(f)$ cannot be obtained from this relation because of the presence of the large breathing disturbance. According to the theory of signal processing, a nonbiased estimate of $Z_R(f)$ can be obtained by using autospectra and cross spectra of input $[p(t)]$ and output $[\dot{v}(t)]$ signals; if $G_{pp}(f)$ and $G_{\dot{v}\dot{v}}(f)$ the autopower spectrum of pressure and flow, and $G_{\dot{v}p}(f)$ their cross power spectrum, the estimated impedance $Z_M(f)$ becomes

$$Z_M(f) = \frac{G_{pp}(f)}{G_{\dot{v}\dot{v}}(f)} = \frac{G_{pp}(f)}{\frac{1}{Z_R(f)} \cdot G_{pp}(f) + G_{BP}(f)} \quad (77.6)$$

which becomes almost coincident with the true value $Z_R(f)$ when a long time average allows sensible reduction of the contribution of the $G_{BP}(f)$ term.

Moreover, since the systematic bias depends mainly on the presence of the breathing noise on both pressure and flow signals, all efforts should be made to reduce this disturbance as early as possible, i.e., at the sensor level. This is achieved by using the impedance tube and by keeping the value of the pneumotachograph impedance as low as possible. Further reduction is usually obtained by high-pass

analog filtering (2 Hz corner frequency) before the ADC and/or by digital filtering before FFT calculations. It is worth noting that the choice of a pseudorandom excitation makes possible the use of a digital comb filter (a multiple narrow bandpass, i.e., a bandpass for each 2 Hz harmonic) [17].

When the FOT is used, it is necessary to ascertain that the coherence [16] between input and output, expressed by the γ^2 function defined below, is sufficiently large:

$$\gamma^2(f) = \frac{|G_{VP}(f)|^2}{G_{VV}(f) \cdot G_{PP}(f)} \quad (77.7)$$

As a rule of the thumb, the calculated $Z_R(f_0)$ (the impedance for a particular value of frequency) is accepted only when the corresponding $\gamma(f_0)$ is larger than 0.9 to 0.95.

Actually, the value of $\gamma(f)$ is the only form of control used; at any rate, some care should be taken to interpret the coherence function as an index for the reliability of respiratory impedance data [18, 19]. Obviously, higher values of the coherence function can be achieved by increasing the pressure input amplitude, but this may lead to an increase of nonlinearity effects [20].

In conventional setups, flow is evaluated by measuring the pressure drop ΔP that develops across the pneumotachograph, whose impedance is known and usually small with respect to the subject's input impedance Z_R . Since these two impedances are in series, the differential pressure ΔP measured by the pressure sensor is small compared with the pressure P applied to both sides of the transducer. Accurate measurements then require the use of highly symmetric sensors [21], where symmetry is expressed by the value of the common-mode rejection ratio, $CMRR = 20 \log P/\Delta P$. In addition to this, however, other sources of error (such as the finite impedance of pressure sensors [22]) are usually present which render the correction procedure ineffective.

All these problems can be globally overcome by the following dynamic calibration procedure [23] that requires two simple preliminary measurements and the availability of a reference impedance Z_{REF} .

If Z_M^∞ denotes the impedance measured when the measuring system is occluded ($Z_R = \infty$), Z_M^{REF} denotes the impedance measured when a known reference impedance is used ($Z_R = Z_{REF}$) and Z_M denotes the impedance measured when the subject is connected to the measuring device, then the subject's corrected impedance is given by

$$Z_R = Z_{REF} \frac{1/Z_M^{REF} - 1/Z_M^\infty}{1/Z_M - 1/Z_M^\infty} \quad (77.8)$$

Z_M^∞ and Z_M^{REF} need not be evaluated each time a new subject is connected to the device, but only when some physical change (e.g., length variations of connecting tubes, replacements of sensors, etc.) has occurred since the last time the instrument was used.

Reference Impedance

The availability of a reference impedance is recommended [24]:

1. To correct the measured impedance using the procedure described above;
2. To compare measurements obtained by different devices, different techniques, and/or different groups.

For these purposes, a compact calibrator [25] has been proposed which displays the following features:

- It is simply reproducible;
- Its impedance value is not too far from typical human values;
- It is tractable from the mathematical point of view;
- Its lowest resonances fall outside the usual working frequency range.

TABLE 77.2 Complex Values of Calibration Impedance

Frequency (Hz)	Impedance (10^5 Pa s m^{-3})		
	Real	Imaginary	Modulus
0	3.09	0.00	3.09
5	3.11	1.11	3.30
10	3.14	2.17	3.82
15	3.20	3.22	4.54
20	3.28	4.26	5.37
25	3.37	5.28	6.26
30	3.47	6.29	7.18
35	3.58	7.28	8.12
40	3.70	8.26	9.05
45	3.82	9.23	9.98
50	3.94	10.17	10.91

The calibrator consists of a bundle of 30 tubelets (each 20.0 cm long and of 2.00 mm inside diameter) and its complex impedance is given in [Table 77.2](#).

77.3 Future Perspectives

Measurements in ventilation strongly depend on the availability of reliable sensors and detectors (pressure, temperature, optical and ultrasonic beams, etc.). The use of these components has been rising steadily in the last decade and this trend is expected to continue in the near future. The foreseeable consequences of this trend on the development of dedicated instrumentation may be

1. The increasing use of transducers of various kinds in all spirometric measurements.
2. The universal use of personal computers (and specialized software) to process and display data.
3. The growing importance of calibration procedures, because the accurate response of a particular transducer is usually reproducible but not always theoretically predictable; on the other hand, this is fundamental to all measurement systems.

Defining Terms

Plethysmography: Method employed to evaluate volume variations, with particular reference to human organs.

Pneumotachography: Methodology for measuring gas flows.

Respiratory impedance: Complex ratio between input pressure difference and induced flow at a particular frequency, when the respiratory apparatus is viewed as a complex network of linear components (resistive, inductive, capacitive).

Spirometry: The measurement of volume changes of the ventilatory system (lungs and chest wall) usually inferred from the movement of gas to and from the system.

Ventilation: Physical interaction of a body of air with the respiratory system, either through spontaneous or mechanically assisted breathing.

78.1 Introduction

The study of blood and its effects on sustaining life date back to the start of understanding human anatomy. There is a diverse background associated with blood chemistry, and knowledge of the makeup and purpose of blood and its components is growing by leaps and bounds. The typical discussion and history of blood chemistry relate to oxygen transport and its effects. This chapter will deal mainly with the measurement of oxygen related to health and critical-care applications, with limited descriptions of noncritical health status measurements. The beginning of blood analysis and the measurement of a person's health status were not practically and conveniently performed until technology advanced. It has been within the last 40 years that routine monitoring began in critical care. Critical-care health monitoring is the focus of this discussion because it has been one of the main motivations for developing analytical measurements. However, most critical-care monitoring has led to diagnostic tools and functional assessment of blood and its components.

Current health care professionals use a variety of common analytical measurements to assess and maintain a person's health. The measurements of interest include hemoglobin, hematocrit, blood gases (O_2 and CO_2), pH, glucose, and concentrations of electrolytes. Blood gas analysis is divided into a wide variety of specific tests. The tests include arterial, mixed venous, and **transcutaneous** oxygen tension; carbon dioxide tension; oxygen and carbon dioxide concentration; oxygen saturation. Each test has a specific purpose in diagnostics. Continuous real-time monitoring of oxygen saturation by pulse oximetry measurements is routinely used in anesthesia and critical-care settings. However, to determine heart and lung efficiency or true tissue oxygenation, other measurements are required. Different measurements are required because of the complex nature of the human body, and no one measurement gives a complete picture of overall status. For example, arterial oxygen saturation does not give a true cardiac output efficiency nor does it give a true tissue oxygenation state. Measurements can also be very misleading. During normal conditions, the measured values correspond very well. For example, under a given temperature and pH, oxygen saturation corresponds to oxygen tension. A fixed relationship occurs under

these conditions. This does not mean the same relationship applies to all circumstances. A change in temperature or pH will shift the oxygen tension to a saturation relationship.

78.2 Background

Most blood chemistry measurements have a long history. In the late 1800s the hydrogen (H^+) electrode was used to measure pH and, in 1925, John Peters at Yale showed a relationship between pH and CO_2 content. The measurement of blood gas started in the early 1920s with *in vitro* analysis of oxygen saturation. It was not until much later, however, that common patient care measurements were accepted. For example, it was not until 1952 in Copenhagen that pH monitoring was performed on artificially ventilated patients. The monitoring of pH was the start of the clinical use of blood gas monitoring. Until that time, physiological measurements were performed only in the laboratory setting. Electrochemical measurements were more common, and performed with a Clark electrode or similar electrode arrangement. Leland Clark made a working model of an oxygen electrode around 1950, which introduced a practical method of measuring oxygen tension. The probe was originally developed to aid in heart bypass instruments. Not long after the Clark electrode was developed, optical transmission analysis tools were developed. The measurement of oxygen saturation, called oximetry, was one of the early optical measurements. Oximetry has a long history dating back more than 50 years to the 1930s. Matthes and Millikan recorded the earliest noninvasive reading around 1935, and Glen Millikan introduced the name **oximetry** in 1942. A real research effort was started during World War II as a part of military aviation. It took almost 60 years for pulse oximetry to become a standard piece of equipment in operating rooms, critical-care units, and emergency health care. On January 1, 1990, the American Society of Anesthesiologists (ASA) made intraoperative monitoring with pulse oximetry a standard [1]. Despite the acceptance of pulse oximetry and its benefits, there still has been little change in pulse oximetry techniques. A good historic perspective on most blood gas analysis is written in a series of articles in the *Journal of Clinical Monitoring* and in *International Anesthesiology Clinics* [2-7].

Oxygen Delivery

As Severinghaus and Astrup [6] note in the history of blood gas analysis, nothing is more important than oxygen supply for life. Therefore, it can be argued that oxygen content and consumption should be one of the most important things to monitor in critical and unconscious patients. It is important to look at the mechanisms for oxygen transport. All human tissue needs oxygen to function, and it is therefore critical to understand how oxygen is delivered. **Hemoglobin** is the binding agent for oxygen in blood, but it is necessary to oxygenate the blood and move it to the tissue that uses the oxygen. A simple explanation is as follows. Oxygen is diffused into blood via the lungs. Blood is then circulated by a system of **arteries**, **veins**, and **capillaries** where the oxygen is diffused to tissue. The tissue also diffuses carbon dioxide to blood in the capillaries, which transports back to the lungs, where the carbon dioxide is diffused to the lungs for expiration. [Figure 78.1](#) shows a diagram of the general makeup of the components of interest. This is a very simplistic view of blood and oxygen transport. There are many other regulatory factors, such as sodium, potassium, calcium, pH, glucose, and so forth, but this simplistic view is a good starting point to understand the measurements that follow. It is also important to note that several measurement options and locations exist for gathering the same or similar data. This makes understanding the interaction and importance of different measurements difficult. For example, arterial and venous blood oxygen tensions are interdependent, but have different readings. Different physical states and health problems cause varying interdependence. A simple requirement to identify whether or not cell tissue is being properly oxygenated becomes very complex. Oxygen delivery to tissue is determined by the differential in partial pressure between cell tissue and capillaries. The partial pressure difference determines the rate and efficiency of diffusion. However, the rate is also dependent on blood flow, concentration of hemoglobin, and the saturation of oxygen. No individual parameter or measurement gives a complete picture of cell oxygen consumption.

FIGURE 78.1 Components involved in oxygen transport. Oxygen is delivered to the epidermis by arteries and exchanged through the capillaries. Veins return the by-product.

Blood Hemoglobin

Blood contains many components, but hemoglobin is the main transporter of oxygen (O_2) to tissue. In addition, blood is responsible for removing the by-product of oxygen expenditure, carbon dioxide (CO_2). Hemoglobin is a good binding agent for oxygen, producing oxyhemoglobin (O_2Hb), also called oxygenated hemoglobin. Hemoglobin is a combination of four peptide chains, each containing several hundred amino acids. Hemoglobin is composed of two elements, heme and globin. Heme is the iron pigment of the electrolytes, and globin is a simple protein. Hemoglobin contains about 6% heme and 94% globin. Hemoglobin is the principal component of red blood cells. Unbound hemoglobin is called deoxyhemoglobin (RHb), or reduced hemoglobin. Hemoglobin also binds to produce additional components, such as, carboxyhemoglobin (COHb), and methemoglobin (MetHb). Methemoglobin is a result of oxidation of ferrous iron in hemoglobin [8]. There are other compounds that are found in blood, but they are usually in very low concentrations and are of interest in more specialized cases.

Measurement Methods

Most blood chemistry analysis measurements are derived from one of two methods: electrochemical and optical. There are other specific measurement techniques, such as gas chromatography, but they are more of a specialized measurement and will not be addressed. Electrochemical measurements are based on the Clark electrode with the blood component or electrolyte of interest using a different ion-specific electrode. The Clark electrode consists of an electrode in a medium. The first electrode for oxygen tension measurements was a platinum electrode and a silver anode. The current or voltage generated at the electrode is measured and is proportional to the amount of that component. The relationship is usually a calculated concentration derived from empirical data. For optical measurements, there are many approaches, but all are based on absorption, reflection, scattering, and fluorescence techniques. One optical probe has been called an optode. The optode is a cross measurement of optical fluorescence and electrochemical measurement. [Figure 78.2](#) shows a diagram of one configuration for an optode arrangement. In an optode, an ion-selective membrane is used to diffuse an ion or compound into the fluorescent dye measurement chamber. The ion is associated with a fluorescent dye, excited with a light source, and the emitted fluorescent light is measured. Many measurements can be obtained, such as oxygen tension, carbon dioxide tension, pH, potassium concentration, calcium concentration, and chloride concentration.

Measurements are listed in one of four categories, (1) invasive or (2) noninvasive measurements and (3) continuous or (4) periodic measurements. **Invasive** measurements can be continuous or periodic, and can be performed *in vivo* or *in vitro*. Invasive **catheter** sensors can record real-time data continuously with no loss of blood sample. **Intra-arterial** measurements can be drawn periodically for minimally invasive measurements with no sample loss, or samples can be withdrawn and discarded. Periodic samples can also be drawn for analysis and measured in a physically different location at a later time. Noninvasive measurements can also be continuous or periodic, but are generally on patient, real-time measurements.

FIGURE 78.2 Chemical fluorescent optode for oxygen tension measurements. Light input through a window excites encased dye. The sample interacts with the dye through a semipermeable membrane. The sample is introduced to the dye via a flow-through chamber.

Noninvasive measurements are always preferred over invasive measurements, because invasive measurements increase risk of infection and usually mean some delay between the time of acquisition and the time results are available. However, noninvasive measurements are not always as accurate as invasive measurements.

78.3 Measurements and Techniques

There are typically several measurement techniques that yield the same or similar data. Each technique will give information about different physical states, such as cardiac efficiency or tissue oxygenation state. For example, oxygen saturation and partial pressure of oxygen are related. However, the exact relationship is dependent on pH and temperature. A text by Kenneth McClatchey on *Clinical Laboratory Medicine*, the International Federation of Clinical Chemistry (IFCC), and instrument operator's manuals are good references for laboratory protocols relating to invasively drawn samples [9,10]. Sample preparation and handling protocols, as well as standard measurement levels and physical states relating to excess or deficient readings are detailed. The range, price, and suppliers for instrumentation are extensive. A standard midrange laboratory blood gas analyzer can cost from \$5,000 to \$50,000. The more common measurements are described below.

Hemoglobin and Hematocrit Concentration

The total concentration of hemoglobin (CtHb) or **hematocrit** (Hct) indicates the oxygen-carrying potential of blood. The combination of amount of hemoglobin, partial pressure of oxygen or percent oxygen saturation, and rate of flow of hemoglobin determines the amount and efficiency of tissue oxygenation. Invasively drawn samples are typically used to measure hemoglobin and hematocrit values.

Hemoglobin

The total hemoglobin concentration is not the same as the red blood cell count, because red blood cells have different amounts of hemoglobin. The total hemoglobin concentration is measured optically by

absorptive intensity at the isosbestic point. The Beers–Lambert law, also referred to as Beer’s law, shown in Equation 78.1 regulates the absorptive property of a substance.

$$I_t = I_0 e^{-DC\alpha_c} \quad (78.1)$$

I_t is the transmitted intensity, I_0 is the incident intensity on the sample, D is the distance light travels through the substance, C is the concentration of the solution, and α_c is the extinction coefficient at a specified wavelength. The isosbestic point is the crossover point in extinction curves for oxyhemoglobin and reduced hemoglobin. The wavelength of 805 nm is an isosbestic point, and at this wavelength the absorption is independent of hemoglobin type. If blood is assumed to be composed of only O_2Hb and RHb , then the absorbance at the isosbestic point determines the total concentration of Hb. The most common error in assuming only O_2Hb and RHb is during elevated $COHb$. $COHb$, however, generally is optically indistinguishable from O_2Hb for absorption. An alternative approach to isosbestic measurement is to calculate $CtHb$. Assuming only O_2Hb and RHb , the total Hb concentration is simply the sum of the two concentrations. A more accurate sum is shown in Equation 78.2.

$$CtHb = O_2Hb + RHb + COHb + MetHb \quad (78.2)$$

Here the four most common Hb derivatives are used to calculate a more accurate $CtHb$. The individual Hb derivatives are measured as outlined below.

Hematocrit

Hematocrit is the volumetric fraction occupied by red blood cells and is generally measured by conductivity. Hematocrit is also referred to as the packed cell volume (PVC). Hematocrit can be determined by conductivity based on the plasma ion content. Hematocrit does not contribute to the conductivity and therefore is inversely proportional to the conductivity. Hematocrit can also be determined optically in various ways. One way is through optical density measurements, where the total optical density is the sum of optical absorbance and optical scattering density. The total optical density is linearly proportional to Hct, and, at clinically relevant Hct levels of 20 to 40%, scattering is dominant over absorption. One optimization study showed that an optimum wavelength of 624 nm, at a measured angle of 90° from the incident light, gave an inverse linear intensity to the Hct level [11].

Oxygen Tension

Oxygen tension or the partial pressure of oxygen (PO_2) is a common measure of oxygenation states. The partial pressure of oxygen in hemoglobin determines how well oxygen is delivered to the cell tissue of the body. The more common partial pressure reference is arterial partial pressure of oxygen (PaO_2). If the partial pressure of oxygen is higher than the surrounding tissue, oxygen is diffused to the tissue. If the partial pressure is lower than the tissue partial pressure, no oxygen is diffused to the tissue, and tissue damage can start to occur. Equation 78.3 shows Henry’s law.

$$C = \alpha_s * PO_2 \quad (78.3)$$

C is the concentration of oxygen (O_2), α_s is the solubility coefficient, and PO_2 is the partial pressure of oxygen. In diffusion, a partial pressure between the tissue and blood supply is trying to maintain equilibrium. Diffusion will occur until the two partial pressures are equal. Equation 78.4 shows diffusion equilibrium.

$$PO_2 = C_1 / \alpha_{s1} = C_2 / \alpha_{s2} \quad (78.4)$$

FIGURE 78.3 Clark-type needle electrode for PO₂ measurements. Oxygen ion interaction through the membrane tip allows the ion concentration to be measured by dissimilar metals.

The rate of oxygen diffusion is dependent on the difference in partial pressure. The larger the difference in partial pressure, the faster the diffusion rate.

The partial pressure difference is partially determined by the oxygen delivery (D_O) rate. Oxygen delivery can be identified as the concentration of arterial oxygen minus the concentration of venous oxygen, times the rate of blood flow (R), as shown in Equation 78.5.

$$D_O = (C_aO_2 - C_vO_2) * R \quad (78.5)$$

C_aO_2 is the arterial oxygen concentration, and C_vO_2 is the venous oxygen concentration. The oxygen delivered, however, is not the oxygen delivered to the tissue. Some oxygen is transpired through the skin. The transpired oxygen allows an alternative approximation measurement of arterial oxygen tension. The more common oxygen tension measurement is arterial oxygen tension. Oxygen tension can be measured electrochemically, transcutaneously, or optically. The techniques are listed below.

Electrochemical PO₂ Measurements

Electrochemical measurements of PO₂ are obtained using a basic Clark electrode with a platinum electrode and a silver/silver chloride reference electrode. Figure 78.3 shows a diagram of one type of Clark electrode. The electrode provides a path for the reduction in Equation 78.6.

The platinum electrode has an affinity with oxygen. If a reference PO₂ at the electrode is known, preferably zero, then the current depends only on the oxygen tension variations of the sample. Early electrodes were consumption measurements where the oxygen is removed and the sample is altered. Oxygen was attracted to the electrode and a current proportional to the oxygen content was observed. Improved electrodes use a semipermeable, constant diffusion membrane. An electrolyte is used with the membrane to improve response, longevity, and stability. An exposed electrode will become coated in whole blood and the sensitivity will degrade. The membrane and electrolyte allow the diffusion of oxygen without the sample directly contacting the electrode. In addition, a properly designed membrane reduces the stirring effect noted by Clark and others using an exposed electrode. The size and location of electrodes have been extensively studied. The exact setup for the electrode can be varied for optimum performance in different

FIGURE 78.4 Chemical fluorescent fiber-optic probe. Dye is encased on a fiber tip by a membrane. Light enters the dye through the fiber and the emitted fluorescence is returned via the fiber. The amount of fluorescence is an indication of the interaction between the dye and the substance in which the fiber tip is placed.

areas. For example, a less permeable diffusion layer reduces the stirring effect and makes the probe more stable, but the result is a slower response time [3,6,12,13].

Transcutaneous Partial Pressure of Oxygen

Partial pressure and oxygen saturation are not always true indicators of actual tissue oxygen consumption. It has been known since 1851 that oxygen is respired from living tissue. A combination of heat and optical means can be used to determine the amount of oxygen expired and correlated to arterial partial pressure under controlled conditions. This method of measuring arterial oxygen partial pressure is called transcutaneous oxygen partial pressure ($P_{tc}O_2$). There are, however, many complications in the measurement of $P_{tc}O_2$. Many studies have tried to correlate arterial oxygen saturation with the measured expired oxygen. The most accurate measurements are made by maintaining a constant temperature as high as 45°C, to assure perfusion. This causes the complication of burns to skin, and sensors need to be moved on a regular basis.

Measurements can be performed polarographically using Clark electrodes or alternatively by mass spectroscopy. Because of the nature of $P_{tc}O_2$, adult measurements are not common, but premature infant hemoglobin and skin are more responsive to $P_{tc}O_2$ measurements, which have had a place in monitoring neonatal oxygenation [7,14].

Optical-Based PO_2

There are many variations on optical-based blood gas measurements. The basic optical measurement for PO_2 is a **fluorescent** measurement. A fiber-optic cable is used to excite a fluorescent dye remotely. The excited dye emits a higher-wavelength signal, known as Stokes shift. The emitted signal is measured and is correlated to the PO_2 value. Figure 78.4 shows a configuration for a fluorescent sensor. Oxygen is used as a fluorescence quencher. Oxygen has a fluorescence-quenching property and attenuates the fluorescent intensity. A zero state can be measured by filling the sample chamber with a zero oxygen concentration mixture. The measured intensity is compared with the incident light source and is used to calculate the concentration of the sample. For oxygen tension, the measurement is done by a fluorescent electrochromic dye, such as pyrenebutyric acid, with an ion-selective membrane such as silicone rubber. The oxygen tension is then calculated using the Stern–Volmer quenching formula, shown in Equation 78.7, and the PO_2 value is calculated empirically.

$$I_0/I = 1 + K * PO_2 \quad \text{or} \quad I(PO_2) = I_0 / (1 + K * PO_2) \quad (78.7)$$

$I(\text{PO}_2)$ and I_0 are the relative fluorescence intensities in the presence of oxygen and in the absence of oxygen, respectively. K is the overall quenching constant and is given in Equation 78.8.

$$K = k^+ * \alpha_{\text{O}} * \tau_0 \quad (78.8)$$

k^+ is the collisional quenching constant, α_{O} is the oxygen solubility coefficient, and τ_0 is the mean lifetime of the excited state at zero PO_2 . The ratio of I to I_0 is then plotted against the PO_2 value. This plot is used to calibrate the sensor empirically for different PO_2 values. $1/I_0$ is the intercept, and the slope is K/I_0 . The system is empirically derived and errors can occur with varying excitation intensity. One way to correct for intensity variations is to use a reference fluorescence dye that is not affected by oxygen quenching. The same procedure can be used to calculate the percent oxygen concentration [15,16].

Oxygen Saturation

There are several readings that are interrelated regarding oxygen saturation. The most common measurements are arterial blood saturation (S_{aO_2}), mixed venus blood saturation (S_{vO_2}), and **photoplethysmogram** arterial blood saturation (S_{pO_2}). S_{pO_2} measurements, also called pulse oximetry measurements, are arterial measurements, but are only related to true arterial saturation. Care must be taken in knowing which measurements are actually taken, because of inaccuracies in various measurements. Saturation measurements can be performed invasively using reflectance or fluorescence oximetry, or noninvasively by transmission or reflectance photoplethysmogram readings.

There is an important relationship between oxygen saturation and partial pressure. A plot shown in Figure 78.5 of arterial oxygen saturation vs. arterial partial pressure is called the oxygen hemoglobin

FIGURE 78.5 Oxygen saturation vs. PO_2 oxygen hemoglobin dissociation curve. The partial pressure shows a sigmoidal relationship to the percent oxygen saturation.

dissociation curve. Partial pressure falls at a linear rate and is a good indicator of changing oxygen delivery to cell tissue. The percent oxygen saturation is nonlinear with respect to partial pressure in a sigmoidal relationship. A partial pressure of 13.3 kPa (100 mmHg) is effectively 100% saturation. An increase in partial pressure above 13.3 kPa (100 mmHg) indicates free oxygen not bound to hemoglobin and in that state does not contribute much to tissue oxygenation. This means the percent saturation gives a delayed notice of desaturation. In a patient with healthy lungs, partial pressure values of greater than 24.0 kPa (180 mmHg) can be measured. A 50% decrease in partial pressure could go undetected using the percent oxygen saturation. The oxygen dissociation curve, as mentioned previously, is dependent on pH and temperature. Under normal conditions, the relationship between partial pressure and saturation is maintained, but under altered conditions, such as low perfusion, the relationship can deviate.

Roughton and Severinghaus [18] describe a computation to approximate the dissociation curve based on the Hill equation. The Hill equation is given in Equation 78.9.

$$Y = \frac{\left(\text{PO}_2 / P_{50}\right)^n}{1 + \left(\text{PO}_2 / P_{50}\right)^n} \quad (78.9)$$

Y is the oxygen saturation, PO_2 is the oxygen partial pressure, and P_{50} is the partial pressure at 6.7 kPa (50 mmHg). The P_{50} point is determined by the temperature and pH of the sample. Temperature and pH correction equations are also presented in References 5, 7, and 17 through 19.

Transmission Oximetry

Continuous $S_a\text{O}_2$ and $S_v\text{O}_2$ measurements are used to help evaluate whether oxygen is being adequately delivered to tissue. Oxygen is either consumed or expired. If oxygen is delivered to tissue and not consumed, then tissue oxygenation is not adequate. Early oximeters used invasively drawn samples and light transmission to measure oxygenation. The basic concept in oximetry is to transmit light through a blood sample, and blood absorbs a determined amount of light according to Beer's law, shown in Equation 78.1. For oximetry applications, hemoglobin is assumed to be composed of only two substances, oxygenated hemoglobin or oxyhemoglobin (O_2Hb) and deoxygenated or reduced hemoglobin (RHb). This is a very simplistic approach, but it is the basis for most oximetry measurements. For *in vivo* measurements, the path length for the light is constant and known. Both the O_2Hb and RHb can be measured simultaneously by using two separate wavelengths. Flash lamps and filter wheels were originally used to illuminate blood samples, and the transmitted signals were measured. Current technology uses light emitting diodes (LEDs) and alternate on and off cycles.

If two light wavelengths are used and the two substances have different extinction coefficients (α_e), or equivalently attenuation coefficients (σ), then the percentage of each substance can be calculated. The extinction coefficients of hemoglobin are well documented. Figure 78.6 is a plot of the extinction coefficients for oxyhemoglobin, reduced hemoglobin, carboxyhemoglobin, and methemoglobin. The two wavelengths of light yielding good results for oximetry are the red (660 nm) and infrared (940 nm) wavelengths. Red has the largest difference between the two extinction curves, and infrared has maximal difference after the isosbestic point where the two extinction curves cross. The functional arterial oxygen saturation ($S_a\text{O}_2$) is calculated using Equation 78.10 given the concentration of O_2Hb and RHb.

$$\text{Functional } S_a\text{O}_2 = C_o / (C_o + C_r) * 100 \quad (78.10)$$

The concentration of oxyhemoglobin is given by C_o and the concentration of deoxygenated hemoglobin is given by C_r . This formula must be adjusted for other contents in blood which influence measurements if present, such as carboxyhemoglobin and methemoglobin. The more accurate fractional saturation is given as the total hemoglobin concentration (tHb) in Equation 78.11.

$$\text{Fractional } S_a\text{O}_2 = C_o / (\text{tHb}) * 100 = C_o / (C_o + C_r + C_c + C_m) * 100 \quad (78.11)$$

FIGURE 78.6 Hemoglobin extinction coefficients plotted by wavelength. The light extinction coefficient varies by wavelength and type of hemoglobin.

C_c is the carboxyhemoglobin (COHb) saturation and C_m is the methemoglobin (MetHb) concentration. To account for COHb and MetHb accurately, four transmission wavelengths would be required, or for accurate S_aO_2 readings the total Hb concentration needs to be known or measured [5,7,20].

Pulse Oximetry

Pulse oximetry is based on the transmission, absorption, and dispersion of light as it passes through hemoglobin. Beer's law, as stated in Equation 78.1, determines the transmission of light through a substance. For pulse oximetry, the light illuminates both arterial and venous blood and the light must traverse all tissue between light source and receiver. Figure 78.7 represents the light path, and indicates a variable (AC) path length as well as a constant (DC) path length.

FIGURE 78.7 Absorption components encountered during transmission oximetry. The arteries, veins, capillaries, and tissue absorb light. The total light absorbed has a steady state (DC) and a varying (AC) signal component. The varying signal is due to the pulsatile arterial volume change.

Photoplethysmogram Time Signal

FIGURE 78.8 Photoplethysmogram with AC and DC components labeled. The light intensity transmitted through the finger varies with time. The signal contains a constant (DC) component and a varying signal (AC) component. The varying signal is due to the pulsatile arterial volume change.

To calculate the pulse oximetry digital photoplethysmogram (DPP) oxygen saturation (S_pO_2), two equations are used. An example of a DPP signal is shown in [Figure 78.8](#) and it indicates the AC and DC DPP components. The first step is to use the red and infrared time signal to calculate an R value. The R value is the normalized ratio of the red to infrared transmitted light intensity and is shown in Equation 78.12.

$$R = \left(AC_r / DC_r \right) / \left(AC_i / DC_i \right) \quad (78.12)$$

The R value for two specific light wavelengths can be plotted against a measured S_aO_2 value, as shown in [Figure 78.9](#). A linear approximation can then be used to calculate a S_pO_2 value. The empirical linear approximation for Figure 78.9 is listed in Equation 78.13.

$$S_pO_2 = 110 - 25R \quad (78.13)$$

The empirical approximation is used to correct for errors in the measured values. Pulse oximeters currently on the market use weighted moving average (WMA) techniques to identify the transmitted AC and DC DPP components. The DC component is the averaged signal intensity. The AC signal is computed using the WMA as a bandpass filter to single out only the AC cardiac signal.

There are many areas where pulse oximetry has limitations. One limitation was already mentioned, and that is the assumption of only two substances in hemoglobin. For most measurements, the percentage of these substances is small enough not to affect the pulse oximetry measurements. There are cases in emergency care when these substances may be present and do affect readings. At present, the user must be aware of the limitations and not use the pulse oximetry reading if the person has any of the additional substances. The solution to this problem is to use additional light sources to calculate the additional substance. The first pulse oximeters tested used a multiple-wavelength light source and could easily be implemented in new instruments.

A second limitation of pulse oximetry is background light. Because pulse oximetry currently uses transmitted light, the photodiode receiver is susceptible to ambient light. Ambient light can be from indoor lighting, sunlight, or phototherapy lights. To correct for this problem, a third light measurement can be collected with no light source, and subtracted from the transmitted intensity. Using a digital microprocessor, the subtraction can be easily performed.

FIGURE 78.9 Measured oxygen saturation vs. R value. Empirically derived 660 to 940 nm ratio and oxygen saturation. The values are used to formulate a first-order equation to calculate the pulse oximetry saturation.

A third limitation is called low **perfusion**. Pulse oximetry is based on having a pulsatile signal. If the pulsatile signal is small compared with the DC signal, usually 1 count in 1000, the R value calculation becomes inaccurate. There are two reasons for the inaccuracy, round-off error and resolution. The round-off error can be compensated for by using more precision during the R value calculations.

Another limitation, which is difficult to eliminate, is motion artifact and autonomic nervous system response. Whenever there is an autonomic nervous system action, there is a transition or movement in the pulse oximetry signal. The most common technique to correct for motion artifact is averaging of consecutive measurements. Averaging works, but it slows the response time and lengthens the processing time. Another improvement would be to identify and eliminate inaccurate readings. This approach, however, is difficult to implement [7,21–23].

Reflectance Oximetry

An alternative technique to consider for DPP is reflectance probe measurements, as shown in [Figure 78.10](#). Reflectance pulse oximetry has been addressed for *in vivo* studies by Mendelson and Ochs [24]. Because reflectance probes can be placed flat on the measurement area, they provide better shielding than a probe

FIGURE 78.10 Reflectance oximetry probe. Red and infrared diodes illuminate the surface alternately and the reflected light is detected in close proximity by a photodiode. An optical barrier is required to eliminate direct light detection.

placed across a finger. However, reflectance measurements have less intensity than transmission measurements. Reflectance probe location and temperature effects have been analyzed. Increased temperature results in perfusion and increased signal intensity.

Schmidt et al. [25] reported an integrated circuit-based optical sensor for *in vivo* surface measurements. A set of equations was derived to estimate the amount of reflectance at a given intensity. The solution is a three-wavelength reflectance probe, with a red LED wavelength emission of 660 nm and a near and far infrared LED. The reflectance depth was calculated to be within 2 mm of the surface of the probe. The third wavelength is used to eliminate errors in measurement due to additional hemoglobin derivatives. The third wavelength was used to calculate a hematocrit value. The saturation was calculated using Equation 78.14.

$$SO_2 = A - B \left(R_{805} / R_{660} \right) \quad (78.14)$$

A and B are constants empirically derived for a specific light source and detector under specific physiological conditions.

A current method to measure S_vO_2 is by reflectance oximetry methods. A bundled fiber-optic cable is placed through a catheter. Light enters by a fiber or fibers and the reflected light is analyzed for oxygen content using spectrophotometry. The probe is similar to the fluorescence probe shown in Figure 78.4 with no chemistry envelope. The reflectance is used to determine the oxygen concentration empirically [24–26].

pH Measurements

Blood pH is very important in sustaining life. There is a small range of values allowable to maintain life, and pH is one of the most tightly regulated parameters in the body. Typical pH measurements are taken invasively either through a catheter probe or as a blood sample measurement. pH is noted as the negative decade logarithm of the molal activity of hydrogen ions. The acid and alkaline hydrogen reactions are given in Equations 70.15 and 70.16, respectively.

The pH level can be determined by electrochemical means. The original pH measurements were performed using hydrogen electrodes after the oxygen (O_2) was eliminated. Current electrochemical measurements use a glass electrode sensitive to hydrogen and a concentrated KCl bridge.

Optical measurements of pH are performed fluorescently. It was determined that pH corresponds to CO_2 tension. Both PCO_2 and pH can be measured using a dye sensitive to hydrogen ions and using a variant of the Henderson–Hasselbalch equation, shown in Equation 78.17.

$$I_0 / I = 1 + K * H^+ \quad (78.17)$$

I is the relative fluorescence intensity, H^+ is the hydrogen ion concentration, and I_0 and K are calibration constants.

pH fluorescence measurements can be obtained using a pH-sensitive dye, such as phenol red. The basic form of phenol red is green absorbing, and the acidic form is blue absorbing. Exciting the phenol red buffer with a green 560 nm and red 600 nm light, the ratio of intensities can be used to calculate the pH according to Equation 78.18.

$$R = k * 10 \left[\frac{-C}{(10^{-6} + 1)} \right] \quad (78.18)$$

FIGURE 78.11 Optical glucose probe. A hollow tube is used to localize fluorescent dye outside the numerical aperture of the fiber. The fiber is used both to introduce excitation light and to collect emitted fluorescent levels. Only dye in the fiber view is illuminated. Dye bound to the hollow tube is not illuminated and is not detected.

k is the system optical constant, C is the green base form intensity, and δ is the difference between the pH and pK of the dye. Intensity shifts are accounted for by measuring the difference in intensity of two different excitation wavelengths. An alternative two-wavelength approach using hydroxypyrene trisulfonic acid (HTA) can be used. The basic form of HTA has a maximum excitation at a wavelength of 460 nm and an acidic maximum excitation wavelength of 410 nm. The ratio of the two fluorescent intensities at 520 nm is used to calculate the pH value [2,6,16,27].

Glucose Measurement

A common **glucose** measurement technique is by enzymatic amperometric measurements. Through selective binding, glucose and other compounds can be measured. The bound glucose changes the conductance and the glucose concentration can be determined.

Another more recent and interesting measurement technique is enzymatic optical measurements. Competitive binding between glucose and a fluorescein-labeled analog is used to determine glucose concentrations. An immobilized binding site is used to bind a fluorescent material, such as fluorescein-labeled dextran. A diagram of a glucose sensor is shown in [Figure 78.11](#). The binding sites are fixed outside the excitation illumination. As the glucose concentration increases, the bound fluorescent material is released into the optical path. As the concentration of glucose increases, the viewed fluorescence increases and the reflected intensity increases. The reflected intensity will follow the concentration of glucose, and the actual response is measured empirically. The probe operation is reversible, allowing the probe to be reused. Reversibility is a requirement for implantable probes, which is the intended application for the optical glucose probe [27,28].

Electrolyte Concentration Measurements

In the clinical setting, it is important to monitor the concentration of various **electrolytes**. Typical measurements include sodium (Na^+), calcium (Ca^{++}), potassium (K^+), chloride (Cl^-), and magnesium (Mg^{++}). The concentrations are typically invasively drawn samples measured in a clinical laboratory. The measurement is performed using an ion-specific electrode, which is similar to the Clark electrode described previously. The clinical significance of different electrolytes is outlined in the text by

McClatchey, *Clinical Laboratory Medicine* [9]. Optical measurement techniques have been performed, but are not typically used in the clinical setting and are not covered here.

78.4 Combined Analysis Techniques

There are many combinations of instruments available. As instruments become more accurate and smaller, the trend is to simplify measurements and increase usefulness of equipment. Several selected instruments are described which have combined blood chemistry measurements into one unit.

CO-Oximetry

CO-oximetry has been noted for some time as the gold standard for oximetry readings. The more typical CO-oximeter does not measure just oxygen saturation, but several hemoglobin concentrations. For example, the Instrumentation Laboratory, Inc., IL 282 CO-oximeter uses an invasively drawn sample and measures total hemoglobin, oxyhemoglobin, carboxyhemoglobin, methemoglobin, and oxygen content in blood. The measurement technique is optical absorption. Four wavelengths at 535, 585.2, 594.5, and 626.6 nm are generated using a hollow cathode lamp. The extinction coefficients are used to calculate the concentration of RHb, O₂Hb, COHb, and MetHb. The total hemoglobin (tHb) concentration is calculated as the sum of the individual hemoglobin groups. The oxygen saturation (S_aO₂) is calculated as the concentration of oxyhemoglobin divided by the total concentration of hemoglobin. The total hemoglobin concentration, however, is usually noted as only the oxyhemoglobin concentration divided by the concentration of reduced hemoglobin and oxyhemoglobin. Therefore, care must be used in comparisons, because variations in S_aO₂ calculations can occur. The oxygen content is calculated as 1.39 times the concentration of oxyhemoglobin [29].

Intra-Arterial Probes

Intra-arterial probes have drawn much interest. They allow continuous or periodic measurements in the clinical setting in real time. These probes also offer minimally invasive measurements. The intent is to use intraarterial measurements on patients who require catheterization. The goal is a small probe that can be inserted into a catheter and not interfere with administering therapies or blood sampling. An optode-type probe is described by Shapiro et al. [30,31]. A fiber-optic probe is described by Gehrich et al. [15] for blood gas monitoring. The probe is designed to measure pH, PCO₂, and PO₂. In addition, a thermocouple is used to adjust for temperature variations, and values are normalized to standard temperatures. The sample drawing of the probe is shown in [Figure 78.12](#). A set of chemical optical fluorescent probes is used.

78.5 Evaluation of Technology

There have been numerous measurement types and techniques used in developing an understanding of blood chemistry. The diverse background has resulted in very good indicators of how blood is used to sustain life. Despite the diverse background, many changes and advances are occurring at an impressive rate. Immediate improvements are being tested and implemented on a regular basis, and novel approaches will be seen in the near future. In addition, there is an explosion of studies being performed to understand how the body works and is put together. A brief overview of some improvements that can be expected follows.

Some basic engineering changes could be performed to enhance accuracy. Oximetry measurements could easily see engineering improvements. New techniques have been tested, but approval and acceptance are slow. There has been progress made in size, with new oximeters that can clip on the finger. The accuracy has seen only moderate improvement. Alternative probes and algorithms have been tested and even patented, but have not been marketed. One example of a patent is for Fourier analysis of pulse

FIGURE 78.12 Combined fiber-optic sensor for pH, PCO₂, PO₂, and temperature correction measurements. Each sensor is bundled into a single enclosure and has separate detection areas.

oximetry signals for arterial saturation measurements. The spectral analysis would allow the possibility to implement some novel filter and analysis routines. This would improve stability from motion artifact. Hardware changes could also bring changes. Resolution could be improved by using more accurate photodiodes and A/D converters, or by using laser diodes for more intense and accurate light illumination. Reflectance probe advances would improve versatility.

The future of blood chemistry should see continued miniaturization. Fiber optics have become a major research direction. Fiber optics allow remote sensing and have reduced the possibility of electrical and magnetic complications for patient monitoring. Miniature fiber-optic sensors are being developed for numerous applications, and the improvement and developments can be applied to biological readings. Miniaturization not only reduces size, but can also improve stability. Small probes also allow multiple readings in one sensor. This trend has already started with blood gas probes being used for intravascular and extravascular measurements. The next trend envisioned is nanoprobes. Implantable glucose probes are already being tested. Sensor and light sources can be implemented on an integrated circuit and continue to shrink. Microsensors are already being used in biomedical application, such as blood pressure sensors and single-cell neural stimulators. Miniature chemistry and thermal-cycling laboratories are being developed into single integrated chips. The same chemical and optical arrangements can be performed for blood chemistry analysis. A complete laboratory measurement system could be at the patient location for continuous monitoring [28–30,32].

The other major anticipated change is the trend for additional and more accurate noninvasive readings. Invasive measurements can mean delays and noncontinuous monitoring, as well as increased possibility of infection. Given equal measurement accuracy, noninvasive measurements are an obvious choice over invasive readings.

It is important to note that measurement techniques will continue to improve, but the rate of growth and utilization will not grow as fast. Acceptance and utilization are dependent on cost and the effort involved in using the instruments. Cost can slow or even eliminate instrumentation from being used. However, with the increasing cost of medical care, there is interest in providing fast diagnosis and recovery for patients. This will provide incentive for improving measurement technique and accuracy.

Defining Terms

Artery: Vessel used to carry blood away from the heart.

Capillary: Semipermeable membrane used to exchange oxygen and other substances with tissue.

Catheter: Surgical instrument inserted into the body for drawing or administering fluids.

Electrolyte: A substance that dissolves into ions, becoming capable of conducting electricity.

Fluorescence: The property of emitting light when exposed to an excitation light.

Glucose (dextrose): Substance found in normal blood, which is the main source of energy in living tissue.

Hematocrit: The total concentration of hemoglobin, or packed red cells, in blood.

Hemoglobin: Oxygen-carrying pigment found in blood, which has the property of reversible oxygenation.

Intra-arterial: Within the artery.

Invasive: Pertaining to the insertion of an instrument into the body.

Oximetry: Photoelectric determination of arterial blood oxygen saturation (S_aO_2).

Perfusion: Pertaining to the passage of fluid through vessels. Low perfusion refers to reduced blood flow.

Photoplethysmogram: Chart of the volume change in an organ or limb. In oximetry it is the chart of the light passed through an ear, nose, or digit. The light intensity varies with the arterial pulse, which is related to the arterial volume.

Transcutaneous: Pertaining to entering through the skin.

Vein: Vessel used to return blood to the heart.

79.1 Introduction

Medical imaging has advanced considerably since the discovery of X-rays by Wilhelm Conrad Röntgen in 1895. Today, in addition to the continued use of X-rays for medical diagnosis, there are imaging methods that use sound (ultrasound), magnetic fields and radio waves (magnetic resonance imaging), and radionuclides (nuclear medicine). Both projection imaging and cross-sectional imaging are routinely used clinically. This chapter will describe the principles behind the various imaging modalities currently in use, and the various measurements routinely made with them.

79.2 Image Information Content

The vast majority of imaging procedures are qualitative in nature, where it is the visual presentation of anatomy that is the measurement outcome. There are also some quantitative measurements, which will be discussed in the section on nuclear medicine. However, since most imaging is concerned only with the qualitative nature of the image, a description of the salient features of image content follows.

There are three primary physical parameters of interest in image content: contrast, noise, and resolution. If these three features are known for a given image (or imaging system), then the entire physical nature of the image has been characterized. There are also psychovisual effects, such as conspicuity [1],

which affect the ability of the observer to detect a particular feature, but these issues are difficult to quantitate and are outside the scope of this handbook.

The first of the physical image features, contrast, is defined as the fraction of the total image signal occupied by a particular object:

$$C = \frac{B - S}{B} \quad (79.1)$$

where S is the signal in the area of interest and B is the background signal. Contrast is determined by the properties of the object being imaged, the imaging modality, the properties of the image detector, postprocessing of the image (such as by digital processing), and the contrast of the display device.

Image noise is a measure of the stochastic nature of the image. All physical measurements, including medical images, contain a certain degree of uncertainty. In X-ray imaging, for example, the physics of X-ray production dictates that the number of X-rays incident on a unit area per unit time are random, and given by a statistical distribution known as the Poisson distribution. The greater the image noise, the less likely it is that one will observe a given object. There is a relationship between the image noise, the contrast and area of an object, and its likelihood of being observed. This is summarized in the Rose model:

$$N = \frac{k^2}{C^2 A} \quad (79.2)$$

where N is the number of quanta (such as X-rays) per unit area needed to discern an object of contrast C and area A , assuming a signal-to-noise of k . Rose found that a signal-to-noise ratio of 5 is typically required to detect a visual object reliably [2].

Resolution is the ability of an imaging system to record faithfully the range of spatial detail in an object. Recording objects with finer spatial detail requires “sharper” imaging detectors. The resolving ability of a detector is largely determined by its point-spread function. The point-spread function describes how well the imaging apparatus can record an infinitesimal point object. No detector is perfectly sharp, and some spread of the infinitesimal dot occurs — the worse the spread, the less resolving the system.

Measurement of Imaging Performance

A linear-systems approach is typically used to quantify the performance of an imaging system. The relations among contrast, noise, and resolution of an imaging system are customarily described by two functions: the modulation transfer function (MTF) and the noise power spectrum (NPS), both of which are functions of spatial frequency. The MTF is the Fourier transform of the point-spread function, and describes the inherent deterministic frequency response of the system. The NPS (also referred to as the Wiener spectrum) is proportional to the square of the Fourier transform amplitude at each frequency, and represents the variance associated with noise in the system at each particular spatial frequency. The ratio of MTF and NPS, properly normalized, is the noise equivalent quanta (NEQ), which is the square of the maximum available signal-to-noise at each spatial frequency u :

$$NEQ(u) \equiv \frac{(\text{large area signal})^2 \cdot MTF^2(u)}{NPS(u)} \quad (79.3)$$

If the NEQ is divided by the number of incident quanta per area (e.g., the number of X-ray photons incident on the detector in X-ray imaging), the result is the detective quantum efficiency (DQE). The

zero-frequency DQE is a measure of the fraction of incident quanta effectively used by the system. Alternatively, the DQE may be viewed as the efficiency with which the system utilizes the available signal-to-noise at each spatial frequency.

The actual measurement of MTF, NPS, and DQE is quite tedious, and will be only briefly summarized here. The interested reader is encouraged to consult the suggested references for the appropriate detail on these measurements. Examples of these measurements will be given for X-ray imaging.

The MTF is typically measured by imaging either a very fine slit (typically 10 to 20 μm) [3-6] or an edge [7]. The profile across the slit image is called the line-spread function (LSF). The Fourier transform of the LSF gives the MTF in the direction perpendicular to the slit. The derivative of values along the edge-response function also gives the line-spread function. Detector response typically varies with energy so it is important to specify the conditions under which MTF is measured. With X-ray imaging it is typical to use a tube voltage of 70 kV with 0.5 mm Cu filtration placed in the beam to simulate the filtering of the X-ray spectrum expected from a patient, although other measurement techniques are also found in the literature.

The NPS is measured by taking an image of a flat field, where there is no structure in the image other than noise. Contemporary methods of NPS measurement on digital systems perform a two-dimensional Fourier transform on the flat-field image [6], although when measuring the NPS of film a scanning slit is used to generate a one-dimensional NPS parallel to the direction of slit movement [8-10]. After appropriate scaling, the square of the amplitude of the two-dimensional Fourier transform is the NPS. There are many details related to measuring the NPS properly, including eliminating background trends, and the size of the region over which the Fourier transform is taken. These are all covered in detail in the references [6,8-18].

Measurement of imaging properties is easier on digital imaging systems than on film, since film must first be digitized at appropriately fine sampling intervals or else corrected for the use of one-dimensional slits [19]. However, the effects of aliasing (fictitious frequency response in a digital system due to limited sampling) makes the interpretation of MTF and NPS in digital systems more difficult than with film [11,12,20].

79.3 X-Ray Imaging

X-ray imaging requires an X-ray-generating apparatus (tube, high voltage supply, and controls) and an appropriate X-ray detector. Typical X-ray detectors include photographic film (almost always used in concert with a fluorescent screen), image intensifiers, computed radiography phosphor plates, and newer dedicated digital detectors.

The X-ray generator is basically a high-voltage step-up transformer with appropriate rectification and control circuitry. Most contemporary generators are three-phase 12-pulse, full-wave rectified to give a very low voltage ripple (3 to 10%) [21]. For procedures requiring very fast pulses of several milliseconds or less (such as coronary angiography), a tetrode-based constant-potential generator is used. The operator selects the tube kilovoltage, tube current, and exposure time appropriate for the examination of interest.

X-ray tubes contain a heated filament (which serves as the cathode) and an anode made of a tungsten/rhenium combination for conventional use or molybdenum for mammography. With the exception of dental tubes, modern clinical X-ray tubes almost always contain a rotating anode to spread the heat out over a larger area, allowing for a greater tube output without damaging the anode. Many tubes contain two filaments, a large one and a small one, depending on tube output and resolution requirements of a particular exam. Measurements on X-ray tubes and generators involve calibrations to assure that kilovoltage, tube output, and exposure time are in good agreement with the control console settings [21]. Calibration of the high voltage is done by commercially available voltage dividers, or by specially designed X-ray film cassettes with calibrating filters inside. Tube output is measured by ion chambers, and exposure time is measured either by a rotating-arm timer test tool placed over a film cassette during an X-ray exposure or by direct plotting of the exposure vs. time output of an ion chamber.

X-Ray Imaging Detectors

The most common detector for X-ray imaging is film. X-ray film is typically placed in a sandwich between two fluorescent screens (or one screen in mammography for improved visibility of small detail). Contemporary screens are made of rare earth compounds such as $\text{Gd}_2\text{O}_2\text{S}$, and serve to convert the X-rays to visible light which exposes the film more efficiently than X-rays alone, thus reducing patient radiation dose. The response of these screen–film combinations has good contrast at intermediate exposure ranges (as given by the film γ , or contrast ratio), but poor contrast at low or high exposures. The contrast and latitude of films are described by the characteristic curve (often referred to as the Hurter–Driffield, or HD curve). Appropriate screen–film combinations are chosen based on the anatomy to be imaged, since screen–film combinations are designed with different contrast, latitude, and exposure sensitivity characteristics [22].

A second type of X-ray detector is the image intensifier, which is used with fluoroscopy. Fluoroscopy uses a low-exposure-rate X-ray output to image a patient continuously, typically to properly position the patient for a subsequent high-exposure film image. The image intensifier (Figure 79.1) comprises a cylindrical glass enclosure, inside of which is an input screen, photocathode, focusing electrodes, accelerating anode, and output screen [21]. The X-rays are absorbed in the input screen (typically CsI), giving off light which liberates electrons from the photocathode. The photoelectrons are then accelerated to the output screen where they strike the output phosphor screen with high energy (~ 30 keV), giving off a bright light, which is viewed by either a video camera or motion-picture (cineradiographic) camera.

A recently developed digital X-ray detector is the photostimulable phosphor, which is referred to commonly as computed radiography [23–25]. This detector uses a special type of phosphor which stores about half of the absorbed X-ray energy in metastable states, which are read out later by laser scanning. The laser light stimulates the phosphor to emit ultraviolet light in proportion to the original X-ray exposure. The photostimulated light is then detected with a photomultiplier tube (PMT) or solid-state photodetector and digitized. The clinical apparatus (Figure 79.2) first does a prescan of the imaging plate to adjust the input range of the analog-to-digital converter based on the image histogram; the digitized signal is then logarithmically transformed and stored, displayed on a video monitor, or printed on film following optional spatial filtering and contrast adjustment.

There are also currently available or in development a variety of other digital X-ray detectors, including selenium plate detectors [26], CCD-camera detectors with fluorescent screens [27], and flat-panel arrays with amorphous silicon [28] or amorphous selenium [29] detector elements.

79.4 Computed Tomography

A diagnostic computed tomography (CT) scanner comprises an X-ray tube with collimation to provide the slice thickness, a linear array of detector elements, and a reconstruction computer. The X-ray tube and the detectors typically rotate in a gantry. The number of detectors used depends on the generation of the scanner. First-generation scanners had only one detector which was translated across the patient with the tube for each projection, and then the entire assembly was rotated to acquire the next projection view. To increase acquisition speed, second-generation scanners used several detectors in a limited fan-beam geometry. Third-generation CT scanners, which are the most common in use today, utilize a large fan array of detectors (852 elements in a current scanner), which completely encompasses the patient and allows slice acquisition times of about 1 s [21]. The X-ray tube and the detector fan array are mechanically coupled and rotate together at high speed (Figure 79.3).

The implementation of electronic slip rings, which allow continuous electric contact, has removed the physical restriction imposed by the high-voltage cables of earlier scanners. Fourth- and fifth-generation scanners have a stationary, complete ring of detectors (typically 1200 to 4800 detectors). In fourth-generation scanners the X-ray tube is rotated alone, while the fifth-generation scanner design has a focused electron beam which traverses multiple target rings. Fifth-generation scanners can acquire a slice

FIGURE 79.1 Schematic diagram of the major components of an image intensifier. The anode is typically at about 30 kV, and the three annular electrodes focus the beam and determine the usable area of the input surface for intensifiers having multiple formats.

fast enough (50 ms per slice and 17 slices per second) to stop cardiac motion [30,31]. These last two generations are not in common use, primarily due to high cost. In recent years, a helical-scan adaptation of third-generation scanners, allowing continuous acquisition of data over a large patient volume, has become clinically popular [32,33].

While the X-ray tubes used for CT (tube potential range 80 to 140 kV) are very similar to general radiographic tubes, the detectors are quite different from conventional radiographic detectors. Detectors used in CT are one-dimensional photon counters which must be efficient and fast. Early CT devices used scintillation detectors, which converted the X-ray energy into light photons that were counted by PMTs. Originally, single-crystal NaI was used, but it proved to be insufficient in dynamic range and had too much afterglow of scintillation light. High-pressure (25 atm) xenon gas later replaced NaI as the detector. Currently, many CT scanners use scintillating ceramics (e.g., CdWO_4 , $(\text{Y,Gd})_2\text{O}_3\text{:Eu}$ and $\text{Gd}_2\text{O}_2\text{S:Pr,Ce}$) coupled to photodiodes, due to the high bulk density of the ceramics.

FIGURE 79.2 Schematic diagram of a typical photostimulable phosphor computed radiography system.

Reconstruction of an Object from Projections

CT is based on the image reconstruction theorem, which states that if one measures enough projections of an object, the two-dimensional distribution of that object may be reconstructed from the projection data. In CT the quantity of interest is the linear attenuation coefficient, μ , at each point in the object. The transmission of X-rays through an object of thickness x can be stated as

$$I(x) = I(0)e^{-\mu x} \quad (79.4)$$

where $I(0)$ is the incident intensity. Each ray from the focal spot of the tube to a discrete detector element is a measure of the line integral of the attenuation coefficient through the patient:

$$\lambda(x_r) = -\ln \frac{I(x_r)}{I(0)} = \int_{\ell} \mu(x_r, y_r) dy_r \quad (79.5)$$

where r represents the reference frame of one of the many projections through the patient.

Image reconstruction requires a method to invert Equation 79.5, in order to extract $\mu(x, y)$ of the object from the measured projection views, λ . The mathematical principles of image reconstruction from an

FIGURE 79.3 Orientation of components in a typical third-generation CT scanner.

infinite number of projections through an object were developed by Radon in 1917 [34]. An approximate solution to the Radon inversion, known as backprojection, was later developed because of the need for rapid computation of images in clinical CT. Backprojection involves smearing the data from each projection through the two-dimensional space of the patient, and summing over all projections. Simple backprojection yields an estimate of the patient structures, but is plagued by artifacts due to the approximate nature of the reconstruction procedure. These artifacts are successfully removed, however, by prefiltering the projection data before backprojecting. The one-dimensional prefiltering is typically performed in frequency space by multiplying by a ramp function. This technique is known as filtered backprojection, and results in more accurate reconstructions of patient anatomy [35].

There are several conditions that can reduce the quality of image reconstruction. First, an insufficient number of angular projections or incomplete sampling of the object can lead to aliasing in the reconstructed view. Second, partial volume effects occur when the object is not of homogeneous composition in a particular voxel, causing the reconstructed pixel value (CT number) to be not representative of the tissue. Third, if the acquisition is not fast enough, patient motion leads to a ghosting artifact in the reconstructed image. Last, beam hardening occurs when a high-density structure, such as the skull, significantly changes the beam energy spectrum. The result is reduced intensity of adjacent structures. Beam hardening can be reduced by slightly altering the shape of the reconstruction filter to improve the reconstruction for a particular tissue type.

To present the reconstructed data in digital format, the CT number (also known as the Hounsfield unit, HU) was developed.

$$\text{CT number} \equiv 1000 \times \frac{\mu_{\text{pixel}} - \mu_{\text{water}}}{\mu_{\text{water}}} \quad (79.6)$$

Using this normalization, pixel values in a CT image are stored as 12-bit integers between -1000 and 3095. A pixel containing only water would have a CT number equal to 0, while one containing bone or muscle would have a positive value and one with only fat or air would have a negative value.

Clinical Measurements

The reconstructed images are only as accurate as the data input to the algorithm; therefore, a rigorous calibration and quality assurance program is vital to the performance of a diagnostic CT scanner. Calibration generates a baseline reference in air for the scanner and calibration values for every possible scan parameter. Detector channel variation and interaction, along with X-ray tube focal spot size and position are quantified. A phantom is used to measure detector response for typical beam widths (1, 3, 5, 7, and 10 mm) and tube potentials (80, 100, 120, and 140 kV). The positioning accuracy of the scanner is also checked.

Quality assurance seeks to establish and maintain consistent image quality [36,37]. A specialized Plexiglas phantom is used to monitor the low-contrast detectability and high-contrast resolution and noise characteristics of the system. The low-contrast portion of the phantom consists of a set of holes of different diameter in a thin polystyrene slab. The 0.75-mm-thick polystyrene, when submerged in water and scanned with a 10 mm slice thickness, yields low contrast in the holes of about 1% (10 HU). The minimum detectable diameter is then found. The high-contrast resolution part of the phantom contains several repeating, equally sized bar/space patterns (spaces filled with water, contrast ~12% or 120 HU) with bar widths from 0.5 to 1.6 mm. The MTF is computed as a plot of the high-contrast frequency response [38]. The noise and uniformity of the scan are assessed with a homogeneous section of the phantom. An ROI is placed in the homogeneous area and the standard deviation is calculated, which should be approximately 3 HU.

79.5 Nuclear Medicine

Nuclear medicine techniques [39,40] use radiopharmaceuticals which are injected into the body to monitor or measure physiological function. Central to nuclear medicine is the role of the radiopharmaceutical as a tracer, that is, an agent with a predictable physiological action that is introduced without perturbing the function of the system. An external detector is used to record radioactivity emanating from the patient to determine the spatial distribution (and often temporal changes in concentration) of the radiopharmaceuticals in specific organs or tissues. Each radiopharmaceutical has an expected biodistribution which a radiologist evaluates to diagnose the medical status of a patient. The radiopharmaceutical can be labeled either with positron-emitting radionuclides, which produce annihilation photons, or can be labeled with “single-photon” radionuclides which emit γ -rays (or sometimes X-rays). This section considers only single-photon-emitting radionuclides, examples of which are given in [Table 79.1](#).

The scintillation camera [41,42] is the most common device for imaging the distribution of single-photon emitting radionuclides *in vivo* ([Figure 79.4](#)). The scintillation camera incorporates a large-field (e.g., 40 by 50 cm) position-sensitive photon detector with a collimator having a large number of small parallel holes (1 to 2 mm diameter, 4 cm length) so that only photons traveling perpendicular to the detector surface are recorded. Photons emitted by the patient and passing through the collimator are absorbed by a 1-cm-thick sodium iodide scintillator coupled to an array of PMTs. The PMT signals are processed to generate signals proportional to the (x,y) -coordinates of the interaction site of the photon in the crystal. In addition, the photomultiplier tube signals are integrated to calculate the photon energy. Events falling within a specified range (typically $\pm 7.5\%$) around the expected radionuclide photon energy are recorded, whereas those outside of this range are rejected as unwanted scatter or background events. An image is integrated from individual events at the calculated position and specified energy, representing detected photons emitted by the radiopharmaceutical. The camera acquires a planar projection image of the radiopharmaceutical distribution in the patient with a spatial resolution of about 1 cm. The image also can be acquired tomographically by rotating the scintillation camera around the axis of the patient.

Adapted from Sorenson and Phelps.⁴²

This technique is called single-photon emission computed tomography (SPECT) and produces cross-sectional images representing the radiopharmaceutical concentration within the patient.

Measurement of Physiological Function

Radionuclide images can be interpreted visually or quantitatively. For example, the radiopharmaceutical $^{99\text{m}}\text{Tc}$]-methylene diphosphonate (MDP) is incorporated into the bone matrix by osteoblastic activity [43]. A radiologist will inspect a nuclear medicine image for sites demonstrating focal uptake of $^{99\text{m}}\text{Tc}$ -MDP to determine the extent and degree of trauma, inflammation, degeneration, metastatic disease, or other skeletal disease processes. Typically, $^{99\text{m}}\text{Tc}$ -MDP images are interpreted visually but are not analyzed to determine the quantity of radiotracer incorporated into the skeleton.

Other nuclear medicine studies are assessed quantitatively in the sense that values extracted from the image represent the radioactivity concentration (and physiological function) in a specific organ or tissue region. Myocardial perfusion imaging with $^{99\text{m}}\text{Tc}$]-hexakis-2-methoxyisobutylisocyanide (MIBI) is an example of one such “quantitative” nuclear medicine study for assessing a patient suspected of having coronary artery disease [44–46]. $^{99\text{m}}\text{Tc}$]-MIBI is a lipophilic cation which accumulates in myocardial tissue roughly in proportion to blood flow [47]. Image data are acquired using SPECT to reconstruct tomograms of the myocardial concentration of $^{99\text{m}}\text{Tc}$]-MIBI which are analyzed to assess regional myocardial blood flow. Although absolute measurements ($\mu\text{Ci/g}$) of tissue activity are difficult (if not impossible) to obtain with SPECT, the images are interpreted “quantitatively” by extracting pixel values from the image to derive diagnostic information [48], rather than relying on “qualitative” visual interpretation of the images. Typically, $^{99\text{m}}\text{Tc}$ -MIBI is imaged in the “short-axis” view which presents the left ventricular myocardium in a series of annuli (or “doughnuts”). The image is analyzed using a “circumferential profile” representing the radionuclide concentration at 6° angular increments around each annular slice of the myocardium [49]. The extracted values are compared with standard values obtained from patients in whom atherosclerotic disease has been excluded by coronary angiography, thereby

FIGURE 79.4 Scintillation camera incorporates collimator, scintillation crystal, photomultiplier tubes, and electronic circuitry to generate position (x,y) and energy (E) of photons emitted by radiopharmaceutical distribution in patient. Only events falling within a specified energy window are recorded by the processing or display device to form the nuclear medicine image.

allowing the nuclear cardiologist to assess both the presence as well as the regional extent of coronary artery disease.

Measurement of Technical Performance

Several parameters generally are measured to assess the performance of the scintillation camera [50-56]. *Spatial resolution* represents the precision with which the position of an event is localized, and can be assessed from the full-width at half-maximum (FWHM) of a profile taken across the image of a point or linear radioactive object having small dimensions in comparison to the resolution of the system. *Spatial linearity* is quantified as the accuracy with which the position of an event is localized, and represents the ability of a scintillation camera to produce a straight image of a straight object. Spatial linearity is measured as the deviation about the best-fit line in an image of a parallel line phantom or a orthogonal hole phantom, expressed as a percentage (ideally less than 1%) of the detector diameter. *Energy resolution* represents the precision with which the energy of a photon is recorded and generally is measured as the FWHM of the photopeak in an energy spectrum (number of detected photons recorded as a function of photon energy) of the radioactive source. *Flood field uniformity* assesses the ability of the camera to record a spatially uniform image when presented with a spatially uniform distribution of photons. An intrinsic measurement is performed by irradiating the uncollimated detector with the point source placed

at a distance equal to at least five times the field of view of the detector. The system uniformity can be checked by irradiating the entire surface of a collimated detector with an extended source of uniform radioactivity. *Sensitivity* represents the number of photons recorded per unit of source radioactivity when the detector is operated either without (intrinsic sensitivity) or with (extrinsic sensitivity) a collimator. *Count-rate linearity* represents the ability of the camera to record a count rate proportional to the photon event rate received by the detector. At low event rates, the measured count rate increases linearly with the actual photon event rate. Because the scintillation camera acts as a paralyzable system, at higher event rates, the measured count rate is lower than that predicted from linear response. At sufficiently high event rates, the measured count rate actually can decrease with increasing photon event rate and eventually can be extinguished when imaging radioactive sources of sufficiently high activities.

79.6 Positron Emission Tomography (PET)

PET involves a physiological administration of a positron-emitting radiopharmaceutical into the human body. The principal advantage of PET over single-photon imaging is the availability of a number of physiologically relevant radiotracers that are labeled with the short-lived positron-emitting radionuclides ^{11}C ($T_{1/2} = 20.4$ min), ^{13}N (9.96 min), ^{15}O (2.04 min), and ^{18}F (109.8 min). A typical PET center consists of a cyclotron for on-site isotope production, a radiochemistry laboratory for synthetic incorporation of the isotopes into organic molecules, and a PET scanner. PET instrumentation is described in detail in several review articles [67,68].

Principle of Coincidence Detection

The proton-rich radioisotopes used with PET imaging undergo β -decay, and emit positrons (antielectrons). A positron travels a short distance and combines with an electron from the surrounding medium. The masses of the positron and electron are converted to electromagnetic radiation in the form of two γ rays of energy 511 keV, which are emitted at nearly 180° to each other. The PET scanner utilizes multiple opposing γ detectors that surround the positron emitter, each defining a linear volume of response between the detectors. Coincidence timing circuitry enables effective localization of the decay events occurring between detector pairs, rejecting events in each detector that originate from outside the volume of response. A typical modern PET scanner employs tens of thousands of small detectors (or analogous position-coded larger detectors), yielding as many as tens of millions of such volumes of response. The coincidence principle is also utilized to measure and correct for attenuation of photons within the body, allowing the measurement of radioactivity concentration in absolute terms (i.e., Bq/mL). In this case, a separate “transmission” measurement scan is performed, using an external positron-emitting source placed adjacent to the subject yet within the volume of response. A “blank” scan is similarly acquired but without the subject in the field of view. The ratio of coincident count rates in the blank/transmission scans multiplies the corresponding coincidence counts in the emission scan to correct for attenuation along each coincidence line of response.

Detector Composition

The choice of detector material for PET scanners is influenced by a number of considerations, including scanner geometry, detection efficiency (stopping power), output signal strength (energy resolution), signal decay time (count rate capability), physical stability (i.e., hygroscopicity), availability, and cost. Inorganic scintillators are best suited for detection of the 511 keV photons. The physical properties of the two most widely used scintillators, NaI(Tl) and bismuth germanate (BGO), are shown in [Table 79.2](#). NaI(Tl) has found application in position-sensitive detector systems that utilize a small number of large crystals observed by multiple PMTs. NaI(Tl) offers the advantages of (1) good energy resolution for effective rejection of scattered radiation, (2) good timing resolution for minimizing the coincidence-resolving time window, (3) availability of large crystals, and (4) relatively low cost. The higher stopping

TABLE 79.2 Physical Properties of Scintillators Commonly Employed in PET Scanners

	NaI(Tl)	BGO
Density (g/cm ³)	3.67	7.13
Effective atomic number	51	75
Index of refraction	1.85	2.15
Relative emission intensity	100	15
Peak wavelength (nm)	410	480
Decay constant (ns)	230	300

FIGURE 79.5 Representation of PET scanner geometries for typical scanners employing (A) multiple rings of small BGO scintillators, and (B) six large NaI(Tl) position-sensitive planar detectors. The arrows represent positron annihilation photons that are emitted 180° from each other and detected in opposing detectors. (Courtesy of Dr. T. Turkington.)

power of BGO is advantageous for detector designs that use smaller crystals with one-to-one PMTs, or position-encoded matrices of crystals [69]. The recently identified lutetium oxyorthosilicate (LSO) is a potential successor to BGO in detector block designs. LSO has a density of 7.4 g/mL, an effective atomic number of 59, a photofluorescent decay time of 40 ns, and light outputs that are $\frac{3}{4}$ that of NaI(Tl) [70].

PET Scanners

PET scanners use a number of different detector compositions and gantry configurations, each with its unique advantages and disadvantages [68]. Figure 79.5 shows two of the most common designs that are currently employed. At present, the majority of commercial designs employ a cylindrical geometry with individual BGO detector blocks arranged to form contiguous rings of detectors, each defining an image plane [71,72]. Most of these scanners have retractable lead (or tungsten) septa which are positioned between detector rings to attenuate photons that are emitted at angles not contained in the image plane. This minimizes the effect of out-of-plane scattered radiation, allowing accurate quantitation of the radioactivity distribution in each image plane by two-dimensional (tomographic) image reconstruction. With the septa retracted, all axial angles are accepted, allowing true three-dimensional volume imaging. Another scanner design uses large-area position-encoded NaI(Tl) detectors, allowing three-dimensional volume imaging [73]. In all cases, computer-assisted image reconstruction is used to produce quantitative images of radiotracer concentration in the body.

The spatial resolution of the radioactivity distributions seen in the PET image is primarily determined by the size of the detector elements. In scanners employing cylindrical detector geometry, the in-plane spatial resolution is highest in the center of the field of view (typically 4 to 5 mm FWHM of the point source response for present state-of-the-art scanners). The spatial resolution slowly degrades as the radius increases due to inadequate stopping of photons within incident detectors for nonperpendicular entrance angles. Likewise, the resolution in the axial direction is determined by the axial dimension of the detector elements.

79.7 Ultrasound Imaging

Ultrasound scanning provides a safe and noninvasive way to image the body. With this modality, brief pulses of sound are emitted by a transducer coupled to the skin surface. The sound pulse propagates through tissue at a fixed speed. Interfaces and other objects reflect portions of the acoustic energy back to the transducer, where they are detected as echoes. The ultrasound scanner forms one-dimensional, or more commonly two-dimensional, images of anatomic structures from the reflected echo patterns. In general imaging applications, ultrasound imaging uses frequencies in the 2 to 10 MHz range. Some newer ultrasound devices, for example, those used in emerging ophthalmology applications, use frequencies as high as 50 MHz [74,75].

Characteristics of Sound Waves in Tissue

The speed at which sound waves propagate through a medium depends on the density and compressibility of the medium. At 22°C, the speed of sound in air is around 300 m s⁻¹, while in fresh water it is 1480 m s⁻¹. Human soft tissues behave somewhat like water, with speeds of sound ranging from 1460 m s⁻¹ for fat to 1620 m s⁻¹ for muscle. The average speed of sound in tissue is taken to be 1540 m s⁻¹ (1.54 mm/μs) [76,77].

Any interface, large or small, can reflect a fraction of the ultrasound energy and produce an echo. The relative amount of energy reflected depends on the change in density and compressibility at the interface; the greater the change in these properties of the materials forming the interface, the greater the amplitude of an echo. Examples of reflectors include organ boundaries, blood vessels, and small scatterers distributed more or less randomly throughout most organs. The majority of the echo data displayed on images can be attributed to this scattering process [77]. Shung [78] has reviewed experimental work on ultrasonic scattering vs. frequency in biological tissues.

As ultrasound pulses travel through tissue, they lose their strength due to attenuation. Attenuation is caused by scatter and reflection at interfaces and by absorption. For typical tissues, the amplitude of a 5-MHz beam decreases by about 50% for each centimeter traveled. The attenuation per unit distance is approximately proportional to the ultrasound frequency, so lower-frequency waves propagate greater distances through tissues than higher-frequency waves [79].

B-Mode Imagers

Figure 79.6 illustrates a typical configuration for an ultrasound imager. The operator places a handheld transducer on the skin surface of the patient. Early instruments utilized “single-element” transducers, but the majority of systems now use transducer arrays [80]. Acoustic pulses emitted by the transducer travel in well-defined beams. This beam can be “steered” in different directions, either mechanically with motors or electronically by using transducers arrays.

The same transducer detects echoes that arrive from interfaces in the body and applies them to the receiver, where they are amplified and processed for display. The instrument converts each echo signal into a dot on the display, the brightness of the dot being proportional to the echo amplitude at the transducer. The “scan converter” memory places dots in a location that corresponds to the reflector locations; information required to do this is the return time for each echo and the beam axis direction when the echo is detected.

The scanner constructs a cross-sectional image by sending out 100 to 200 such ultrasound beams, each in a slightly different direction, somewhat like a searchlight scanning the night sky. Echoes received from each beam direction are placed in the image memory using the scheme mentioned above. The entire image is updated at rates of 15 to 30 scans per second, producing a real-time image on the display monitor. This technique is referred to as B-mode imaging because echo signals simply modulate the intensity, or brightness, of the display at locations corresponding to their anatomic origin.

FIGURE 79.6 Components in a typical B-mode ultrasound device.

Doppler Techniques

Ultrasound instruments commonly provide Doppler records as well as B-mode images. Fundamentally, the Doppler effect is a change in the frequency of reflected waves when there is relative motion between the transducer and reflector. For motion directly toward or directly away from the transducer, the Doppler signal frequency f_d is given by

$$f_d = \frac{2f_0v}{c} \quad (79.7)$$

where f_0 is the frequency of the transmitted ultrasound, v is the velocity of the reflector, and c is the speed of sound. Thus, the Doppler signal frequency provides information on reflector velocity.

Continuous wave (CW) Doppler instruments consist of a transducer with separate transmitting and receiving elements, a transmitter–receiver unit, and a signal display. They extract a Doppler signal from the complex echo pattern, usually by heterodyning the echo signal with a signal that is coherent with the transmitted wave, and then low pass filtering. The most common applications are to detect and measure

blood flow. With a 5-MHz ultrasound frequency and blood velocity of 50 cm/s, the Doppler signal frequency is 3.25 kHz, i.e., in the audible frequency range. A simple loudspeaker may be all that is necessary for interpreting the Doppler signal, but very often a real-time spectral analyzer is available.

Pulsed Doppler instruments are a bit more complicated, but allow the operator to define precisely the distance from the transducer from which Doppler signals are selected. In pulsed Doppler, an acoustic pulse is transmitted along a fixed beam line. Resultant echo signals are amplified and subjected to Doppler processing methods, similar to those outlined for the CW instrument. An operator-adjusted gate captures the waveform from the depth of interest, and a sample-hold device retains the value of this waveform until a subsequent pulse–echo sequence. Because the phase of the echo signal from moving reflectors changes from one pulse–echo sequence to the next, a Doppler signal can be constructed from the behavior over time of the sample-hold value.

Color Doppler Imaging

Color flow imagers may be thought of as extensions of pulsed Doppler machines. Rather than detecting Doppler signals from a single location, color flow imagers detect signals from all depths covered by the ultrasound beam, and for many beam directions. Most instruments extract and display the mean Doppler signal frequency for each location throughout the scanned field [81,82]. A color Doppler image is almost always combined with a B-mode image to provide both anatomic and flow data from the scanned plane.

Measurement of Ultrasound Instrument Performance

Defining “image quality” in ultrasound, and specifying quantifiable factors that relate to optimal B-mode imaging, is controversial to say the least. Important factors that are considered include spatial and contrast resolution, sensitivity, penetration depth, and geometric accuracy.

High-quality ultrasound imagers interrogate the scanned field using a sufficient number of individual beam lines (more than 100) such that gaps between lines can be ignored in resolution considerations. An exception may be in color flow imaging, where sparse line densities are needed for sufficient frame rates [77]. Thus, spatial resolution is dictated by the volume of the ultrasound pulse propagating through the tissue. The dimension of this pulse volume in the direction the pulse travels, i.e., the axial resolution, is determined by the duration of the pulse emitted by the transducer, while the dimension perpendicular to the beam axis, or the “lateral resolution” is determined by the beam width. Although ultrasound beam energy is concentrated near the axis, it is the nature of beams from finite-sized apertures that the intensity falls off gradually with increasing distance from the beam axis. Finally, the size of the ultrasound beam perpendicular to the image plane determines the “slice thickness,” the width of the volume of tissue contributing to the echo data viewed in the image plane.

A variety of methods have been used for determining in-plane resolution. The lateral and axial dimensions of a reflector whose size is small enough that it can be considered a pointlike object are frequently used [83]. For a 3.5-MHz transducer, this “spot-size,” can be as small as 0.7 mm in the axial dimension and 1 to 2 mm laterally. Smaller spot sizes are found with higher-frequency imagers, such as those using 10 MHz scan heads. Also, larger spot sizes are obtained with scanners that use fixed-focus, single-element transducers.

Slice thickness has been measured using a planar sheet of scatterers scanned with the ultrasound scanning plane intersecting the sheet at a 45° angle [83]. If the slice thickness were negligible, the image of the sheet in this projection would be a straight, horizontal line. The finite thickness of the scanned slice causes a thickening of the line; in fact, for the 45° orientation the vertical size of the image of the sheet corresponds to the slice thickness. For all ultrasound imaging systems, except annular array transducers, the slice thickness is the worst measure of spatial resolution, ranging from the 10 mm to 2 to 3 mm, depending on depth, for a 3.5-MHz transducer.

Physicians commonly use ultrasound imagers to detect cancerous tumors, for which the echoes are slightly stronger or weaker than the surrounding region. “Contrast-detail” tests [84,85] measure the

smallest object that can be visualized at a fixed backscatter difference. Spherical mass detectability [86] assesses capabilities to visualize realistic focal lesions. Masses in the latter detection test are characteristic of actual tumors; furthermore, they are easily distributed throughout the scanning plane, assessing resolution at all depths.

Scanner sensitivity is an important performance feature, especially because spatial resolution can be enhanced with higher-frequency transducers. However, this is at the expense of increased ultrasound beam attenuation and poorer penetration. Although absolute measurements of sensitivity of scanners have been done [87], most centers rely upon clinically meaningful “maximum visualization distances” [83,88] for estimating and comparing sensitivity. Geometric accuracy also is important, as images frequently are used to determine structure dimensions, such as fetal head size when determining gestational age [89]. Calibration of distance measurements are done following standard protocols [83,90]; fortunately, modern scanners with digitally based image formation maintain their accuracy much better than previous systems, and many physicists maintain that tests for geometric accuracy are not crucial in routine performance assessments.

79.8 Magnetic Resonance Imaging (MRI)

Magnetic resonance (MR) imaging is a new medical imaging modality which uses magnetic fields and radiofrequency (RF) energy to produce images of the body. The technique is based on nuclear magnetic resonance (NMR) [91], which is a quantum mechanical phenomenon exhibited by atoms having either an odd number of protons or neutrons. Such atoms have a nonzero nuclear magnetic moment, μ , and will precess (or rotate) about an external magnetic field (\mathbf{B}_0) with a frequency of $\omega_0 = \gamma \mathbf{B}_0$, where γ is the gyromagnetic ratio which for ^1H is 42.57 MHz/T. A number of isotopes (including ^1H , ^{31}P , ^{23}Na , ^2H) exhibit the NMR phenomena; however, the majority of MR scanners image ^1H . This is because, relative to other isotopes, ^1H has a high inherent sensitivity and abundance in tissue. Therefore, the following discussion is limited to ^1H MR imaging. When placed in a \mathbf{B}_0 field, ^1H nuclei align their spins either parallel or antiparallel to \mathbf{B}_0 , with a slight excess in the lower energy parallel state. At $T = 25^\circ\text{C}$ and $|\mathbf{B}_0| = 1.5\text{ T}$, an excess of ~ 5 in 10^6 atoms are in the parallel state (this excess increases with \mathbf{B}_0 and T^{-1}). Because there are $\sim 10^{23}$ ^1H per milliliter of tissue, this excess, when summed over even a small volume, results in a net magnetization, $\mathbf{M} = \Sigma \mu$.

MR Imaging Techniques

The Bloch equations [91,92] are a set of phenomenological equations that succinctly describe the evolution of the net magnetization $\mathbf{M}(\mathbf{r},t)$ during an MR imaging experiment:

$$\frac{\partial \mathbf{M}(\mathbf{r},t)}{\partial t} = \gamma \mathbf{M}(\mathbf{r},t) \times \mathbf{B}(\mathbf{r},t) - \frac{M_x(t)\hat{x} + M_y(t)\hat{y}}{T_2} + \frac{(M_z(t) - M_0)\hat{z}}{T_1} \quad (79.8)$$

where $\mathbf{M}(\mathbf{r},t) = (M_x(t), M_y(t), M_z(t))$; M_0 is the initial (or equilibrium) magnetization, $\mathbf{B}(\mathbf{r},t) = \mathbf{B}_0 + \mathbf{G}(\mathbf{r},t) \cdot \mathbf{r} + \mathbf{B}_1(t)$ is the total applied magnetic field and includes terms representing the static field, \mathbf{B}_0 , the field gradients, $\mathbf{G}(\mathbf{r},t) \cdot \mathbf{r}$; and the magnetic field component of any applied RF excitation, $\mathbf{B}_1(t)$; and T_1 and T_2 are the characteristic relaxation times of the tissues being imaged. The coordinate system is described in Figure 79.7. The \mathbf{B}_0 and $\mathbf{G}(\mathbf{r},t) \cdot \mathbf{r}$ fields are parallel to z , and the \mathbf{B}_1 field is orthogonal to z . Every MR imaging experiment consists of an excitation phase, in which the equilibrium magnetization is tipped away from z (the longitudinal axis) and into the transverse (x - y) plane. This is followed by a detection phase, in which the signal emitted by the excited spins is manipulated so that an echo forms. The echo-time (TE) and the repetition-time (TR) denote the time between excitation and echo formation,

FIGURE 79.7 Graphical depiction of the MR imaging process showing the effect of the B_1 -excitation pulse (a–b) and formation of a spin-echo (c–f). In (a) an RF pulse, B_1 , is applied along the x axis causing the net magnetization to tip away from equilibrium, M_0 , as it precesses about z. Viewed in the rotating frame of reference, this corresponds to a nutation by some angle α in the y' – z plane. After application of an $\alpha = 90^\circ$ pulse, M lies in the x' – y' plane (c) and is subject to variations in the local magnetic field which cause the individual spins to precess at different frequencies, i.e., μ_1 and μ_n in (d). The local field variations could be due to gradients or field inhomogeneity, the latter effect leading to T_2^* signal loss. By applying an $\alpha = 180^\circ$ RF pulse along y' , the spins are rotated about y' (e) and are refocused into an echo (f).

and the time between successive excitation phases, respectively. Starting at equilibrium, RF energy at ω_0 is applied to create an oscillating $\mathbf{B}_1(t)$ field which tips \mathbf{M} toward the transverse plane, at which time it begins to precess about z (Figure 79.7a). Viewed in a frame of reference rotating at $-\omega_0$ about z (x', y', z), the RF excitation corresponds to tipping \mathbf{M} through an angle α from z (Figure 79.7b). Gradients, $\mathbf{G}(\mathbf{r}, t)$, are then applied so that spatial information is encoded into the precessional frequency of \mathbf{M} , $\omega = \gamma[\mathbf{B}_0 + \mathbf{G}(\mathbf{r}, t) \cdot \mathbf{r}]$. Additional gradients and/or RF-excitation pulses are used to refocus the magnetization into an echo (Figure 79.7c through f). The precessing transverse component of the magnetization ($M_{xy} = M_x + jM_y$) induces a signal (EMF) in the receiver coil, and this is recorded during echo formation. The experiment is repeated many times (normally 128 to 256) using predetermined gradient strengths [93] so that a complete data set is collected. These data are in spatial-frequency space (known as \mathbf{k} -space) and images are reconstructed after taking the multidimensional Fourier transform of \mathbf{k} -space [94]. Gradients can be used to encode spatial information along all axes, so either two-dimensional (planar) or three-dimensional (volume) imaging is possible with MR.

MR Image Contrast

Excited spins undergo two principal relaxation processes, spin-lattice and spin-spin relaxation. Spin-lattice relaxation occurs when spins lose energy to surrounding molecules and return to the equilibrium position, M_0 . Spin-spin relaxation is due to local interactions which cause spins to precess at different rates, resulting in a reduction in M_{xy} (Figure 79.7d). Field inhomogeneity due to an imperfect magnet is reversible ($\delta\mathbf{B}(\mathbf{r})$), while inhomogeneity due to variations in local chemical structure is not. The relaxation times T1 and T2 characterize spin-lattice and spin-spin relaxation processes, respectively, and from the Bloch equation (Equation 79.8) the following equations can be derived for the relaxation of spins tipped by $\alpha = 90^\circ$ at $t = 0$:

$$M_z(t) = M_0(1 - e^{-t/T_1}) \quad \text{and} \quad M_{xy}(t) = M_{xy}(t=0)e^{-t/T_2} \quad (79.9)$$

Together with the differences in the inherent proton density between tissues, differences in T1 and T2 are the basis of the contrast seen in MR images. A spin-echo (SE) acquisition uses one or more additional RF excitations with $\alpha = 180^\circ$ to refocus the reversible component of spin-spin relaxation so that one or more echoes are formed. Equation 79.9 shows that images with primarily T1 weighting, T2 weighting, or proton density weighting result when relative to T1 and T2: TR and TE are short, TR and TE are long, and TR is long and TE is short, respectively. In practice, images with a pure weighting are not obtainable because image contrast is due to a mixture of these contrast mechanisms. Gradient-recalled echo (GRE) imaging uses additional gradients, instead of an $\alpha = 180^\circ$ pulse, to produce echoes and results in images with significantly shorter TR and TE than SE techniques. GRE images, however, do not refocus the reversible component of spin-spin relaxation and are thus susceptible to T2* signal loss, where $1/T_2^* = 1/T_2 + 2\pi\gamma|\delta\mathbf{B}(\mathbf{r})|$. This leads to lower signal-to-noise in GRE images compared with SE images. Since TR is short compared with T1, GRE images tend to have T1 weighting. If TE approaches T2*, then the T2* weighting becomes significant.

MR Instrumentation

The key components of a modern MR imaging system include a magnet, a pulse sequencer, gradient and shim coils, and an RF transmitter/receiver — the function of which are controlled by a host computer (Figure 79.8). To obtain the \mathbf{B}_0 -field, most commercial scanners use superconducting magnets, although some special-purpose (and often lower-cost) scanners may use resistive magnets. Superconducting magnets generally have field strengths between 0.5 and 4.0 T, while resistive magnets normally have field strengths < 0.3 T. The improved signal-to-noise ratio obtained with superconducting designs is offset by the need for periodic cryogen replacement. More modern magnets, however, minimize this cost by including a cryogen reliquefier. Two sets of auxiliary gradient coils are located within the main magnet

FIGURE 79.8 Overview of an MR scanner showing key components.

to provide spatially varying fields, $\mathbf{G}(\mathbf{r},t)$, and to allow shimming of the \mathbf{B}_0 -field. Current gradient coil hardware can generate maximum gradients of up to 40 mT/m with rise times of 120 μs and allow fields of view from 4 to 48 cm. Shim coils improve the homogeneity of the \mathbf{B}_0 field by decreasing $\delta\mathbf{B}(\mathbf{r})$ to a few parts per million in order to minimize $T2^*$ effects and spatial distortions. Modern scanners incorporate a digital RF subsystem which excites the spins and then records the emitted signals via one or more RF coils within the magnet. An RF synthesizer is coupled to both the RF transmitter and receiver, so that synchronous detection is possible. The RF system is connected either to separate transmit and receive coil(s) or to a combined transmit/receive coil(s).

To acquire an MR image, the host computer interacts with the operator who defines the imaging parameters (such as α , TR and TE, slice location, and field of view). The parameters are then translated into instructions which are executed on a synchronous state machine known as a pulse sequencer. This device provides real-time control of the gradient and RF waveforms as well as other control functions, such as unblanking the RF receiver and enabling the ADC during an echo. Data are collected and demodulated by the receiver, and then images are reconstructed using specialized hardware built normally around a fast-array processor. The images are sent to the host computer for operator station display, archival or filming. In addition, many MR scanners incorporate devices for monitoring heart and respiration rate, and allow these signals to trigger or gate image acquisition. Future MR imaging systems will probably include higher \mathbf{B}_0 -field and gradients, and faster data processing/reconstruction hardware. In addition to current imaging apparatus, it is likely that dedicated instruments will be increasingly used to study the heart and for performing neurofunctional imaging and MR-guided interventional procedures.

80.1 Introduction

Signals from sensors do not usually have suitable characteristics for display, recording, transmission, or further processing. For example, they may lack the amplitude, power, level, or bandwidth required, or they may carry superimposed interference that masks the desired information.

Signal conditioners, including amplifiers, adapt sensor signals to the requirements of the receiver (circuit or equipment) to which they are to be connected. The functions to be performed by the signal conditioner derive from the nature of both the signal and the receiver. Commonly, the receiver requires a single-ended, low-frequency (dc) voltage with low output impedance and amplitude range close to its power-supply voltage(s). A typical receiver here is an analog-to-digital converter (ADC).

Signals from sensors can be analog or digital. Digital signals come from position encoders, switches, or oscillator-based sensors connected to frequency counters. The amplitude for digital signals must be compatible with logic levels for the digital receiver, and their edges must be fast enough to prevent any false triggering. Large voltages can be attenuated by a voltage divider and slow edges can be accelerated by a Schmitt trigger.

Analog sensors are either self-generating or modulating. *Self-generating sensors* yield a voltage (thermocouples, photovoltaic, and electrochemical sensors) or current (piezo- and pyroelectric sensors) whose

bandwidth equals that of the measurand. Modulating sensors yield a variation in resistance, capacitance, self-inductance or mutual inductance, or other electrical quantities. *Modulating sensors* need to be excited or biased (semiconductor junction-based sensors) in order to provide an output voltage or current. Impedance variation-based sensors are normally placed in voltage dividers, or in Wheatstone bridges (resistive sensors) or ac bridges (resistive and reactance-variation sensors). The bandwidth for signals from modulating sensors equals that of the measured in dc-excited or biased sensors, and is twice that of the measurand in ac-excited sensors (sidebands about the carrier frequency) (see Chapter 81). Capacitive and inductive sensors require an ac excitation, whose frequency must be at least ten times higher than the maximal frequency variation of the measurand. Pallás-Areny and Webster [1] give the equivalent circuit for different sensors and analyze their interface.

Current signals can be converted into voltage signals by inserting a series resistor into the circuit. Graeme [2] analyzes current-to-voltage converters for photodiodes, applicable to other sources. Henceforth, we will refer to voltage signals to analyze transformations to be performed by signal conditioners.

80.2 Dynamic Range

The **dynamic range** for a measurand is the quotient between the measurement range and the desired resolution. Any stage for processing the signal from a sensor must have a dynamic range equal to or larger than that of the measurand. For example, to measure a temperature from 0 to 100°C with 0.1°C resolution, we need a dynamic range of at least $(100 - 0)/0.1 = 1000$ (60 dB). Hence a 10-bit ADC should be appropriate to digitize the signal because $2^{10} = 1024$. Let us assume we have a 10-bit ADC whose input range is 0 to 10 V; its resolution will be $10\text{ V}/1024 = 9.8\text{ mV}$. If the sensor sensitivity is 10 mV/°C and we connect it to the ADC, the 9.8 mV resolution for the ADC will result in a $9.8\text{ mV}/(10\text{ mV}/^\circ\text{C}) = 0.98^\circ\text{C}$ resolution! In spite of having the suitable dynamic range, we do not achieve the desired resolution in temperature because the output range of our sensor (0 to 1 V) does not match the input range for the ADC (0 to 10 V).

The basic function of voltage amplifiers is to amplify the input signal so that its output extends across the input range of the subsequent stage. In the above example, an amplifier with a gain of 10 would match the sensor output range to the ADC input range. In addition, the output of the amplifier should depend only on the input signal, and the signal source should not be disturbed when connecting the amplifier. These requirements can be fulfilled by choosing the appropriate amplifier depending on the characteristics of the input signal.

80.3 Signal Classification

Signals can be classified according to their amplitude level, the relationship between their source terminals and ground, their bandwidth, and the value of their output impedance. Signals lower than around 100 mV are considered to be low level and need amplification. Larger signals may also need amplification depending on the input range of the receiver.

Single-Ended and Differential Signals

A *single-ended signal* source has one of its two output terminals at a constant voltage. For example, Figure 80.1a shows a voltage divider whose terminal L remains at the power-supply reference voltage regardless of the sensor resistance, as shown in Figure 80.1b. If terminal L is at ground potential (grounded power supply in Figure 80.1a), then the signal is single ended and grounded. If terminal L is isolated from ground (for example, if the power supply is a battery), then the signal is single ended and floating. If terminal L is at a constant voltage with respect to ground, then the signal is single ended and driven off ground. The voltage at terminal H will be the sum of the signal plus the off-ground voltage. Therefore, the off-ground voltage is common to H and L; hence, it is called the **common-mode voltage**. For example, a thermocouple bonded to a power transistor provides a signal whose amplitude depends on the temperature of the transistor case, riding on a common-mode voltage equal to the case voltage.

(a)

(b)

FIGURE 80.1 Classes of signals according to their source terminals. A voltage divider (a) provides a single-ended signal (b) where terminal L is at a constant voltage. A Wheatstone bridge with four sensors (c) provides a balanced differential signal which is the difference between two voltages v_H and v_L having the same amplitude but opposite signs and riding on a common-mode voltage V_c . For differential signals much smaller than the common-mode voltage, the equivalent circuit in (e) is used. If the reference point is grounded, the signal (single-ended or differential) will be grounded; if the reference point is floating, the signal will also be floating.

A *differential signal* source has two output terminals whose voltages change simultaneously by the same magnitude but in opposite directions. The Wheatstone bridge in [Figure 80.1c](#) provides a differential signal. Its equivalent circuit ([Figure 80.1d](#)) shows that there is a differential voltage ($v_d = v_H - v_L$) proportional to x and a common-mode voltage ($V_c = V/2$) that does not carry any information about x . Further, the two output impedances are balanced. We thus have a balanced differential signal with a superimposed common-mode voltage. Were the output impedances different, the signal would be unbalanced. If the bridge power supply is grounded, then the differential signal will be grounded; otherwise, it will be floating. When the differential signal is very small as compared with the common-mode voltage, in order to simplify circuit analysis it is common to use the equivalent circuit in [Figure 80.1e](#). Some differential signals (grounded or floating) do not bear any common-mode voltage.

(c)

(d)

FIGURE 80.1 (continued)

Signal conditioning must ensure the compatibility between sensor signals and receivers, which will depend on the relationship between input terminals and ground. For example, a differential and grounded signal is incompatible with an amplifier having a grounded input terminal. Hence, amplifiers must also be described according to their input topology.

Narrowband and Broadband Signals

A *narrowband signal* has a very small frequency range relative to its central frequency. Narrowband signals can be dc, or static, resulting in very low frequencies, such as those from a thermocouple or a weighing

(e)

FIGURE 80.1 (continued)

scale, or ac, such as those from an ac-driven modulating sensor, in which case the exciting frequency (carrier) becomes the central frequency (see Chapter 81).

Broadband signals, such as those from sound and vibration sensors, have a large frequency range relative to their central frequency. Therefore, the value of the central frequency is crucial; a signal ranging from 1 Hz to 10 kHz is a broadband instrumentation signal, but two 10 kHz sidebands around 1 MHz are considered to be a narrowband signal. Signal conditioning of ac narrowband signals is easier because the conditioner performance only needs to be guaranteed with regard to the carrier frequency.

Low- and High-Output-Impedance Signals

The output impedance of signals determines the requirements of the input impedance of the signal conditioner. Figure 80.2a shows a voltage signal connected to a device whose input impedance is Z_d . The voltage detected will be

$$v_d = v_s \frac{Z_d}{Z_d + Z_s} \quad (80.1)$$

Therefore, the voltage detected will equal the signal voltage only when $Z_d \gg Z_s$; otherwise $v_d \neq v_s$ and there will be a *loading effect*. Furthermore, it may happen that a low Z_d disturbs the sensor, changing the value of v_s and rendering the measurement useless or, worse still, damaging the sensor.

At low frequencies, it is relatively easy to achieve large input impedances even for high-output-impedance signals, such as those from piezoelectric sensors. At high frequencies, however, stray input capacitances make it more difficult. For narrowband signals this is not a problem because the value for Z_s and Z_d will be almost constant and any attenuation because of a loading effect can be taken into account later. However, if the impedance seen by broadband signals is frequency dependent, then each frequency signal undergoes different attenuations which are impossible to compensate for.

Signals with very high output impedance are better modeled as current sources, Figure 80.2b. The current through the detector will be

(a)

(b)

FIGURE 80.2 Equivalent circuit for a voltage signal connected to a voltage detector (a) and for a current signal connected to a current detector (b). We require $Z_d \gg Z_s$ in (a) to prevent any loading effect, and $Z_d \ll Z_s$ in (b) to prevent any shunting effect.

$$i_d = i_s \frac{Z_s}{Z_d + Z_s} \quad (80.2)$$

In order for $i_d = i_s$, it is required that $Z_d \ll Z_s$, which is easier to achieve than $Z_d \gg Z_s$. If Z_d is not low enough, then there is a *shunting effect*.

80.4 General Amplifier Parameters

A *voltage amplifier* produces an output voltage which is a proportional reproduction of the voltage difference at its input terminals, regardless of any common-mode voltage and without loading the voltage source. Figure 80.3a shows the equivalent circuit for a general (differential) amplifier. If one input terminal is connected to one output terminal as in Figure 80.3b, the amplifier is single ended; if this common terminal is grounded, the amplifier is single ended and grounded; if the common terminal is isolated from ground, the amplifier is single ended and floating. In any case, the output power comes from the power supply, and the input signal only controls the shape of the output signal, whose amplitude is determined by the *amplifier gain*, defined as

(a)

(b)

FIGURE 80.3 General amplifier, differential (a) or single ended (b). The input voltage controls the amplitude of the output voltage, whose power comes from the power supply.

$$G = \frac{v_o}{v_d} \quad (80.3)$$

The ideal amplifier would have any required gain for all signal frequencies. A practical amplifier has a gain that rolls off at high frequency because of parasitic capacitances. In order to reduce noise and reject interference, it is common to add reactive components to reduce the gain for out-of-band frequencies further. If the gain decreases by n times 10 when the frequency increases by 10, we say that the gain (downward) slope is $20n$ dB/decade. The corner (or -3 dB) frequency f_0 for the amplifier is that for which the gain is 70% of that in the bandpass. (Note: $20 \log 0.7 = -3$ dB). The *gain error* at f_0 is then 30%, which is too large for many applications. If a maximal error ϵ is accepted at a given frequency f , then the corner frequency for the amplifier should be

$$f_0 = \frac{f(1-\epsilon)}{\sqrt{2\epsilon-\epsilon^2}} \approx \frac{f}{\sqrt{2\epsilon}} \quad (80.4)$$

For example, $\epsilon = 0.01$ requires $f_0 = 7f$, $\epsilon = 0.001$ requires $f_0 = 22.4f$. A broadband signal with frequency components larger than f would undergo amplitude distortion. A narrowband signal centered on a frequency larger than f would be amplified by a gain lower than expected, but if the actual gain is measured, the gain error can later be corrected.

Whenever the gain decreases, the output signal is delayed with respect to the output. In the above amplifier, an input sine wave of frequency f_0 will result in an output sine wave delayed by 45° (and with relative attenuation 30% as compared with a sine wave of frequency $f \gg f_0$). Complex waveforms having frequency components close to f_0 would undergo shape (or phase) distortion. In order for a waveform to be faithfully reproduced at the output, the phase delay should be either zero or proportional to the frequency (linear phase shift). This last requirement is difficult to meet. Hence, for broadband signals it is common to design amplifiers whose bandwidth is larger than the maximal input frequency. Narrowband signals undergo a delay which can be measured and corrected.

An ideal amplifier would have infinite *input impedance*. Then no input current would flow when connecting the signal, Figure 80.2a, and no energy would be taken from the signal source, which would remain undisturbed. A practical amplifier, however, will have a finite, yet large, input impedance at low frequencies, decreasing at larger frequencies because of stray input capacitances. If sensors are connected to conditioners by coaxial cables with grounded shields, then the capacitance to ground can be very large (from 70 to 100 pF/m depending on the cable diameter). This capacitance can be reduced by using driven shields (or guards) (see Chapter 89). If twisted pairs are used instead, the capacitance between wires is only about 5 to 8 pF/m, but there is an increased risk of capacitive interference.

Signal conditioners connected to remote sensors must be protected by *limiting* both *voltage* and *input currents*. Current can be limited by inserting a power resistor (100Ω to $1 \text{ k}\Omega$, 1 W for example), a PTC resistor or a fuse between each signal source lead and conditioner input. Input voltages can be limited by connecting diodes, zeners, metal-oxide varistors, gas-discharge devices, or other surge-suppression nonlinear devices, from each input line to dc power-supply lines or to ground, depending on the particular protecting device. Some commercial voltage limiters are Thyzorb® and Transzorb® (General Semiconductor), Transil® and Trisil® (SGS-Thomson), SIOV® (Siemens), and TL7726 (Texas Instruments).

The ideal amplifier would also have zero *output impedance*. This would imply no loading effect because of a possible finite input impedance for the following stage, low output noise, and unlimited output power. Practical amplifiers can indeed have a low output impedance and low noise, but their output power is very limited. Common signal amplifiers provide at best about 40 mA output current and sometimes only 10 mA. The power gain, however, is quite noticeable, as input currents can be in the picoampere range (10^{-12} A) and input voltages in the millivolt range (10^{-3} V); a 10 V, 10 mA output would mean a power gain of 10^{14} ! Yet the output power available is very small (100 mW). Power amplifiers

are quite the opposite; they have a relatively small power gain but provide a high-power output. For both signal and power amplifiers, output power comes from the power supply, not from the input signal.

Some sensor signals do not require amplification but only *impedance transformation*, for example, to match their output impedance to that of a transmission line. Amplifiers for impedance transformation (or matching) and $G = 1$ are called buffers.

80.5 Instrumentation Amplifiers

For instrumentation signals, the so-called **instrumentation amplifier** (IA) offers performance closest to the ideal amplifier, at a moderate cost (from \$1.50 up). Figure 80.4a shows the symbol for the IA and Figure 80.4b its input/output relationship; ideally this is a straight line with slope G and passing through the point $(0,0)$, but actually it is an off-zero, seemingly straight line, whose slope is somewhat different from G . The output voltage is

$$v_o = v_a + (v_{os} + v_b + v_r + v_n)G + v_{ref} \quad (80.5)$$

where v_a depends on the input voltage v_d , the second term includes offset, drift, noise, and interference-rejection errors, G is the designed gain, and v_{ref} is the reference voltage, commonly 0 V (but not necessarily, thus allowing output level shifting). Equation 80.5 describes a worst-case situation where absolute values for error sources are added. In practice, some cancellation between different error sources may happen.

Figure 80.5 shows a circuit model for *error analysis* when a practical IA is connected to a signal source (assumed to be differential for completeness). Impedance from each input terminal to ground (Z_c) and between input terminals (Z_d) are all finite. Furthermore, if the input terminals are both connected to ground, v_o is not zero and depends on G ; this is modeled by V_{os} . If the input terminals are grounded through resistors, then v_o also depends on the value of these resistors; this is modeled by current sources I_{B+} and I_{B-} , which represent input bias or leakage currents. These currents need a return path, and therefore a third lead connecting the signal source to the amplifier, or a common ground, is required. Neither V_{os} nor I_{B+} nor I_{B-} is constant; rather, they change with temperature and time: slow changes (<0.01 Hz) are called drift and fast changes are described as noise (hence the noise sources e_n , i_{n+} and i_{n-} in Figure 80.5). Common specifications for IAs are defined in Reference 3.

If a voltage v_c is simultaneously applied to both inputs, then v_o depends on v_c and its frequency. The *common-mode gain* is

$$G_c(f) = \frac{V_o(v_d = 0)}{V_c} \quad (80.6)$$

In order to describe the output voltage due to v_c as an input error voltage, we must divide the corresponding $v_o(v_c)$ by G (the normal- or differential-mode gain, $G = G_d$). The **common-mode rejection ratio** (CMRR) is defined as

$$\text{CMRR} = \frac{G_d(f)}{G_c(f)} \quad (80.7)$$

and is usually expressed in decibels ($\{\text{CMRR}\}_{\text{dB}} = 20 \log \text{CMRR}$). The input error voltage will be

$$\frac{v_o(v_c)}{G_d} = \frac{G_c v_c}{G_d} = \frac{v_c}{\text{CMRR}} \quad (80.8)$$

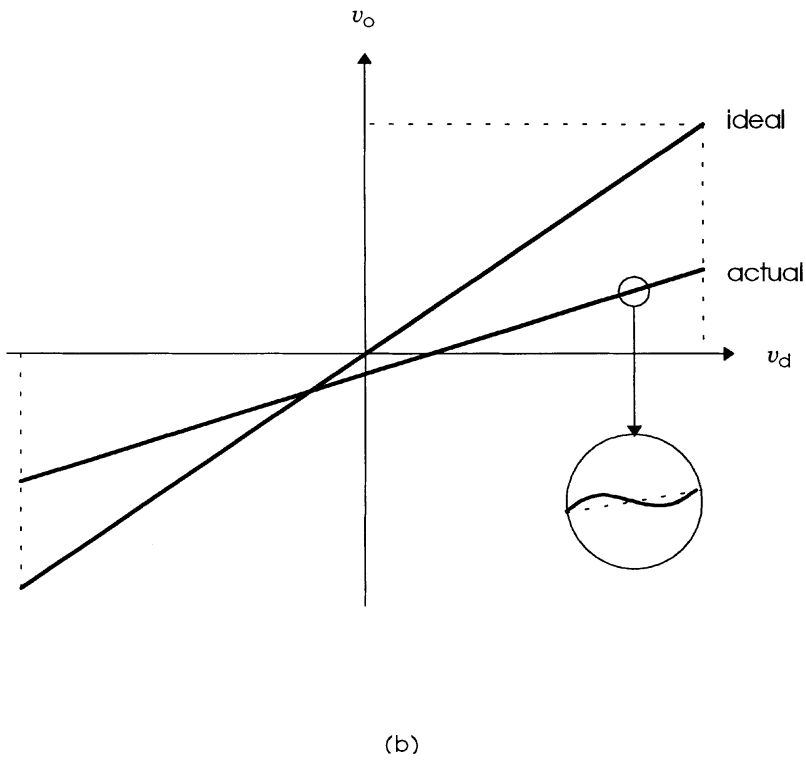

FIGURE 80.4 Instrumentation amplifier. (a) Symbol. (b) Ideal and actual input/output relationship. The ideal response is a straight line through the point (0,0) and slope G .

In the above analysis we have assumed $Z_c \ll R_o$; otherwise, if there were any unbalance (such as that for the source impedance in [Figure 80.5](#)), v_c at the voltage source would result in a differential-mode voltage at the amplifier input,

$$v_d(v_c) = v_c \left(\frac{R_o + \Delta R_o}{Z_c + R_o + \Delta R_o} - \frac{R_o}{Z_c + R_o} \right) \quad (80.9)$$

FIGURE 80.5 A model for a practical instrumentation amplifier including major error sources.

$$= v_c \frac{Z_c \Delta R_o}{(Z_c + R_o + \Delta R_o)(Z_c + R_o)} \approx v_c \frac{\Delta R_o}{Z_c}$$

which would be amplified by G_d . Then, the effective common-mode rejection ratio would be

$$\frac{1}{\text{CMRR}_e} = \frac{\Delta R_o}{Z_c} + \frac{1}{\text{CMRR}} \quad (80.10)$$

where the CMRR is that of the IA alone, expressed as a fraction, not in decibels. Stray capacitances from input terminals to ground will decrease Z_c , therefore reducing CMRR_e .

The ideal amplifier is unaffected by power supply fluctuations. The practical amplifier shows output fluctuations when supply voltages change. For slow changes, the equivalent input error can be expressed as a change in input offset voltages in terms of the *power supply rejection ratio* (PSRR),

$$\text{PSRR} = \frac{\Delta V_{os}}{\Delta V_s} \quad (80.11)$$

The terms in Equation 80.5 can be detailed as follows. Because of gain errors we have

$$v_a = v_d \left(G + e_G + \frac{\Delta G}{\Delta T} \times \Delta T + e_{\text{NLG}} \right) \quad (80.12)$$

where G is the differential gain designed, e_G its absolute error, $\Delta G/\Delta T$ its thermal drift, ΔT the difference between the actual temperature and that at which the gain G is specified, and e_{NLG} is the nonlinearity gain error, which describes the extent to which the input/output relationship deviates from a straight

line (insert in Figure 80.4b). The actual temperature T_j is calculated by adding to the current ambient temperature T_a the temperature rise produced by the power P_D dissipated in the device. This rise depends on the thermal resistance θ_{JA} for the case

$$T_j = T_a + P_D \times \theta_{JA} \quad (80.13)$$

where P_D can be calculated from the respective voltage and current supplies

$$P_D = |V_{S+}| |I_{S+}| + |V_{S-}| |I_{S-}| \quad (80.14)$$

The terms for the equivalent *input offset error* will be

$$v_{os} = V_{os}(T_a) + \frac{\Delta V_{os}}{\Delta T} \times (T_j - T_a) \quad (80.15)$$

$$v_b = (I_{B+} - I_{B-}) R_o + I_{B+} \Delta R_o = I_{os} R_o + I_B \Delta R_o \quad (80.16)$$

where T_a is the ambient temperature in data sheets, $I_{os} = I_{B+} - I_{B-}$ is the offset current, $I_B = (I_{B+} + I_{B-})/2$, and all input currents must be calculated at the actual temperature,

$$I = I(T_a) + \frac{\Delta I}{\Delta T} \times (T_j - T_a) \quad (80.17)$$

Error contributions from finite *interference rejection* are

$$v_r = \frac{v_c}{\text{CMRR}_e} + \frac{\Delta V_s}{\text{PSRR}} \quad (80.18)$$

where the CMRR_e must be that at the frequency for v_c , and the PSRR must be that for the frequency of the ripple ΔV_s . It is assumed that both frequencies fall inside the bandpass for the signal of interest v_d .

The equivalent *input voltage noise* is

$$v_n = \sqrt{e_n^2 B_e + i_n^2 - R_o^2 B_{i+} + i_n^2 - R_o^2 B_{i-}} \quad (80.19)$$

where e_n^2 is the voltage noise power spectral density of the IA, i_n^2 and i_n^2 are the current noise power spectral densities for each input of the IA, and B_e , B_{i+} , and B_{i-} are the respective noise equivalent bandwidths of each noise source. In Figure 80.5, the transfer function for each noise source is the same as that of the signal v_d . If the signal bandwidth is determined as $f_h - f_l$ by sharp filters, then

$$B_e = f_h - f_l + f_{ce} \ln \frac{f_h}{f_l} \quad (80.20)$$

$$B_{i+} = B_{i-} = f_h - f_l + f_{ci} \ln \frac{f_h}{f_l} \quad (80.21)$$

where f_{ce} and f_{ci} are, respectively, the frequencies where the value of voltage and current noise spectral densities is twice their value at high frequency, also known as corner or 3 dB frequencies.

Another noise specification method states the peak-to-peak noise at a given low-frequency band (f_A to f_B), usually 0.1 to 10 Hz, and the noise spectral density at a frequency at which it is already constant, normally 1 or 10 kHz. In these cases, if the contribution from noise currents is negligible, the equivalent input voltage noise can be calculated from

$$v_n = \sqrt{v_{nL}^2 + v_{nH}^2} \quad (80.22)$$

where v_{nL} and v_{nH} are, respectively, the voltage noise in the low-frequency and high-frequency bands expressed in the same units (peak-to-peak or rms voltages). To convert rms voltages into peak-to-peak values, multiply by 6.6. If the signal bandwidth is from f_1 to f_h , and $f_1 = f_A$ and $f_h > f_B$, then Equation 80.22 can be written

$$v_n = \sqrt{v_{nL}^2 + (6.6e_n)^2 (f_h - f_B)} \quad (80.23)$$

where v_{nL} is the peak-to-peak value and e_n is the rms voltage noise as specified in data books. Equation 80.23 results in a peak-to-peak calculated noise that is lower than the real noise, because noise spectral density is not constant from f_B up. However, it is a simple approach providing useful results.

For signal sources with high output resistors, thermal and excess noise from resistors (see Chapter 54) must be included. For first- and second-order filters, noise bandwidth is slightly larger than signal bandwidth. Motchenbacher and Connelly [4] show how to calculate noise bandwidth, resistor noise, and noise transfer functions when different from signal transfer functions.

Low-noise design always seeks the minimal bandwidth required for the signal. When amplifying low-frequency signals, if a large capacitor C_i is connected across the input terminals in Figure 80.5, then noise and interference having a frequency larger than $f_0 = 1/2\pi(2R_o)C_i$ ($f_0 \ll f_s$) will be attenuated.

Another possible source of error for any IA, not included in Equation 80.5, is the *slew rate limit* of its output stage. Because of the limited current available, the voltage at the output terminal cannot change faster than a specified value SR. Then, if the maximal amplitude A of an output sine wave of frequency f exceeds

$$A = \frac{SR}{2\pi f} \quad (80.24)$$

there will be a waveform distortion.

Table 80.1 lists some basic specifications for IC instrumentation amplifiers whose gain G can be set by an external resistor or a single connection.

Instrumentation Amplifiers Built from Discrete Parts

Instrumentation amplifiers can be built from discrete parts by using operational amplifiers (op amps) and a few resistors. An *op amp* is basically a differential voltage amplifier whose gain A_d is very large (from 10^5 to 10^7) at dc and rolls off (20 dB/decade) from frequencies of about 1 to 100 Hz, becoming 1 at frequencies from 1 to 10 MHz for common models (Figure 80.6a), and whose input impedances are so high (up to $10^{12} \Omega \parallel 1 \text{ pF}$) that input currents are almost negligible. Op amps can also be modeled by the circuit in Figure 80.5, and their symbol is that in Figure 80.4a, deleting IA. However, because of their large gain, op amps cannot be used directly as amplifiers; a mere 1 mV dc input voltage would saturate any op amp output. Furthermore, op amp gain changes from unit to unit, even for the same model, and for a given unit it changes with time, temperature, and supply voltages. Nevertheless, by providing external feedback, op amps are very flexible and far cheaper than IAs. But when the cost for external components and their connections, and overall reliability are also considered, the optimal solution depends on the situation.

^a For the INA110, the gain nonlinearity error is specified as percentage of the full-scale output.

^b Input current drift for the INA110KP approximately doubles for every 10°C increase, from 25°C (10 pA-typ) to 125°C (10 nA-typ).

^c The PSRR for the INA110 is specified as an input offset $\pm(10 + 180/G)$ $\mu\text{V/V}$ maximum.

Figure 80.6b shows an amplifier built from an op amp with external feedback. If input currents are neglected, the current through R_2 will flow through R_1 and we have

$$v_d = v_s - v_o \frac{R_1}{R_1 + R_2} \quad (80.25)$$

$$v_o = A_d v_d \quad (80.26)$$

Therefore,

$$\frac{v_o}{v_s} = \frac{A_d \left(1 + \frac{R_2}{R_1} \right)}{A_d + 1 + \frac{R_2}{R_1}} = \frac{G_i}{1 + \frac{G_i}{A_d}} \quad (80.27)$$

where $G_i = 1 + R_2/R_1$ is the ideal gain for the amplifier. If G_i/A_d is small enough (G_i small, A_d large), the gain does not depend on A_d but only on external components. At high frequencies, however, A_d becomes smaller and, from Equation 80.27, $v_o < G_i v_s$ so that the bandwidth for the amplifier will reduce for large gains. Franco [5] analyzes different op amp circuits useful for signal conditioning.

Figure 80.7 shows an IA built from three op amps. The input stage is fully differential and the output stage is a *difference amplifier* converting a differential voltage into a single-ended output voltage. Difference amplifiers (op amp and matched resistors) are available in IC form: AMP 03 (Analog Devices) and INA 105/6 and INA 117 (Burr-Brown). The gain equation for the complete IA is

$$G = \left(1 + 2 \frac{R_2}{R_1} \right) \frac{R_4}{R_3} \quad (80.28)$$

Pallás-Areny and Webster [6] have analyzed matching conditions in order to achieve a high CMRR. Resistors R_2 do not need to be matched. Resistors R_3 and R_4 need to be closely matched. A potentiometer connected to the v_{ref} terminal makes it possible to trim the CMRR at low frequencies.

The *three-op-amp IA* has a symmetrical structure making it easy to design and test. IAs based on an IC difference amplifier do not need any user trim for high CMRR. The circuit in Figure 80.8 is an IA that lacks these advantages but uses only two op amps. Its gain equation is

(a)

(b)

FIGURE 80.6 (a) Open loop gain for an op amp. (b) Amplifier based on an op amp with external feedback.

FIGURE 80.7 Instrumentation amplifier built from three op amps. R_3 and R_4 must be matched.

FIGURE 80.8 Instrumentation amplifier built from two op amps. R_1 and R_2 must be matched.

FIGURE 80.9 Instrumentation amplifier based on the switched-capacitor technique. First switches SW1 and SW2 close while SW3 and SW4 are open, and C_S charges to $v_H - v_L$. Then SW1 and SW2 open and SW3 and SW4 close, charging C_H to $v_H - v_L$.

$$G = 1 + \frac{R_2}{R_1} + \frac{2R_2}{R_G} \quad (80.29)$$

R_1 and R_2 must be matched and R_G should be comparable to R_2 .

Another approach to build an IA is by the *switched-capacitor* technique (Figure 80.9). Switches SW1 and SW2 close together and charge C_S (1 μF) to the voltage difference $v_H - v_L$; next, SW1 and SW2 open and SW3 and SW4 close, so that C_H (0.1 to 1 μF) also charges to $v_H - v_L$. Then SW1 and SW2 close again, SW3 and SW4 open, and so on. While C_S is being charged C_H holds the previous voltage difference. Therefore, the maximal frequency for the input signal must be at least ten times lower than the switching frequency. This circuit has a high CMRR because the charge at C_S is almost insensitive to the input common-mode voltage. Furthermore, it converts the differential signal to a single-ended voltage. The LTC 1043 (Linear Technology) includes two sets of four switches to implement this circuit.

Composite Instrumentation Amplifiers

Instrumentation amplifiers have a very limited bandwidth. They achieve a gain of 10 at 2.5 MHz, at best. Moreover, their inputs must be either dc-coupled or, if ac-coupled with input series capacitors, there must be a path for bias currents; if that path is a resistor from each input to ground, then the common-mode input impedance Z_c decreases and noise may increase.

A larger bandwidth for a given gain can be obtained by cascade connection of two or more amplifiers. However, if the additional gain is provided by a single-ended amplifier after the IA, then the overall CMRR is that of the IA, which is small at high frequencies. The circuit in Figure 80.10a is a broadband IA with large CMRR because the CMRR for the second stage is multiplied by the differential gain for the first stage, which can be very high if implemented by broadband op amps. The overall gain is

$$G = G_1 G_2 = \left(1 + \frac{2R_b}{R_a} \right) G_{IA} \quad (80.30)$$

An IA can be *ac-coupled* by feeding back its dc output to the reference terminal as shown in Figure 80.10b. The high-pass corner frequency is $f_0 = 1/(2\pi R_0 C_0)$.

80.6 Single-Ended Signal Conditioners

Floating signals (single ended or differential) can be connected to amplifiers with single-ended grounded input. Grounded single-ended can be connected to *single-ended amplifiers*, provided the difference in

(a)

(b)

FIGURE 80.10 Composite instrumentation amplifiers. (a) Broadband IA with large CMRR; (b) ac-coupled IA.

ground potentials from signal to amplifier is not too large. [Figure 80.11a](#) shows a simple single-ended amplifier based on an IA. However, op amps are better suited than IAs for single-ended amplifiers and signal conditioners performing additional functions.

[Figure 80.11b](#) shows an *inverting amplifier* whose gain is $G = -R_2/R_1$, and whose input impedance is R_1 . The capacitor on the dashed line (10 pF or larger) prevents gain peaking and oscillation. If a capacitor C replaces R_2 , input signals are integrated and inverted. If C replaces R_1 instead, input signals are differentiated and inverted. The circuit in [Figure 80.11c](#) has $G = 1$ for dc and signals of low frequency relative to $f_1 = 1/(2\pi R_1 C_1)$ (offset and drift included) and $G = 1 + R_2/R_1$ for high-frequency signals. The

circuit in [Figure 80.11d](#) calculates the average for n voltages. The difference between two voltages can be obtained from the difference amplifier in [Figure 80.7](#) (output stage).

Op amps must be carefully selected according to the application. For dc circuits, chopper op amps offer the best performance. For low-impedance signals, op amps with bipolar input transistors are better. For high-impedance signals, op amps with FET input transistors offer lower input currents, but they have larger drift and voltage noise. [Table 80.2](#) lists some parameters for several different op amps. Some manufacturers provide selection guides on floppy disk which suggest the most appropriate model for a set of user-defined values for some parameters.

80.7 Carrier Amplifiers

A **carrier amplifier** is a conditioner for extremely narrowband ac signals from ac-driven sensors. A carrier amplifier is made of a sine wave oscillator, to excite the sensor bridge, an ac voltage amplifier for the bridge output, a synchronous demodulator (see [Chapter 84](#)) and a low-pass filter ([Figure 80.12](#)). The NE5520/1 (Philips) are carrier amplifiers in IC form intended for (but not limited to) LVDTs driven at a frequency from 1 to 20 kHz.

Carrier amplifiers make it possible to recover the amplitude and phase of the modulating signal after amplifying the output modulated waveform from the bridge. This is useful first because ac amplifiers are not affected by offset, drift, or low-frequency noise, and therefore the bridge output can easily be

FIGURE 80.11 (continued)

amplified. Second, the *phase-sensitive demodulator* yields not only the amplitude but also the sign of the measurand. If the measurement range includes positive and negative values for the measurand, phase detection is essential.

A further advantage of carrier amplifiers is their extremely narrow frequency response, determined by the output low-pass filter. In the demodulator, the product of the modulated carrier of frequency f_c by the reference signal, also of frequency f_c , results in a baseband component and components at nf_c ($n \geq 2$). The output low-pass filter rejects components other than the baseband. If the corner frequency for this filter is f_0 , then the passband for the system is $f_c \pm f_0$. Therefore, any interference of frequency f_i added to the modulated signal will be rejected if falling outside that passband. The ability to discriminate signals of interest from those added to them is described by the *series* (or *normal*) *mode rejection ratio* (SMRR), and is usually expressed in decibels. In the present case, using a first-order low-pass filter we have

$$\text{SMRR} = 20 \log \frac{v_o(f_c)}{v_o(f_i)} = 20 \log \frac{\sqrt{1 + (f_c - f_i)^2}}{f_0} \approx 20 \log \frac{|f_c - f_i|}{f_0} \quad (80.31)$$

Specified values are maximal unless otherwise stated and those for noise, which are typical (typ = typical, av = average); nonspecified parameters are indicated by a dash).

^a Values estimated from graphs.

^b I_B doubles every 10°C.

^c I_B doubles every 7.25°C.

^d I_B is almost constant up to 85°C.

^e I_B is almost constant up to 75°C.

^f I_{B+} and I_{B-} show a different behavior with temperature.

^g I_B doubles every 10°C above about 65°C.

A power-line interference superimposed on a 10 kHz carrier will undergo an 80-dB attenuation if the output low-pass filter has $f_0 = 1$ Hz. The same interference superimposed on the baseband signal would be attenuated by only 35 dB.

FIGURE 80.12 Elements for a carrier amplifier.

Carrier amplifiers can be built from a precision sine wave oscillator — AD2S99 (Analog Devices), 4423 (Burr-Brown), SWR300 (Thaler) — or a discrete-part oscillator, and a demodulator (plus the output filter). Some IC demodulators are based on switched amplifiers (AD630, OPA676). The floating capacitor in Figure 80.9 behaves as a synchronous demodulator if the switch clock is synchronous with the carrier, and its duty cycle is small (less than 10%), so that switches SW1 and SW2 sample the incoming modulated waveform for a very short time [7].

80.8 Lock-In Amplifiers

A *lock-in amplifier* is based on the same principle as a carrier amplifier, but instead of driving the sensor, here the carrier signal drives the experiment, so that the measurand is frequency translated. Lock-in amplifiers are manufactured as equipment intended for recovering signals immersed in high (asynchronous) noise. These amplifiers provide a range of driving frequencies and bandwidths for the output filter. Some models are vectorial because they make it possible to recover the in-phase and quadrature (90° out-of-phase) components of the incoming signal, by using two demodulators whose reference signals are delayed by 90° . Still other models use bandpass filters for the modulated signal and two demodulating stages. Meade [8] analyzes the fundamentals, specifications, and applications of some commercial lock-in amplifiers.

80.9 Isolation Amplifiers

The maximal common-mode voltage withstood by common amplifiers is smaller than their supply voltage range and seldom exceeds 10 V. Exceptions are the INA 117 (Burr-Brown) and similar difference amplifiers whose common-mode range is up to ± 200 V, and the IA in Figure 80.9 when implemented by high-voltage switches (relays, optorelays). Signals with large off-ground voltages, or differences in ground potentials exceeding the input common-mode range, result in permanent amplifier damage or destruction, and a safety risk, in spite of an exceptional CMRR: a 100 V common-mode 60 Hz voltage at the input of a common IA having a 120 dB CMRR at power-line frequency does not result in a $100 \text{ V}/10^6 = 100 \mu\text{V}$ output, but a burned-out IA.

Figure 80.13a shows a signal source grounded at a point far from the amplifier ground. The difference in voltage between grounds v_i not only thwarts signal measurements but can destroy the amplifier. The solution is to prevent this voltage from forcing any large current through the circuit and at the same time to provide an information link between the source and the amplifier. Figure 80.13b shows a solution: the signal source and the amplifier have separated (isolated) power supplies and the signal is coupled to the amplifier through a transformer acting as an isolation barrier for v_i . Other possible barriers are optocouplers (IL300-Siemens) and series capacitors (LTC1145-Linear Technology). Those barriers impose a large series impedance (isolation impedance, Z_i) but do not usually have a good low-frequency

(a)

(b)

FIGURE 80.13 (a) A large difference in ground potentials damages amplifiers. (b) An isolation amplifier prevents large currents caused by this difference from flowing through the circuit.

response, hence the need to modulate and then demodulate the signal to transfer through it. The subsystem made of the modulator and demodulator, plus sometimes an input and an output amplifier and a dc–dc converter for the separate power supply, is called an **isolation amplifier**. The ability to reject the voltage difference across the barrier (isolation-mode voltage, v_i) is described by the **isolation mode rejection ratio (IMRR)**, expressed in decibels,

$$\text{IMRR} = 20 \log \frac{\text{OUTPUT Voltage}}{\text{ISOLATION - MODE Voltage}} \quad (80.32)$$

Ground isolation also protects people and equipment from contact with high voltage because Z_i limits the maximal current. Some commercial isolation amplifiers are the AD202, AD204, and AD210 (Analog Devices) and the ISOxxx series (Burr-Brown).

Table 80.3 summarizes the compatibility between signal sources and amplifiers. When grounded, amplifiers and signals are assumed to be grounded at different physical points.

80.10 Nonlinear Signal-Processing Techniques

Limiting and Clipping

Clippers or *amplitude limiters* are circuits whose output voltage has an excursion range restricted to values lower than saturation voltages. Limiting is a useful signal processing technique for signals having the information encoded in parameters other than the amplitude. For example, amplitude limiting is convenient before homodyne phase demodulators. *Limiting* can also match output signals levels to those required for TTL circuits (0 to 5 V). Limiting avoids amplifier saturation for large input signal excursions, which would result in a long recovery time before returning to linear operation.

Limiting can be achieved by op amps with diodes and zeners in a feedback loop. Figure 80.14a shows a positive voltage clipper. When v_s is positive, v_o is negative and R_2/R_1 times larger; the diode is reverse biased and the additional feedback loop does not affect the amplifier operation. When v_s is negative and large enough, v_o forward biases the diode (voltage drop V_f) and the zener clamps at V_z , the output amplitude thus being limited to $v_o = V_f + V_z$ until $|v_s| < (V_f + V_z)R_1/R_2$ (Figure 80.14b). The circuit then acts again as an inverting amplifier until v_s reaches a large negative value.

A negative voltage clipper can be designed by reversing the polarity of the diode and zener. To limit the voltage in both directions, the diode may be substituted by another zener diode. The output is then limited to $|v_o| < V_{z1} + V_{f2}$ for negative inputs to $|v_o| < V_{f1} + V_{z2}$ for positive inputs. If $V_{z1} = V_{z2}$, then the voltage limits are symmetrical. Jung [9] gives component values for several precision limiters.

Logarithmic Amplification

The dynamic range for common linear amplifiers is from 60 to 80 dB. Sensors such as photodetectors, ionizing radiation detectors, and ultrasound receivers can provide signals with an amplitude range wider than 120 dB. The only way to encompass this wide amplitude range within a narrower range is by amplitude compression. A logarithmic law compresses signals by offering equal-output amplitude changes in response to a given ratio of input amplitude increase. For example, a scaling of 1 V/decade means that the output would change by 1 V when the input changes from 10 to 100 mV, or from 100 mV to 1 V. Therefore, *logarithmic amplifiers* do not necessarily amplify (enlarge) input signals. They are rather converters providing a voltage or current proportional to the ratio of the input voltage, or current, to a reference voltage, or current.

Logarithmic conversion can be obtained by connecting a bipolar transistor as a feedback element of an op amp, Figure 80.15a. The collector current i_C and the base-emitter voltage have an exponential relationship. From the Ebers–Moll model for a transistor, if $v_{CB} = 0$, then

$$i_C = I_S \left(e^{v_{BE}/v_T} - 1 \right) \quad (80.33)$$

where $v_T = kT/q = 25$ mV at room temperature, and I_S is the saturation current for the transistor. In Figure 80.15a the input voltage is converted into an input current and the op amp forces the collector current of the transistor to equal the input current, while maintaining $v_{CB} \approx 0$ V. Hence, provided $i_C \gg I_S$, for $v_s > 0$,

$$v_o = \frac{v_T}{\log e} \log \frac{v_s}{RI_S} \quad (80.34)$$

The basic circuit in Figure 80.15a must be modified in order to provide temperature stability, phase compensation, and scale factor correction; reduce bulk resistance error; protect the base-emitter junction;

TABLE 80.3 Compatibility between Signal Sources and Conditioners

Conditioner input Signal source				
	Incompatible unless grounds are very close	Compatible if CMRR is large	Compatible	Compatible

accept negative input voltages and other improvements. Wong and Ott [10] and Peyton and Walsh [11] describe some common circuit techniques to implement these and additional functions. The LOG100 (Burr-Brown) is a logarithmic converter using this so-called transdiode technique. The AD640 (Analog Devices) and TL441 (Texas Instruments) use different techniques.

Figure 80.15b shows a basic *antilog* or *exponential converter* for negative input voltages. The transistor and the resistor have interchanged positions with respect to Figure 80.15a. For $v_s < 0$,

$$v_o = I_S R e^{v_s/v_T} \quad (80.35)$$

Positive voltages require an input *pn*p transistor instead.

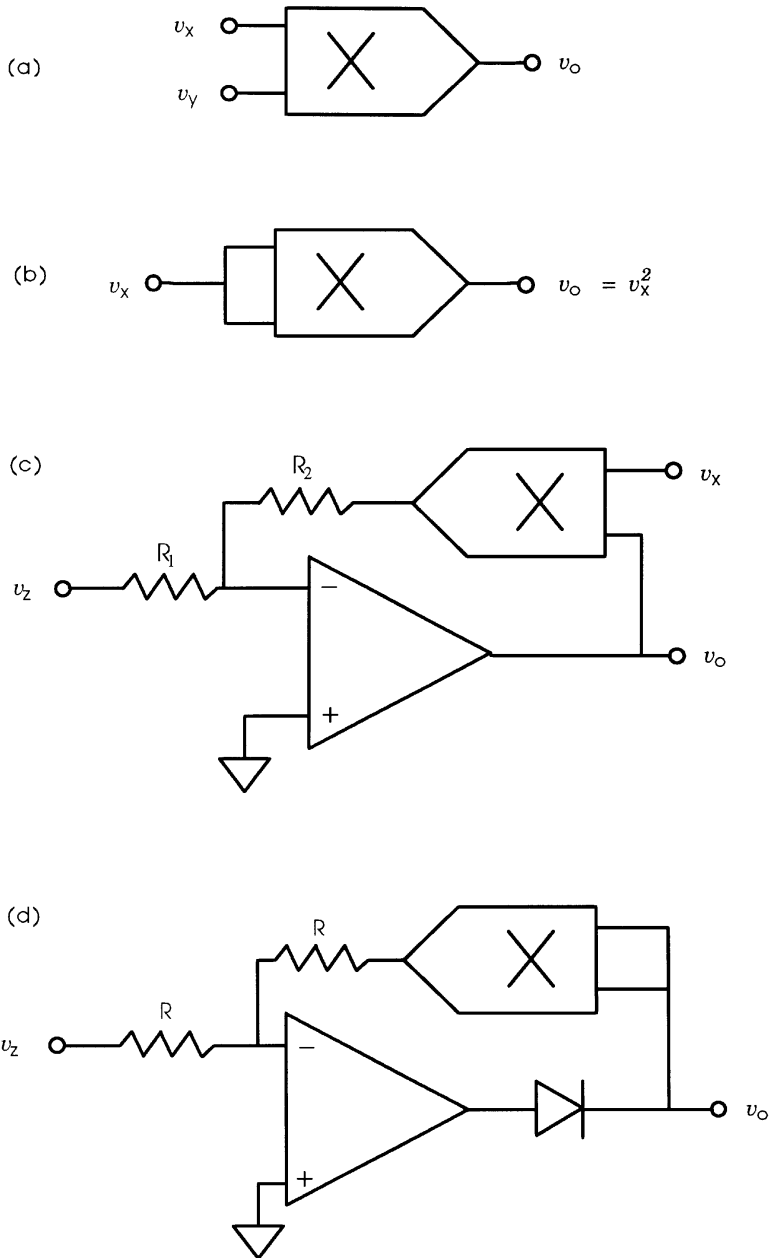

FIGURE 80.16 (a) Symbol for an analog multiplier. (b) Voltage squarer from an analog multiplier. (c) Two-quadrant analog divider from a multiplier and op amp feedback. (d) Square rooter from a multiplier and op amp feedback.

Multiplication and Division

Analog multiplication is useful not only for analog computation but also for modulation and demodulation, for voltage-controlled circuits (amplifiers, filters) and for linearization [12]. An *analog multiplier* (Figure 80.16a) has two input ports and one output port offering a voltage

$$v_o = \frac{v_x v_y}{V_m} \quad (80.36)$$

where V_m is a constant voltage. If inputs of either polarity are accepted, and their signs preserved, the device is a *four-quadrant multiplier*. If one input is restricted to have a defined polarity but the other can change sign, the device is a *two-quadrant multiplier*. If both inputs are restricted to only one polarity, the device is an *one-quadrant multiplier*. By connecting both inputs together, we obtain a voltage squarer (Figure 80.16b).

Wong and Ott¹⁰ describe several multiplication techniques. At low frequencies, one-quadrant multipliers can be built by the log–antilog technique, based on the mathematical relationships $\log A + \log B = \log AB$ and then antilog $(\log AB) = AB$. The AD538 (Analog Devices) uses this technique. Currently, the most common multipliers use the transconductance method, which provides four-quadrant multiplication and differential ports. The AD534, AD633, AD734, AD834/5 (Analog Devices), and the MPY100 and MPY600 (Burr-Brown), are *transconductance multipliers*. A digital-to-analog converter can be considered a multiplier accepting a digital input and an analog input (the reference voltage). A multiplier can be converted into a *divider* by using the method in Figure 80.16c. Input v_x must be positive in order for the op amp feedback to be negative. Then

$$v_o = -V_m \frac{R_2}{R_1} \frac{v_z}{v_x} \quad (80.37)$$

The log–antilog technique can also be applied to dividing two voltages by first subtracting their logarithms and then taking the antilog. The DIV100 (Burr-Brown) uses this technique. An analog-to-digital converter can be considered a divider with digital output and one dc input (the reference voltage). A multiplier can also be converted into a square rooter as shown in Figure 80.16d. The diode is required to prevent circuit latch-up [10]. The input voltage must be negative.

80.11 Analog Linearization

Nonlinearity in instrumentation can result from the measurement principle, from the sensor, or from sensor conditioning. In pressure-drop flowmeters, for example, the drop in pressure measured is proportional to the square of the flow velocity; hence, flow velocity can be obtained by taking the square root of the pressure signal. The circuit in Figure 80.16d can perform this calculation. Many sensors are linear only in a restricted measurand range; other are essentially nonlinear (NTC, LDR); still others are linear in some ranges but nonlinear in other ranges of interest (thermocouples). Linearization techniques for particular sensors are described in the respective chapters.

Nonlinearity attributable to sensor conditioning is common, for example, when resistive (linear) sensors are placed in voltage dividers or bridges. The Wheatstone bridge in Figure 80.17a, for example, includes a linear sensor but yields a nonlinear output voltage,

$$v_s = V \left(\frac{1+x}{2+x} - \frac{1}{2} \right) = \frac{Vx}{2(2+x)} \quad (80.38)$$

The nonlinearity arises from the dependence of the current through the sensor on its resistance, because the bridge is supplied at a constant voltage. The circuit in Figure 80.17b provides a solution based on one op amp which forces a constant current V/R_0 through the sensor. The bridge output voltage is

$$v_s = \frac{V + v_a}{2} = V \frac{x}{2} \quad (80.39)$$

In addition, v_s is single ended. The op amp must have a good dc performance.

(a)

(b)

FIGURE 80.17 (a) A Wheatstone bridge supplied at a constant voltage and including a single sensor provides a nonlinear output voltage. (b) By adding an op amp which forces a constant current through the sensor, the output voltage is linearized.

80.12 Special-Purpose Signal Conditioners

Table 80.4 lists some signal conditioners in IC form intended for specific sensors and describes their respective functions. The decision whether to design a signal conditioner from parts or use a model from Table 80.4 is a matter of cost, reliability, and availability. Signal conditioners are also available as sub-systems (plug-in cards and modules), for example, series MB from Keithley Metrabyte, SCM from Burr-Brown, and 3B, 5B, 6B, and 7B from Analog Devices.

Defining Terms

Carrier amplifier: Voltage amplifier for narrowband ac signals, that includes in addition a sine wave oscillator, a synchronous demodulator, and a low-pass filter.

Common-mode rejection ratio (CMRR): The gain for a differential voltage divided by the gain for a common-mode voltage in a differential amplifier. It is usually expressed in decibels.

Common-mode voltage: The average of the voltages at the input terminals of a differential amplifier.

Differential amplifier: Circuit or device that amplifies the difference in voltage between two terminals, none of which is grounded.

Dynamic range: The measurement range for a quantity divided by the desired resolution.

Instrumentation amplifier: Differential amplifier with large input impedance and low offset and gain errors.

Isolation amplifier: Voltage amplifier whose ground terminal for input voltages is independent from the ground terminal for the output voltage (i.e., there is a large impedance between both ground terminals).

Isolation Mode Rejection Ratio (IMRR): The amplitude of the output voltage of an isolation amplifier divided by the voltage across the isolation impedance yielding that voltage.

Signal conditioner: Circuit or device that adapts a sensor signal to an ensuing circuit, such as an analog-to-digital converter.

Voltage buffer: Voltage amplifier whose gain is 1, or close to 1, and whose input impedance is very large while its output impedance is very small.

Further Information

B.W.G. Newby, *Electronic Signal Conditioning*, Oxford, U.K.: Butterworth-Heinemann, 1994, is a book for those in the first year of an engineering degree. It covers analog and digital techniques at beginners' level, proposes simple exercises, and provides clear explanations supported by a minimum of equations.

P. Horowitz and W. Hill, *The Art of Electronics*, 2nd ed., Cambridge, U.K.: Cambridge University Press, 1989. This is a highly recommended book for anyone interested in building electronic circuits without worrying about internal details for active components.

M.N. Horenstein, *Microelectronic Circuits and Devices*, 2nd ed., Englewood Cliffs, NJ: Prentice-Hall, 1996, is an introductory electronics textbook for electrical or computer engineering students. It provides many examples and proposes many more problems, for some of which solutions are offered.

J. Dostál, *Operational Amplifiers*, 2nd ed., Oxford, U.K.: Butterworth-Heinemann, 1993, provides a good combination of theory and practical design ideas. It includes complete tables which summarize errors and equivalent circuits for many op amp applications.

T.H. Wilmshurst, *Signal Recovery from Noise in Electronic Instrumentation*, 2nd ed., Bristol, U.K.: Adam Hilger, 1990, describes various techniques for reducing noise and interference in instrumentation. No references are provided and some demonstrations are rather short, but it provides insight into very interesting topics.

Manufacturers' data books provide a wealth of information, albeit nonuniformly. Application notes for special components should be consulted before undertaking any serious project. In addition, application notes provide handy solutions to difficult problems and often inspire good designs. Most manufacturers offer such literature free of charge. The following have shown to be particularly useful and easy to obtain: *1993 Applications Reference Manual*, Analog Devices; *1994 IC Applications Handbook*, Burr-Brown; *1990 Linear Applications Handbook* and *1993 Linear Applications Handbook Vol. II*, Linear Technology; *1994 Linear Application Handbook*, National Semiconductor; *Linear and Interface Circuit Applications*, Vols. 1, 2, and 3, Texas Instruments.

R. Pallás-Areny and J.G. Webster, *Analog Signal Processing*, New York: John Wiley & Sons, 1999, offers a design-oriented approach to processing instrumentation signals using standard analog integrated circuits, that relies on signal classification, analog domain conversions, error analysis, interference rejection and noise reduction, and highlights differential circuits.

81.1 Introduction

It is often the case in instrumentation and communication systems that an information-bearing signal may not be in an optimal form for direct use. In such cases, the information-bearing signal may be used to alter some characteristic of a second signal more suited to the application. This process of altering one signal by means of another is known as **modulation**; the original information is called the *baseband signal*, and the signal modulated by the baseband signal is termed the *carrier* (because it “carries” the information). Recovery of the original information requires a suitable demodulation process to reverse the modulation process.

A prominent use of modulation techniques is found in radio communication. The extremely long wavelengths of electromagnetic waves at frequencies found in a typical audio signal make direct transmission impractical, because of constraints on realistic antenna size and bandwidth. Successful radio communication is made possible by using the original audio (baseband) signal to modulate a carrier signal of a much higher frequency and transmitting the modulated carrier by means of antennas of feasible size. Another example is found in the use of modems to transmit digital data by the telephone network. Digital data are not directly compatible with analog local subscriber connections, but these data may be used to modulate audible signals which may be carried over local telephone lines. Instrumentation systems use modulation techniques for telemetry (where the distances may be on the order of centimeters for implanted medical devices to hundreds of millions of kilometers for deep-space probes), for processing signals in ways for which the original signals are unsuited (such as magnetic recording of low-frequency and dc signals), and for specialized amplification purposes (carrier and lock-in amplifiers).

Techniques that modulate the amplitude of the carrier are full-carrier **amplitude modulation** (AM), reduced- or suppressed-carrier double-sideband amplitude modulation (DSB), single-sideband suppressed-carrier modulation (SSB), vestigial-sideband modulation (VSB), and on-off keying (OOK). Techniques that modulate the frequency or phase angle of the carrier include **frequency modulation**

(FM), phase modulation (PM), frequency-shift keying (FSK), and phase-shift keying (PSK). Simultaneous variation of amplitude and phase are applied in quadrature amplitude modulation (QAM). Each technique has its own particular uses. Full-carrier AM is used in radio broadcasting; VSB is used in television broadcasting. DSB appears in instrumentation systems utilizing carrier amplifiers and modulating sensors, while SSB finds use in certain high-frequency radio communications. FM is used in broadcasting (radio and television audio) and point-to-point mobile communications. OOK is commonly used to transmit digital data in optical fiber links. FSK, PSK, and QAM are found in digital communications; analog QAM carries the chrominance (color) information in color television broadcasting. The emphasis of this particular chapter will be instrumentation systems; those interested principally in communications applications could begin by consulting References 1 through 4.

81.2 Generalized Modulation

We begin by making two assumptions: (1) the highest frequency present in the baseband signal is considerably less than the carrier frequency and (2) the results derived in the following chapter pertain to sinusoidal carriers but may be extended to other periodic carrier signals (such as square waves and triangle waves). Equation 81.1 gives a general expression for a modulated sinusoidal carrier signal of radian frequency ω_c :

$$f_s(t) = A_c(t) \cos[\omega_c t + \phi(t)] \quad (81.1)$$

Information may be carried by $f_s(t)$ by modulation of its amplitude $A_c(t)$, its phase angle $\phi(t)$, or, in some cases, both (note that frequency modulation is a form of phase **angle modulation**). Equation 81.1 may be recast in an equivalent form:

$$f_s(t) = f_i(t) \cos(\omega_c t) - f_q(t) \sin(\omega_c t) \quad (81.2)$$

$$\begin{aligned} \text{where } f_i(t) &= A_c(t) \cos[\phi(t)] \\ f_q(t) &= A_c(t) \sin[\phi(t)] \end{aligned}$$

Equation 81.2 gives $f_s(t)$ as the sum of a cosinusoidal carrier term with time-varying amplitude $f_i(t)$ and a sinusoidal (quadrature) carrier term with time-varying amplitude $f_q(t)$ and is thus known as the carrier-quadrature description of $f_s(t)$. The terms $f_i(t)$ and $f_q(t)$ are known, respectively, as the in-phase and quadrature components of $f_s(t)$. Carlson [1] gives the Fourier transform of a signal in carrier-quadrature form:

$$F_s(\omega) = \frac{1}{2} \left[F_i(\omega - \omega_c) + F_i(\omega + \omega_c) \right] + \frac{j}{2} \left[F_q(\omega - \omega_c) + F_q(\omega + \omega_c) \right] \quad (81.3)$$

where $F_i(\omega)$: $f_i(t)$ and $F_q(\omega)$: $f_q(t)$ are Fourier transform pairs. Notice that the spectra of both $F_i(\omega)$ and $F_q(\omega)$ are both translated by $\pm\omega_c$. Modulation of the carrier in any sense causes energy to appear at frequencies (known as *sidebands*) other than the carrier frequency. Sidebands will be symmetrically distributed relative to the carrier in all but the specialized cases of VSB and single-SSB.

81.3 Amplitude Modulation

AM that appears in instrumentation systems takes the form of double-sideband AM on which we will focus some degree of attention. VSB and SSB are encountered in communications systems but not in instrumentation systems; interested readers may refer to References 1 through 3.

FIGURE 81.1 Time-domain representation of a baseband and the resulting full-carrier AM signal. The time scale is arbitrary.

Double-Sideband Amplitude Modulation

AM applied to a sinusoidal carrier is described by

$$f_s(t) = A_c [k + \mu f_m(t)] \cos(\omega_c t) \quad (81.4)$$

where A_c is the amplitude of the unmodulated carrier, k is the proportion of carrier present in the modulated signal, μ is the modulation index, $f_m(t)$ is the modulating baseband signal (presumed to be a real bandpass signal), and ω_c is the carrier radian frequency. The modulation index relates the change in amplitude of the modulated signal to the amplitude of the baseband signal. The value of k ranges from 1 in full-carrier AM to 0 in suppressed-carrier double-sideband modulation. The peak value of the modulated signal is $k + \mu f_m(t)$ which may take on any positive value consistent with the dynamic range of the modulator and demodulating system; note that phase reversal of the carrier occurs if $k + \mu f_m(t)$ becomes negative. Figure 81.1 represents a full-carrier AM signal and its baseband signal. Recasting Equation 81.4 in carrier-quadrature form gives $f_i = A_c [k + \mu f_m(t)]$ and $f_q = 0$. The Fourier transform of this signal is

$$F_s(\omega) = \frac{A_c}{2} \left\{ k\delta(\omega - \omega_c) + k\delta(\omega + \omega_c) + \mu [F_m(\omega - \omega_c) + F_m(\omega + \omega_c)] \right\} \quad (81.5)$$

where $\delta(\omega - \omega_c)$ and $\delta(\omega + \omega_c)$ are unit impulses at $+\omega_c$ and $-\omega_c$, respectively, and represent the carrier component of $F_s(\omega)$. The frequency domain representation of $F_s(\omega)$ also contains symmetric sidebands

FIGURE 81.2 Time-domain representation of a DSB suppressed-carrier signal. Regions demarcated by double arrows indicate phase inversion of the modulated signal relative to the unmodulated carrier. This is in contrast to full-carrier AM in which the modulated signal is always in phase with the carrier.

about the carrier with the upper sideband arising from the positive-frequency component of $F_m(\omega)$ and the lower sideband from the negative-frequency component. A double-sideband AM signal thus has a bandwidth twice as large as that of the baseband signal.

Figure 81.2 shows a time-domain representation of a suppressed-carrier DSB signal with the same baseband modulation as in Figure 81.1. The information in a full-carrier AM signal is found in the time-varying amplitude of the modulated signal, but the information carried by the suppressed-carrier DSB signal is found both in the amplitude and instantaneous phase of the modulated signal (note that the phase of the DSB signal is inverted relative to the carrier when the baseband signal is negative and in phase when the baseband signal is positive). AM is a linear modulation technique; the sum of multiple AM signals produced from a common carrier by different baseband signals is the same as one AM signal produced by the sum of the baseband signals.

Generation of Double-Sideband AM Signals

AM in radio transmitters is frequently performed by applying the modulating waveform to the supply voltage to a nonlinear radiofrequency power amplifier with a resonant-circuit load as described by Carlson [1]. Low-level AM may be achieved by direct multiplication of the carrier signal by $[k + \mu f_m(t)]$.

AM signals often arise in instrumentation systems as the result of the use of an ac drive signal to a modulating sensor. Figure 81.3 shows an example in which a balanced sensor is excited by a sinusoidal carrier. The output voltage of the differential amplifier will be zero when the sensor is balanced; a nonzero output voltage appears when the sensor is unbalanced. The magnitude of the voltage indicates the degree of imbalance in the sensor, and the phase of the output voltage relative to the carrier determines the

FIGURE 81.3 A balanced sensor with ac excitation and a differential-amplifier output stage. Typical sensors which might be found in this role are resistive Wheatstone bridges, differential-capacitance pressure sensors or accelerometers, or linear-variable differential transformers (LVDTs). Variation in the sensor measurand produces a DSB suppressed-carrier signal at the amplifier output.

FIGURE 81.4 Envelope detector for full-carrier AM signals.

direction of imbalance. The suppressed-carrier DSB signal of Figure 81.2 would be seen at the amplifier output if we substitute the sensor measurand for the baseband signal of Figure 81.2. The technique of applying ac excitation to a balanced sensor may be required for inductive or capacitive sensors; it may also be desirable in the case of resistive sensors (such as strain-gage bridges) requiring high-gain amplifiers. In these circumstances, amplification of an ac signal minimizes both $1/f$ noise and dc offset problems associated with high-gain dc-coupled amplifiers.

Envelope Demodulation of Double-Sideband AM Signals

Full-carrier AM signals are readily demodulated by the simple envelope detector shown in Figure 81.4. The components of the RC low-pass filter are chosen such that $\omega_m \ll (1/RC) \ll \omega_c$. Envelope detection, however, cannot discriminate phase and is thus unsuitable for demodulation of signals in which phase reversal of the carrier occurs (such as reduced-carrier or suppressed-carrier signals). Synchronous demodulation is required for such signals.

Synchronous Demodulation of Double-Sideband AM Signals

Figure 81.5 shows two methods of synchronous demodulation. In Figure 81.5(a), the modulated signal is multiplied by $\cos(\omega_c t)$; in Figure 81.5(b), the modulated signal is gated by a square wave synchronous with $\cos(\omega_c t)$. Consider the multiplying circuit of Figure 81.5(a); the Fourier transform $F_d(\omega)$ of $f_d(t) = f_s(t) \cos(\omega_c t)$ is given by

$$F_d(\omega) = \frac{(A_c k)}{4} [\delta(\omega - 2\omega_c) + \delta(\omega + 2\omega_c) + 2\delta(\omega)] + \frac{(\mu A_c)}{4} [F_m(\omega - 2\omega_c) + F_m(\omega - 2\omega_c) + 2F_m(\omega)] \quad (81.6)$$

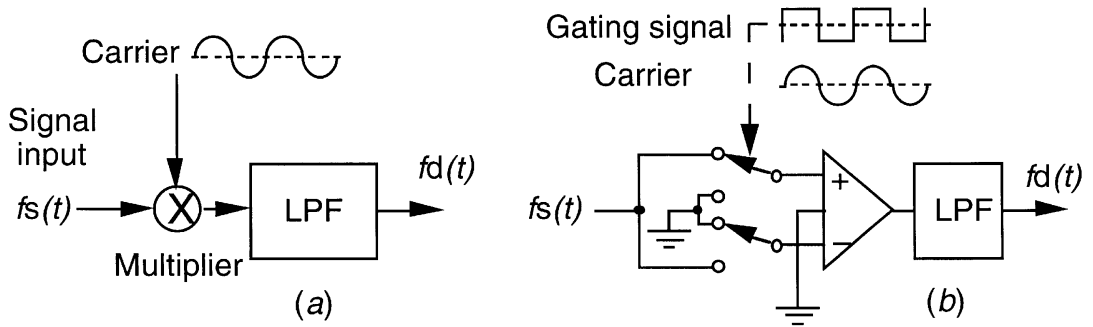

FIGURE 81.5 Multiplying (a) and switching (b) synchronous demodulators. The blocks marked LPF represent low-pass filters.

The spectral components translated by $\pm 2\omega_c$ may be removed by low-pass filtering; the result, translated into the time domain, is

$$f_d(t) = \frac{A_c k}{2} + \frac{\mu A_c}{2} f_m(t) \quad (81.7)$$

We thus have a dc component of $A_c k/2$ and the original baseband signal $f_m(t)$ multiplied by a scale factor of $\mu A_c/2$. The gating circuit of Figure 81.5(b) may be analyzed in a similar manner; the action of gating is equivalent to multiplying $f_s(t)$ by a square wave with levels of ± 1 . The Fourier series representation of such a square wave is given by

$$f_g(t) = \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n+1)} \cos[(2n+1)\omega_c t] \quad (81.8)$$

Low-pass filtering of the product of Equations 81.4 and 81.8 gives

$$f_d(t) = \frac{2A_c k}{\pi} + \frac{2\mu A_c}{\pi} f_m(t) \quad (81.9)$$

The baseband signal is again recovered, although the scale factor is somewhat larger than that of the multiplying case. Demodulators like those of Figure 81.5(a) are called multiplying demodulators; circuits Figure 81.5(b) are known as switching demodulators. Nowicki [5] and Meade [6] discuss and compare both types of synchronous demodulators in greater detail.

We have so far made the implicit assumption that the demodulating signal is perfectly synchronized with the carrier of the modulated signal. Let us now consider the case where there exists a phase shift between these two signals. Assume that a signal expressed in carrier-quadrature form is multiplied by a demodulating signal $\cos(\omega_c t + \theta)$. The result, after suitable low-pass filtering, is

$$f_d(t) = \frac{f_i(t)}{2} \cos(\theta) + \frac{f_q(t)}{2} \sin(\theta) \quad (81.10)$$

Equation 81.10 is an important result; we see that both the level and polarity of the demodulated signal are functions of the synchronization between the demodulating signal and the modulated carrier. Synchronous demodulation is thus often called phase-sensitive demodulation. It was previously mentioned

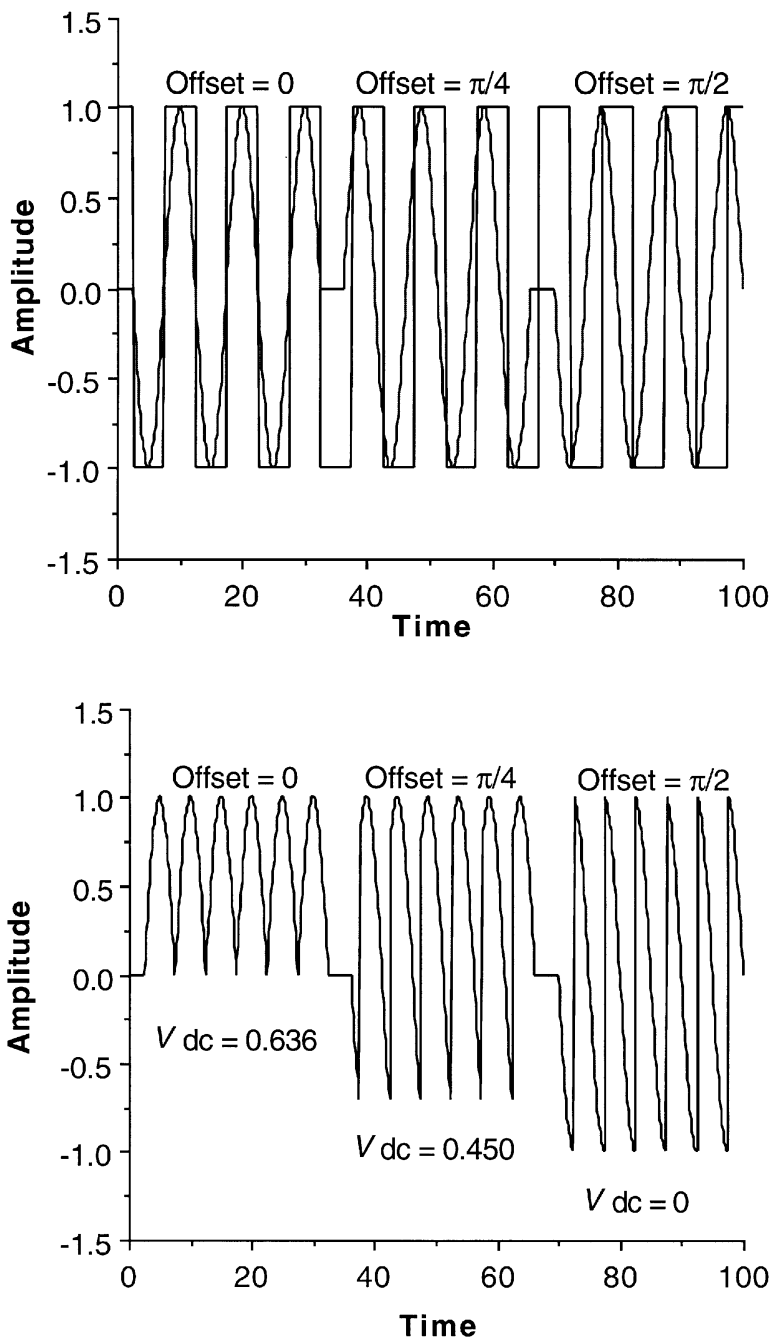

FIGURE 81.6 Gating of a constant-amplitude sinusoidal by a square wave in a switching phase-sensitive demodulator with various phase offsets between the carrier and the square wave. The upper trace shows the carrier and the square wave; the lower trace shows the signals which appear at the output of the differential amplifier in Figure 81.5(b). The dc output voltages of the low-pass filter are indicated for each value of phase offset.

that a DSB AM signal has no quadrature component $f_q(t)$; a phase shift of an odd integral multiple of $\pi/2$ radians between the carrier and the demodulating signal will produce a synchronous demodulator output of zero. Use of a square wave gating signal in place of the sinusoid would produce the same result as Equation 81.10 except that the recovered signals would be multiplied by $2/\pi$ instead of $1/2$.

Figure 81.6 shows the effect of phase between the gating signal and the incoming signal in a switching phase-sensitive demodulator. A sinusoid with a constant amplitude of 1 is gated by a square wave which has levels of ± 1 ; the amplifier outputs before low-pass filtering are shown for phase offsets of 0, $\pi/4$, and $\pi/2$ radians. The dc levels which would be recovered by low-pass filtering are also shown. Note that the demodulator output with phase offset of zero takes the form of a full-wave rectified sine which has only positive excursions. As the phase offset between the gating signal and the sinusoid increases, however, the dc component decreases as the gated signal shows increasing negative excursions and decreasing positive excursions. An offset of $\pi/2$ radians produces an output whose positive and negative excursions are symmetric and thus has no dc component. Synchronization of the demodulating signal with the modulated carrier is thus crucial for accurate demodulation. Synchronization of the demodulating signal with the modulated carrier is straightforward in instrumentation applications in which the carrier signal may be provided directly to the demodulator, such as the electrical impedance tomography applications discussed by Webster [7]. This becomes more difficult if the carrier cannot be directly provided but must be inferred or recovered from the incoming signal. Hershberger [8] employs a phase-locked loop to perform the carrier synchronization in a synchronous detector for radio receiver applications. Modulated signals which contain both in-phase and quadrature components may be demodulated by an I-Q demodulator which is comprised of two parallel synchronous demodulators (one driven by $\cos(\omega_c t)$ and the other by $\sin(\omega_c t)$); Breed [9] notes that any form of modulation may in principle be demodulated by this method although less expensive techniques are suitable for many applications (such as the envelope detector for full-carrier AM). A common instrumentation application for simultaneous I-Q demodulation is the electrical impedance bridge (often called an LCR bridge).

Synchronous demodulators are valuable in lock-in amplifier applications for the recovery of signals otherwise masked by noncoherent noise. Assume that the low-pass filter of a synchronous demodulator has a bandwidth of Ω ; only those components of the incoming signal which lie within $\pm\Omega$ of ω_c will appear at the low-pass filter output. A demodulator with extremely high selectivity may be built by use of a narrow low-pass filter, providing remarkable improvement in output signal-to-noise ratio. The use of an AD630 switching demodulator to recover a signal from broadband noise whose rms value is 100 dB greater than that of the modulated signal is shown in Reference 10. Synchronous demodulation may also be of benefit in applications in which the input signal-to-noise ratio is not so extreme; components of noise which are in quadrature with respect to the carrier produce no output from a synchronous demodulator, whereas an envelope detector responds to the instantaneous sum of the signal and all noise components.

Examples

Figure 81.7 shows this lock-in amplifier application of the AD630; this particular integrated circuit has on-chip precision resistances which allow the device to be used with a minimal number of external components. The LM1496 balanced modulator/demodulator integrated circuit is frequently used in phase-sensitive demodulation applications; further information (including application examples) is found in manuals and data books published by the manufacturers of that particular device (National Semiconductor, Motorola, and Philips). Webster [11] shows the design of a diode-ring phase-sensitive demodulator. High-speed CMOS switches (such as the 74HC4053) may also be utilized in switching demodulators.

81.4 Angle (Frequency and Phase) Modulation

Recall from Equation 81.1 that we may modulate a carrier by varying its phase angle in accordance with the baseband signal. Consider a signal of the form:

$$f_s(t) = A_c \cos[\omega_c t + \Delta\phi x_m(t)] \quad (81.11)$$

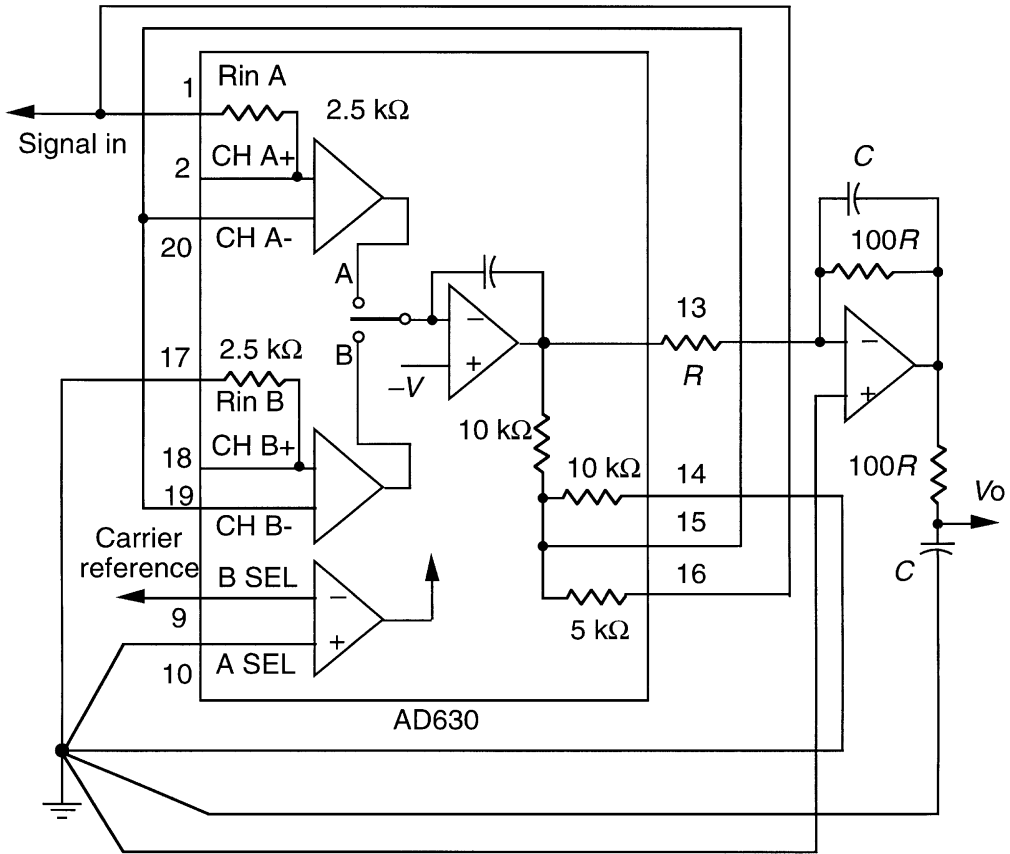

FIGURE 81.7 Lock-in amplifier circuit utilizing the Analog Devices AD630 switching balanced demodulator. This particular device is attractive for the small number of external components required and its high performance. The two-pole low-pass filter shown has a dc gain of 100 and a corner frequency of $0.00644/RC$. The principal drawback of this filter is its dc output impedance which is $100R$. This limitation could be avoided by replacing this filter by a pair of single-pole active filters or a single-amplifier two-pole filter (such as the Sallen-Key type of network). Resistances depicted within the outline of the AD630 are internal to the device itself; numbers at the periphery of the device are pin numbers. Pins labeled CH A+, CH A-, CH B+, and CH B- indicate the sense of the A and B channels of the device. Pins Rin A and Rin B are electrically connected to the CH A+ and CH B+ pins, respectively, through internal $2.5\text{ k}\Omega$ resistances.

The instantaneous phase angle is $\omega_c t + \Delta\phi x_m(t)$; the phase relative to the unmodulated carrier is $\Delta\phi x_m(t)$. The carrier is thus phase-modulated by $x_m(t)$. The instantaneous frequency is $\omega_c + \Delta\phi [dx_m(t)/dt]$; if $x_m(t)$ is the integral of baseband signal $f_m(t)$, the instantaneous frequency becomes $\omega_c + \Delta\phi f_m(t)$. The frequency deviation $\Delta\phi f_m(t)$ is proportional to the baseband signal; the carrier is frequency modulated by $f_m(t)$. We may write the general expression for an FM signal as

$$f_s(t) = A_c \cos \left[\omega_c t + \Delta\omega \int_{-\infty}^t f_m(\tau) d\tau \right] \quad (81.12)$$

(The change in notation from $\Delta\phi$ to $\Delta\omega$ is intended to emphasize that the signal represented by Equation 81.12 is frequency modulated.) Figure 81.8 shows a time-domain representation of an FM signal. Note the signal has constant amplitude; this is also true of a phase-modulated signal.

FIGURE 81.8 Time-domain representation of an FM signal and its baseband signal. The time scale is arbitrary.

Consider frequency modulation with a baseband signal $f_m = A_m \cos(\omega_m t)$; substitution into Equation 81.12 and performing the integration gives

$$f_s(t) = A_c \cos[\omega_c t + \beta \sin(\omega_m t)] \quad (81.13)$$

in which β (called the modulation index) has replaced $\Delta\omega A_m / \omega_m$. The carrier-quadrature form of Equation 81.13 is

$$f_s(t) = A_c \left\{ \cos[\beta \sin(\omega_m t)] \cos(\omega_c t) - \sin[\beta \sin(\omega_m t)] \sin(\omega_c t) \right\} \quad (81.14)$$

We note from Equation 81.14 that, unlike AM, the FM signal contains both in-phase and quadrature components and that the amplitudes of both are nonlinear functions of the modulation index. The terms $\cos[\beta \sin(\omega_m t)]$ and $\sin[\beta \sin(\omega_m t)]$ are generally expanded in terms of Bessel functions (see Schwartz [3] for detailed analysis). The Bessel function expression of an FM signal is

$$f_s(t) = A_c \sum_{n=-\infty}^{\infty} J_n(\beta) \cos(\omega_c + n\omega_m)t \quad (81.15)$$

where J_n represents a Bessel function of the first kind of order n . Beyer [12] provides tables of $J_0(\beta)$ and $J_1(\beta)$ and gives formulae for computing higher-order Bessel functions. We also note that $J_{-n}(\beta) = (-1)^n J_n(\beta)$. The approximations $J_0(\beta) = 1$ and $J_1(\beta) = (\beta/2)$ are valid for low values of the modulation index

($\beta < 0.2$); the higher-order Bessel functions are negligible under these circumstances. A carrier with sinusoidal frequency modulation with a low modulation index will show sidebands spaced at $\pm\omega_m$ about the carrier; such narrowband FM would be indistinguishable from full-carrier AM on a spectrum analyzer display (which shows the amplitudes of spectral components but not their phase relationships). As modulation index increases, however, new sideband pairs appear at $\pm 2\omega_m, \pm 3\omega_m, \pm 4\omega_m$, etc. as the higher-order Bessel functions become significant. The amplitude of the carrier component of $f_s(t)$ varies with $J_0(\beta)$; the carrier component disappears entirely for certain values of modulation index. These characteristics are unlike AM in which the carrier component of the modulated signal is constant and in which only one sideband pair is produced for each spectral component of the baseband signal. FM is an inherently nonlinear modulation process; the sum of multiple FM signals derived from a single carrier with individual baseband signals does not give the same result as frequency modulation of the carrier by the sum of the baseband signals. The spectrum of a phase modulated signal is similar to that of an FM signal, but the modulation index of a phase-modulated signal does not vary with ω_m . Figure 81.8 shows a time-domain representation of an FM signal and the original baseband signal.

Generation of Phase- and Frequency-Modulated Signals

FM signals may arise directly in instrumentation systems such as turbine-type flowmeters or Doppler velocity sensors. Direct FM signals may be generated by applying the baseband signal to a voltage-controlled oscillator (VCO); Sherwin and Regan [13] demonstrate this technique in a system which generates direct FM using the LM566 VCO to transmit analog information over 60-Hz power lines. In radiofrequency applications, the oscillator frequency may be varied by application of the baseband signal to a voltage-variable reactance (such as a varactor diode). Indirect FM may be generated by phase modulation of the carrier by the integrated baseband signal as in Equation 81.12; DeFrance [14] gives an example of a phase modulator circuit.

Demodulation of Phase- and Frequency-Modulated Signals

PM signals may be demodulated by the synchronous demodulator circuits previously described; they are, however, sensitive to the signal amplitude as well as phase and require a limiter circuit to produce an output proportional to phase alone. Figure 81.9 shows simple digital phase demodulators. Figure 81.10 shows three of the more common methods of FM demodulation. Figure 81.10(a) shows a quadrature detector of the type commonly used in integrated-circuit FM receivers. A limiter circuit suppresses noise-induced amplitude variations in the modulated signal; the limiter output then provides a reference signal to a synchronous (phase-sensitive) demodulator. The limiter output voltage is also coupled (via a small capacitor $C1$) to a quadrature network consisting of L , R , and $C2$. The phase of the voltage across the quadrature network relative to the limiter output is given by

$$\phi[V_q(\omega)] = \tan^{-1} \frac{-\omega L/R}{\left[1 - (\omega/\omega_0)^2\right]} \quad (81.16a)$$

where

$$\omega_0 = \frac{1}{\sqrt{L(C_1 + C_2)}} \quad (81.16b)$$

The variation in phase is nearly linear for frequencies close to ω_0 . The phase-sensitive demodulator recovers the baseband signal from the phase shift between the quadrature-network voltage and the reference signal. The quadrature network also causes the amplitude of V_q to vary with frequency, but the variation in phase with respect to frequency predominates over amplitude variation in the vicinity of ω_0 .

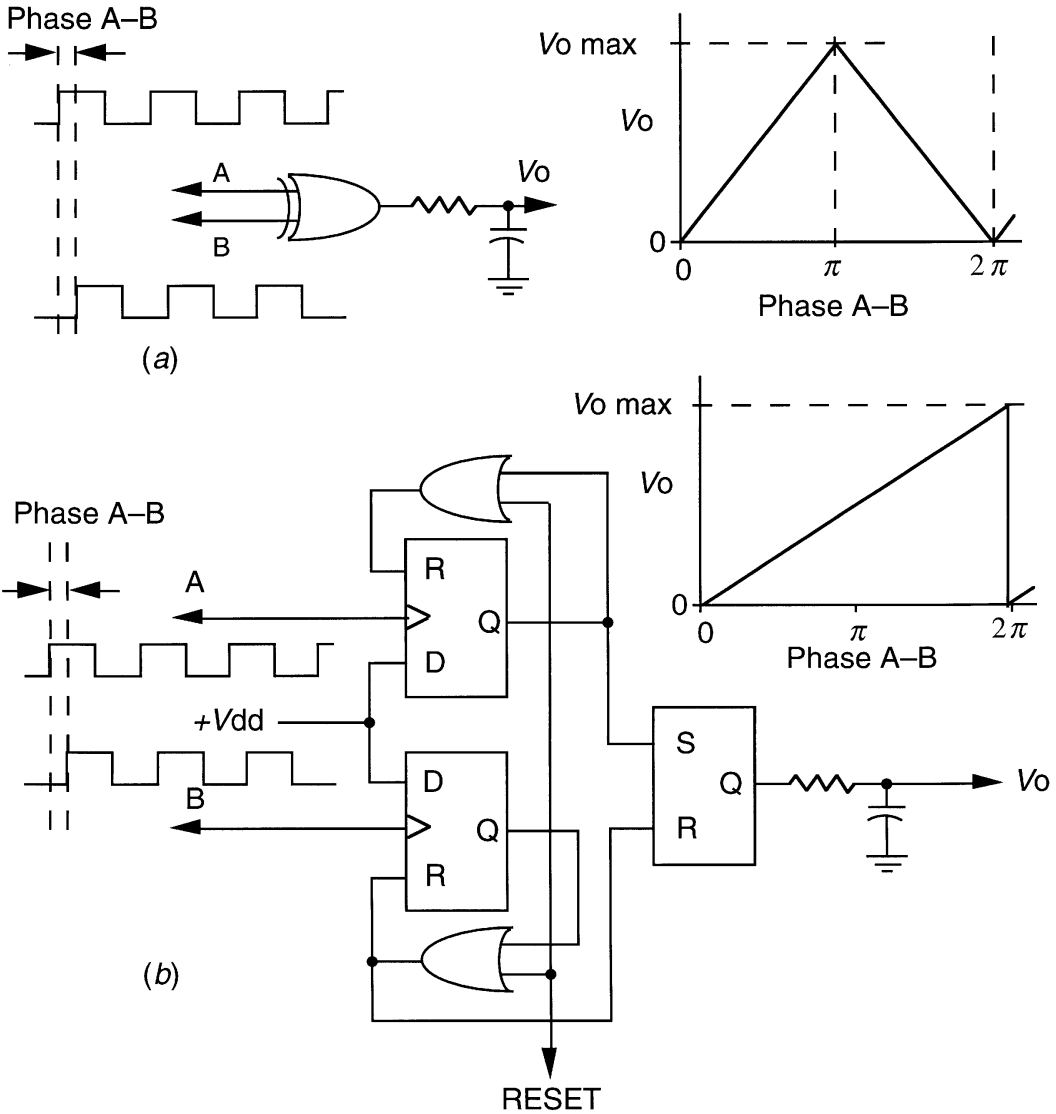

FIGURE 81.9 Examples of digital phase detectors. The exclusive-OR gate in (a) requires input signals with 50% duty cycle and produces an output voltage proportional to phase shift over the range of 0 to π radians (0° to 180°). Phase shifts between π and 2π radians produce an output voltage negatively proportional to phase. The edge-triggered RS flip-flop circuit in (b) functions with signals of arbitrary duty cycle and has a monotonic relationship between phase and output voltage over the full range of 0 to 2π radians. The circuit may be initialized by means of the RESET line. D-type flip-flops with RS capability (such as the CD4013) may be used in this circuit.

There is also generally enough voltage across the quadrature network to force the phase-sensitive demodulator into a nonlinear regime in which its output voltage is relatively insensitive to the amplitude of the voltage across the quadrature network. Figure 81.10(b) shows a frequency-to-voltage converter which consists of a monostable (one-shot) triggered on each zero crossing of the modulated signal. The pulse output of the one-shot is integrated by the low-pass filter to recreate the original baseband signal. Figure 81.10(c) shows a phase-locked loop. The phase comparator circuit produces an output voltage proportional to the phase difference between the input signal and the output of a VCO; that voltage is filtered and used to drive the VCO. Assume that $\phi_1(t)$ and $\omega_1(t)$ represent the phase and frequency of the

FIGURE 81.10 FM demodulators. A quadrature detector circuit is shown in (a). The phase shift of V_q (the voltage across the quadrature network consisting of L , C_2 , and R) relative to the output voltage of the limiter varies linearly with frequency for frequencies close to ω_0 . The synchronous (phase-sensitive) demodulator produces an output proportional to the phase shift. A frequency-to-voltage converter is shown in (b). A monostable multivibrator (one-shot) produces a pulse of fixed width and amplitude with each cycle of the modulated signal. The average voltage of these pulses is proportional to the modulated signal frequency. The 74HC4538 contains two independent edge-triggered monostable multivibrators which may be triggered by a rising edge (as shown) or a falling edge (by applying the clock pulse to the B input and connecting the A input to V_{dd}). A phase-locked loop is shown in (c). The operation of the phase-locked loop is described in the text.

input signal as functions of time with corresponding Laplace transforms $\Phi_1(s)$ and $\Omega_1(s)$. The VCO output phase and frequency are represented by $\phi_2(t)$ and $\omega_2(t)$ with corresponding Laplace transforms $\Phi_2(s)$ and $\Omega_2(s)$. The phase detector produces an output voltage given by

$$v_\phi(t) = k_\phi [\phi_1(t) - \phi_2(t)] \quad (81.17)$$

The corresponding Laplace transform expression is

$$V_\phi(s) = k_f [\Phi_1(s) - \Phi_2(s)] \quad (81.18)$$

This voltage is filtered by the loop filter and is applied to the VCO which produces a frequency proportional to the control voltage. The Laplace transform of the VCO frequency is

$$\Omega_2(s) = k_\omega k_\phi H(s) [\Phi_1(s) - \Phi_2(s)] \quad (81.19)$$

Since $\Phi_1(s) = \Omega_1(s)/s$ and $\Phi_2(s) = \Omega_2(s)/s$, we may write

$$\Omega_2(s) = \left[\frac{k_\omega k_\phi H(s)}{s + k_\omega k_\phi H(s)} \right] \Omega_1(s) \quad (81.20)$$

Assume that the input frequency is a step function of height ω_1 ; this gives $\Omega_1(s) = \omega_1/s$. Inserting this into Equation 81.20 gives

$$\Omega_2(s) = \left[\frac{k_\omega k_\phi H(s)}{s + k_\omega k_\phi H(s)} \right] \frac{\omega_1}{s} \quad (81.21)$$

Application of the final value theorem of the Laplace transform to Equation 81.21 gives ω_1 as the asymptotic limit of $\omega_2(t)$; the output frequency of the VCO matches the input frequency. The VCO input voltage is ω_1/k_ω and is thus proportional to the input frequency. If the input frequency is varied by some baseband signal, the VCO input voltage follows that baseband signal. The phase-locked loop thus may serve as an FM detector; Taub and Schilling [2] give an extensive analysis. If we assume the simplest loop filter transfer function $H(s) = 1$, the bracketed term of Equation 81.19 takes the form of a single-pole low-pass filter with corner frequency $\omega_{-3dB} = k_\omega k_\phi$. The VCO output frequency tracks slowly varying input frequencies quite well, but the response to rapidly varying input frequencies is limited by the low-pass behavior of the loop. Baseband spectral components which lie below the loop corner frequency are recovered without distortion, but baseband spectral components beyond the loop corner frequency are attenuated. A single-pole RC low-pass filter is often used for the loop filter; the transfer function of the complete phase-locked loop with such a filter is:

$$\frac{\Omega_2(s)}{\Omega_1(s)} = \left[\frac{k_\omega k_\phi p_1}{s^2 + s p_1 + k_\omega k_\phi p_1} \right] \quad (81.22)$$

where $p_1 = 1/RC$. Note that the loop transfer function is of that of a second-order low-pass filter and thus may exhibit dynamics such as resonance and underdamped transient response depending on the values of the parameters k_ω , k_ϕ , and p_1 .

FIGURE 81.11 Use of phase-sensitive demodulation to measure torque in a rotating shaft as described by Sokol et al. [15]. Typical waveforms and the points in the circuit where they are found are indicated. The RC coupling to the S and R terminals of the CD4013 flip-flop provides for edge triggering.

Examples

Sokol et al. [15] describe the use of phase-sensing techniques to a shaft torque-sensing application in [Figure 81.11](#). Two identical gears are coupled by springs in a device known as a torque hub. The teeth of the gears induce signals in variable-reluctance magnetic sensors as the shaft rotates, and the Schmitt trigger circuits transform the reluctance sensor outputs (approximately sinusoidal signals with amplitudes proportional to shaft rotational velocity) into square waves of constant amplitude. The springs compress with increasing torque, shifting the phase of the magnetic pickup signals (and hence the square waves) relative to each other. The relative phase of the square waves is translated to a dc voltage by a flip-flop phase detector and RC low-pass filter. The suppression of amplitude variation by the Schmitt trigger circuits causes no loss of information; the torque measurement is conveyed by phase alone.

Cohen et al. [16] in [Figure 81.12](#) describe the use of a direct FM technique to perform noninvasive monitoring of human ventilation. Elastic belts with integral serpentine inductors encircle the chest and abdomen; these inductors are parts of resonant tank circuits of free-running radiofrequency oscillators. Ventilation causes the inductor cross-sectional areas to vary, changing their inductances and thus varying

FIGURE 81.12 Use of FM techniques in measurement of human ventilation (adapted from Cohen et al. [16]). An independent oscillator was used for each inductive belt, and the oscillator outputs were optically coupled to the demodulator circuits for the purpose of electrical isolation of the subject from equipment operated from the 60 Hz ac line. One of two demodulators is shown; the value of C_x was either 470 pF for use at a nominal frequency of 850 kHz or 220 pF for use at a nominal frequency of 1.5 MHz. Numbers adjacent to the CD74HC4046 and TL081 devices are pin numbers.

the frequencies of the oscillators. Figure 81.12 also shows one of two phase-locked loop demodulator circuits which are identical except for the value of one capacitor in the VCO circuit. The phase-locked loop utilizes a single-pole RC low-pass loop filter.

Bachman [17,18] in Figure 81.13 describes a novel application of FM techniques to provide a sensing function which would otherwise be difficult to achieve (measurement of deviations in mass flow of fine seeds in an agricultural implement). A capacitive sensing cell was constructed and made part of a discriminator circuit driven at a constant frequency; the flow of seeds through the sensing capacitor shifts the resonant frequency of the discriminator and produces a change in the discriminator output voltage. An ac-coupled differential amplifier provides an output proportional to changes in the mass flow.

81.5 Instrumentation and Components

Integrated Circuits

Table 81.1 lists certain integrated circuits which may be used in application of the modulation techniques covered in this chapter. This is not an exhaustive list of all useful types nor of all manufacturers. Most

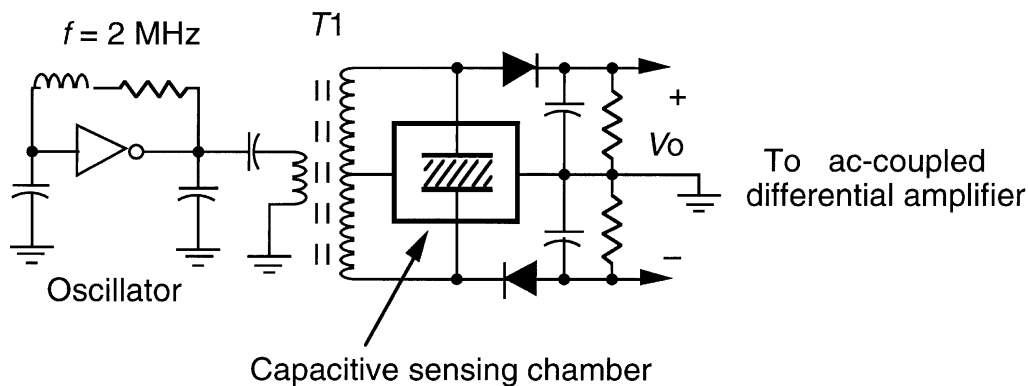

FIGURE 81.13 FM demodulator technique applied to measurement of the flow of small seeds in an agricultural machine application. The relative permittivity of the seeds causes the resonant frequency of the discriminator circuit to shift and to produce a change in the output voltage. The claimed sensitivity of this circuit is on the order of tens of femtofarads. The cross-hatched region of the sensing chamber represents the active area through which the seeds flow.

TABLE 81.1 Integrated Circuits Used in the Application of Modulation Techniques

Designation	Function	Manufacturer(s)	Approximate Price, \$
AD630JN	Balanced modulator/demodulator	Analog Devices	14.78
LM1496N	Balanced modulator/demodulator	National, Motorola, Philips	1.80

MC3363P	FM receiver system	Motorola	3.84
MC4044P	Phase/frequency detector	Motorola	18.29
74HC4538	Dual retriggerable monostable (one-shot)	Harris, Motorola	2.00

integrated circuits are available in a number of packages and performance grades; the prices given are indicative of the pricing of the least expensive versions purchased in small quantities. The AD532, AD533, and AD633 four-quadrant multipliers may be used to make balanced modulator and multiplying demodulator circuits. The AD650 may be used as either a voltage-to-frequency or frequency-to-voltage converter. The Motorola MC3362P and MC3363P are single-chip narrowband FM receivers which are useful in communications or in digital telemetry via FSK. Table 81.2 provides contact information for each of these companies.

Instrumentation

Oscilloscopes and spectrum analyzers are frequently employed in analysis of modulated signals or systems utilizing modulation techniques; both types of instruments are covered elsewhere. Certain types of specialized instrumentation are available from various manufacturers. Table 81.3 shows a short list of representative types. These instruments include scalar modulation analyzers, vector signal and modulation analyzers, signal sources with analog or digital modulation capability, and instruments for analysis of television color signals (vectorscopes). Hewlett-Packard produces a line of instruments known as modulation-domain analyzers which permit the user to characterize frequency, phase, and time interval as functions of time. Table 81.4 provides contact information for each of these companies.

Defining Terms

Modulation: The process of encoding the source information onto a bandpass signal with a carrier frequency f_c .

Amplitude modulation (AM): Continuous wave modulation, where the amplitude of the carrier varies linearly with the amplitude of the modulating signal.

Angle modulation: Continuous wave modulation, where the angle of the carrier varies linearly with the amplitude of the modulating signal.

Frequency modulation (FM): Continuous wave modulation, where the frequency of the carrier varies linearly with the amplitude of the modulating signal.

Frequency Devices

82.1 Introduction

In its broadest sense, a filter can be defined as a signal processing system whose output signal, usually called the *response*, differs from the input signal, called the *excitation*, such that the output signal has some prescribed properties. In more practical terms an electric filter is a device designed to suppress, pass, or separate a group of signals from a mixture of signals according to the specifications in a particular application. The application areas of filtering are manifold, for example to band-limit signals before sampling to reduce aliasing, to eliminate unwanted noise in communication systems, to resolve signals into their frequency components, to convert discrete-time signals into continuous-time signals, to demodulate signals, etc. Filters are generally classified into three broad classes: *continuous-time*, *sampled-data*, and *discrete-time* filters depending on the type of signal being processed by the filter. Therefore, the concept of signals are fundamental in the design of filters.

A *signal* is a function of one or more independent variables such as time, space, temperature, etc. that carries information. The independent variables of a signal can either be continuous or discrete. Assuming that the signal is a function of time, in the first case the signal is called continuous-time and in the second, discrete-time. A continuous-time signal is defined at every instant of time over a given interval, whereas a discrete-time signal is defined only at discrete-time instances. Similarly, the *values* of a signal can also be classified in either continuous or discrete.

In real-world signals, often referred to as analog signals, both amplitude and time are continuous. These types of signals cannot be processed by digital machines unless they have been converted into discrete-time signals. By contrast, a digital signal is characterized by discrete signal values, that are defined only at discrete points in time. Digital signal values are represented by a finite number of digits, which are usually binary coded. The relationship between a continuous-time signal and the corresponding discrete-time signal can be expressed in the following form:

$$x(kT) = x(t)_{t=kT}, \quad k = 0, 1, 2, \dots, \quad (82.1)$$

where T is called the sampling period.

Filters can be classified on the basis of the input, output, and internal operating signals. A continuous data filter is used to process continuous-time or analog signals, whereas a digital filter processes digital signals. Continuous data filters are further divided into *passive* or *active* filters, depending on the type of elements used in their implementation. Perhaps the earliest type of filters known in the engineering community are *LC* filters, which can be designed by using discrete components like inductors and capacitors, or crystal and mechanical filters that can be implemented using *LC* equivalent circuits. Since no external power is required to operate these filters, they are often referred to as *passive* filters. In contrast, *active* filters are based on active devices, primarily *RC* elements, and amplifiers. In a sampled data filter, on the other hand, the signal is sampled and processed at discrete instants of time. Depending on the type of signal processed by such a filter, one may distinguish between an *analog sampled data* filter and a *digital* filter. In an analog sampled data filter the sampled signal can principally take any value, whereas in a digital filter the sampled signal is a digital signal, the definition of which was given earlier. Examples of analog sampled data filters are switched capacitor (SC) filters and charge-transfer device (CTD) filters made of capacitors, switches, and operational amplifiers.

82.2 Filter Classification

Filters are commonly classified according to the filter function they perform. The basic functions are: low-pass, high-pass, bandpass, and bandstop. If a filter passes frequencies from zero to its cutoff frequency Ω_c and stops all frequencies higher than the cutoff frequencies, then this filter type is called an ideal **low-pass filter**. In contrast, an ideal **high-pass filter** stops all frequencies below its cutoff frequency and passes all frequencies above it. Frequencies extending from Ω_1 to Ω_2 are passed by an ideal **bandpass filter**, while all other frequencies are stopped. An ideal bandstop filter stops frequencies from Ω_1 to Ω_2 and passes all other frequencies. [Figure 82.1](#) depicts the magnitude functions of the four basic **ideal filter** types.

So far we have discussed ideal filter characteristics having rectangular magnitude responses. These characteristics, however, are physically not realizable. As a consequence, the ideal response can only be approximated by some nonideal realizable system. Several classical approximation schemes have been developed, each of which satisfies a different criterion of optimization. This should be taken into account when comparing the performance of these filter characteristics.

82.3 The Filter Approximation Problem

Generally the input and output variables of a linear, time-invariant, causal filter can be characterized either in the time-domain through the convolution integral given by

$$y(t) = \int_0^t h_a(t-\tau)x(\tau) d\tau \quad (82.2)$$

or, equivalently, in the frequency-domain through the transfer function

FIGURE 82.1 The magnitude function of an ideal filter is 1 in the passband and 0 in the stopband as shown for (a) low-pass, (b) high-pass, (c) bandpass, and (d) stopband filters.

$$H_a(s) = \frac{Y(s)}{X(s)} = \frac{\sum_{i=0}^N b_i s^i}{1 + \sum_{i=0}^N a_i s^i} \Leftrightarrow H_a(s) = \frac{b_N}{a_N} \prod_{i=1}^N \left(\frac{s - s_{0i}}{s - s_{\infty i}} \right) \quad (82.3)$$

where $H_a(s)$ is the Laplace transform of the impulse response $h_a(t)$ and $X(s)$, $Y(s)$ are the Laplace transforms of the input signal $x(t)$ and the output or the filtered signal $y(t)$. $X(s)$ and $Y(s)$ are polynomials in $s = \sigma + j\Omega$ and the overall transfer function $H_a(s)$ is a real rational function of s with real coefficients. The zeroes of the polynomial $X(s)$ given by $s = s_{\infty i}$ are called the poles of $H_a(s)$ and are commonly referred to as the *natural frequencies* of the filter. The zeroes of $Y(s)$ given by $s = s_{0i}$ which are equivalent to the zeroes of $H_a(s)$ are called the *transmission zeroes* of the filter. Clearly, at these frequencies the filter output is zero for any finite input. Stability restricts the poles of $H_a(s)$ to lie in the left half of the s -plane excluding the $j\Omega$ -axis, that is $\text{Re}\{s_{\infty i}\} < 0$. For a stable transfer function $H_a(s)$ reduces to $H_a(j\Omega)$ on the $j\Omega$ -axis, which is the continuous-time Fourier transform of the impulse response $h_a(t)$ and can be expressed in the following form:

$$H_a(j\Omega) = |H_a(j\Omega)| e^{j\theta(\Omega)} \quad (82.4)$$

where $|H_a(j\Omega)|$ is called the magnitude function and $\theta(\Omega) = \arg H_a(j\Omega)$ is the phase function. The gain magnitude of the filter expressed in decibels (dB) is defined by

$$\alpha(\Omega) = 20 \log |H_a(j\Omega)| = 10 \log |H_a(j\Omega)|^2 \quad (82.5)$$

Note that a filter specification is often given in terms of its attenuation, which is the negative of the gain function also given in decibels. While the specifications for a desired filter behavior are commonly given in terms of the loss response $\alpha(\Omega)$, the solution of the filter approximation problem is always carried out with the help of the characteristic function $C(j\Omega)$ giving

$$\alpha(\Omega) = 10 \log \left[1 + |C(j\Omega)|^2 \right] \quad (82.6)$$

FIGURE 82.2 The squared magnitude function of an analog filter can have ripple in the passband and in the stopband.

Note that $\alpha(\Omega)$ is not a rational function, but $C(j\Omega)$ can be a polynomial or a rational function and approximation with polynomial or rational functions is relatively convenient. It can also be shown that frequency-dependent properties of $|C(j\Omega)|$ are in many ways identical to those of $\alpha(\Omega)$. The approximation problem consists of determining a desired response $|H_a(j\Omega)|$ such that the typical specifications depicted in [Figure 82.2](#) are met. This so-called tolerance scheme is characterized by the following parameters:

- Ω_p Passband cutoff frequency (rad/s)
- Ω_s Stopband cutoff frequency (rad/s)
- Ω_c -3 dB cutoff frequency (rad/s)
- ϵ Permissible error in passband given by $\epsilon = (10^{r/10} - 1)^{1/2}$, where r is the maximum acceptable attenuation in dB; note that $10 \log 1/(1 + \epsilon^2)^{1/2} = -r$
- $1/A$ Permissible maximum magnitude in the stopband, i.e., $A = 10^{\alpha/20}$, where α is the minimum acceptable attenuation in dB; note that $20 \log (1/A) = -\alpha$.

The **passband** of a low-pass filter is the region in the interval $[0, \Omega_p]$ where the desired characteristics of a given signal are preserved. In contrast, the **stopband** of a low-pass filter (the region $[\Omega_s, \infty)$) rejects signal components. The **transition band** is the **region** between $(\Omega_s - \Omega_p)$, which would be 0 for an ideal filter. Usually, the amplitudes of the permissible ripples for the magnitude response are given in decibels.

The following sections review four different classical approximations: Butterworth, Chebyshev Type I, elliptic, and Bessel.

Butterworth Filters

The frequency response of an N th-order Butterworth low-pass filter is defined by the squared magnitude function

$$\left|H_a(j\Omega)\right|^2 = \frac{1}{1 + \left(\Omega/\Omega_c\right)^{2N}} \quad (82.7)$$

It is evident from the Equation 82.7 that the Butterworth approximation has only poles, i.e., no finite zeros and yields a maximally flat response around zero and infinity. Therefore, this approximation is also

called maximally flat magnitude (MFM). In addition, it exhibits a smooth response at all frequencies and a monotonic decrease from the specified cutoff frequencies.

Equation 82.7 can be extended to the complex s -domain, resulting in

$$H_a(s)H_a(-s) = \frac{1}{1 + \left(\frac{s}{j\Omega_c}\right)^{2N}} \quad (82.8)$$

The poles of this function are given by the roots of the denominator

$$s_k = \Omega_c e^{j\pi[1/2+(2k+1)/2N]}, \quad k=0, 1, \dots, 2N-1 \quad (82.9)$$

Note that for any N , these poles lie on the unit circle of radius Ω_c in the s -plane. To guarantee stability, the poles that lie in the left half-plane are identified with $H_a(s)$. As an example, we will determine the transfer function corresponding to a third-order Butterworth filter, i.e., $N=3$.

$$H_a(s)H_a(-s) = \frac{1}{1 + (-s^2)^3} = \frac{1}{1 - s^6} \quad (82.10)$$

The roots of denominator of Equation 82.10 are given by

$$s_k = \Omega_c e^{j\pi[1/2+(2k+1)/6]}, \quad k=0, 1, 2, 3, 4, 5 \quad (82.11)$$

Therefore, we obtain

$$\begin{aligned} s_0 &= \Omega_c e^{j\pi 2/3} = -1/2 + j\sqrt{3}/2 \\ s_1 &= \Omega_c e^{j\pi} = -1 \\ s_2 &= \Omega_c e^{j\pi 4/3} = -1/2 - j\sqrt{3}/2 \\ s_3 &= \Omega_c e^{j\pi 5/3} = 1/2 - j\sqrt{3}/2 \\ s_4 &= \Omega_c e^{j2\pi} = 1 \\ s_5 &= \Omega_c e^{j\pi/3} = 1/2 + j\sqrt{3}/2 \end{aligned} \quad (82.12)$$

The corresponding transfer function is obtained by identifying the left half-plane poles with $H_a(s)$. Note that for the sake of simplicity we have chosen $\Omega_c = 1$.

$$H_a(s) = \frac{1}{(s+1)(s+1/2-j\sqrt{3}/2)(s+1/2+j\sqrt{3}/2)} = \frac{1}{1+2s+2s^2+s^3} \quad (82.13)$$

Table 82.1 gives the Butterworth denominator polynomials up $N=5$.

Table 82.2 gives the Butterworth poles in real and imaginary components and in frequency and Q .

	-0.707	0.707	1.000	0.707	-1.382	0.971	1.689	0.611
	-0.259	0.966	1.000	1.932	-0.931	1.662	1.905	1.023
7	-1.000	0.000	1.000	—	-1.684	0.000	1.684	—
	-0.901	0.434	1.000	0.555	-1.612	0.589	1.716	0.532
	-0.623	0.782	1.000	0.802	-1.379	1.192	1.822	0.661
	-0.223	0.975	1.000	2.247	-0.910	1.836	2.049	1.126
8	-0.981	0.195	1.000	0.510	-1.757	0.273	1.778	0.506
	-0.831	0.556	1.000	0.601	-1.637	0.823	1.832	0.560
	-0.556	0.831	1.000	0.900	-1.374	1.388	1.953	0.711
	-0.195	0.981	1.000	2.563	-0.893	1.998	2.189	1.226

In the next example, the order N of a low-pass Butterworth filter is to be determined whose cutoff frequency (-3 dB) is $\Omega_c = 2$ kHz and stopband attenuation is greater than 40 dB at $\Omega_s = 6$ kHz. Thus the desired filter specification is

$$20 \log |H_a(j\Omega)| \leq -40, \quad \Omega \geq \Omega_s \tag{82.14}$$

or equivalently,

$$|H_a(j\Omega)| \leq 0.01, \quad \Omega \geq \Omega_s \tag{82.15}$$

It follows from Equation 82.7

$$\frac{1}{1 + (\Omega_s / \Omega_c)^{2N}} = (0.01)^2 \tag{82.16}$$

Solving the above equation for N gives $N = 4.19$. Since N must be an integer, a fifth-order filter is required for this specification.

Chebyshev Filters or Chebyshev I Filters

The frequency response of an N th-order Chebyshev low-pass filter is specified by the squared-magnitude frequency response function

$$\left| H_a(j\Omega) \right|^2 = \frac{1}{1 + \varepsilon^2 T_N^2(\Omega/\Omega_p)} \quad (82.17)$$

where $T_N(x)$ is the N th-order Chebyshev polynomial and ε is a real constant less than 1 which determines the ripple of the filter. Specifically, for nonnegative integers N , the N th-order Chebyshev polynomial is given by

$$T_N(x) = \begin{cases} \cos(N \cos^{-1} x), & |x| \leq 1 \\ \cosh(N \cosh^{-1} x), & |x| \geq 1 \end{cases} \quad (82.18)$$

High-order Chebyshev polynomials can be derived from the recursion relation

$$T_{N+1}(x) = 2xT_N(x) - T_{N-1}(x) \quad (82.19)$$

where $T_0(x) = 1$ and $T_1(x) = x$.

The Chebyshev approximation gives an **equiripple** characteristic in the passband and is maximally flat near infinity in the stopband. Each of the Chebyshev polynomials has real zeros that lie within the interval $(-1,1)$ and the function values for $x \in [-1,1]$ do not exceed $+1$ and -1 .

The pole locations for Chebyshev filter can be determined by generating the appropriate Chebyshev polynomials, inserting them into Equation 82.17, factoring, and then selecting only the left half plane roots. Alternatively, the pole locations P_k of an N th-order Chebyshev filter can be computed from the relation, for $k = 1 \rightarrow N$

$$P_k = -\sin \Theta_k \sinh \beta + j \cos \Theta_k \cosh \beta \quad (82.20)$$

where $\Theta_k = (2k - 1)\pi/2N$ and $\beta = \sinh^{-1}(1/\varepsilon)$.

Note: P_{N-k+1} and P_k are complex conjugates and when N is odd there is one real pole at

$$P_{N+1} = -2 \sinh \beta$$

For the Chebyshev polynomials, Ω_p is the last frequency where the amplitude response passes through the value of ripple at the edge of the passband. For odd N polynomials, where the ripple of the Chebyshev polynomial is negative going, it is the $[-1/(1 + \varepsilon^2)]^{(1/2)}$ frequency and for even N , where the ripple is positive going, is the 0 dB frequency.

The Chebyshev filter is completely specified by the three parameters ε , Ω_p , and N . In a practical design application, ε is given by the permissible passband ripple and Ω_p is specified by the desired passband cutoff frequency. The order of the filter, i.e., N , is then chosen such that the stopband specifications are satisfied.

Elliptic or Cauer Filters

The frequency response of an N th-order elliptic low-pass filter can be expressed by

$$\left|H_a(j\Omega)\right|^2 = \frac{1}{1 + \epsilon^2 F_N^2\left(\Omega/\Omega_p\right)} \quad (82.21)$$

where $F_N(\cdot)$ is called the Jacobian elliptic function. The elliptic approximation yields an equiripple passband and an equiripple stopband. Compared with the same-order Butterworth or Chebyshev filters, the elliptic design provides the sharpest transition between the passband and the stopband. The theory of elliptic filters, initially developed by Cauer, is involved, therefore for an extensive treatment refer to Reference 1.

Elliptic filters are completely specified by the parameters ϵ , α , Ω_p , Ω_s , and N

where ϵ = passband ripple

a = stop band floor

Ω_p = the frequency at the edge of the passband (for a designated passband ripple)

Ω_s = the frequency at the edge of the stopband (for a designated stopband floor)

N = the order of the polynomial

In a practical design exercise, the desired passband ripple, stopband floor, and Ω_s are selected and N is determined and rounded up to the nearest integer value. The appropriate Jacobian elliptic function must be selected and $H_a(j\Omega)$ must be calculated and factored to extract only the left plane poles. For some synthesis techniques, the roots must be expanded into polynomial form.

This process is a formidable task. While some filter manufacturers have written their own computer programs to carry out these calculations, they are not readily available. However, the majority of applications can be accommodated by use of published tables of the pole/zero configurations of low-pass elliptic transfer functions. An extensive set of such tables for a common selection of passband ripples, stopband floors, and shape factors is available in Reference 2.

Bessel Filters

The primary objectives of the preceding three approximations were to achieve specific loss characteristics. The phase characteristics of these filters, however, are nonlinear. The Bessel filter is optimized to reduce nonlinear phase distortion, i.e., a maximally flat delay. The transfer function of a Bessel filter is given by

$$H_a(s) = \frac{B_0}{B_N(s)} = \frac{B_0}{\sum_{k=0}^N B_k s^k}, \quad B_k = \frac{(2N-k)!}{2^{N-k} k! (N-k)!} \quad k = 0, 1, \dots, N \quad (82.22)$$

where $B_N(s)$ is the N th-order Bessel polynomial. The overall squared-magnitude frequency response function is given by

$$\left|H_a(j\Omega)\right|^2 = 1 - \frac{\Omega^2}{2N-1} + \frac{2(N-1)\Omega^4}{(2N-1)^2(2N-3)} + \dots \quad (82.23)$$

To illustrate Equation 82.22 the Bessel transfer function for $N = 4$ is given below:

$$H_a(s) = \frac{105}{105 + 105s + 45s^2 + 10s^3 + s^4} \quad (82.24)$$

Table 82.2 lists the factored pole frequencies as real and imaginary parts and as frequency and Q for Bessel transfer functions that have been normalized to $\Omega_c = -3$ dB.

82.4 Design Examples for Passive and Active Filters

Passive R, L, C Filter Design

The simplest and most commonly used passive filter is the simple, first-order ($N = 1$) R - C filter shown in Figure 82.3. Its transfer function is that of a first-order Butterworth low-pass filter. The transfer function and -3 dB Ω_c are

$$H_a(s) = \frac{1}{RCs + 1} \quad \text{where} \quad \Omega_c = \frac{1}{RC} \quad (82.25)$$

While this is the simplest possible filter implementation, both source and load impedance change the dc gain and/or corner frequency and its rolloff rate is only first order, or -6 dB/octave.

To realize higher-order transfer functions, passive filters use R, L, C elements usually configured in a ladder network. The design process is generally carried out in terms of a doubly terminated two-port network with source and load resistors R_1 and R_2 as shown in Figure 82.4. Its symbolic representation is given below.

The source and load resistors are normalized in regard to a reference resistance $R_B = R_1$, i.e.,

$$r_1 = \frac{R_1}{R_B} = 1, \quad r_2 = \frac{R_2}{R_B} = \frac{R_2}{R_1} \quad (82.26)$$

The values of L and C are also normalized in respect to a reference frequency to simplify calculations. Their values can be easily scaled to any desired set of actual elements.

$$l_v = \frac{\Omega_B L_v}{R_B}, \quad c_v = \Omega_B C_v R_B \quad (82.27)$$

FIGURE 82.3 A passive first-order RC filter can serve as an antialiasing filter or to minimize high-frequency noise.

FIGURE 82.4 A passive filter can have the symbolic representation of a doubly terminated filter.

FIGURE 82.5 Even and odd N passive all-pole filter networks can be realized by several circuit configurations (N odd, above; N even, below).

Low-pass filters, whose magnitude-squared functions have no finite zero, i.e., whose characteristic functions $C(j\Omega)$ are polynomials, can be realized by lossless ladder networks consisting of inductors as the series elements and capacitors as the shunt elements. These types of approximations, also referred to as *all-pole approximations*, include the previously discussed Butterworth, Chebyshev Type I, and Bessel filters. Figure 82.5 shows four possible ladder structures for even and odd N , where N is the filter order.

In the case of doubly terminated Butterworth filters, the normalized values are precisely given by

$$a_\nu = 2 \sin \left(\frac{(2\nu-1)\pi}{2N} \right), \quad \nu = 1, \dots, N \quad (82.28)$$

where a_ν is the normalized L or C element value. As an example we will derive two possible circuits for a doubly terminated Butterworth low-pass of order 3 with $R_B = 100 \Omega$ and a cutoff frequency $\Omega_c = \Omega_B = 10$ kHz. The element values from Equation 82.28 are

$$l_1 = 2 \sin \left(\frac{(2-1)\pi}{6} \right) = 1 \Rightarrow L_1 = \frac{R_B}{\Omega_c} = 1.59 \text{ mH}$$

$$c_2 = 2 \sin \left(\frac{(4-1)\pi}{6} \right) = 2 \Rightarrow C_2 = \frac{2}{\Omega_c R_B} = 3.183 \text{ nF} \quad (82.29)$$

$$l_3 = 2 \sin \left(\frac{(6-1)\pi}{6} \right) = 1 \Rightarrow L_3 = \frac{R_B}{\Omega_c} = 1.59 \text{ mH}$$

A possible realization is shown in Figure 82.6.

FIGURE 82.6 A third-order passive all-pole filter can be realized by a doubly terminated third-order circuit.

Table 82.3. Element Values for low-pass filter circuits

Filter Type	r_2	$N = 2$, Element Number		$N = 3$, Element Number		
		1	2	1	2	3
Butterworth	∞	1.4142	0.7071	1.5000	1.3333	0.5000
	1	1.4142	1.4142	1.0000	2.0000	1.0000
Chebyshev type I 0.1-dB ripple	∞	0.7159	0.4215	1.0895	1.0864	0.5158
	1	—	—	1.0316	1.1474	1.0316
Chebyshev type I 0.5 dB ripple	∞	0.9403	0.7014	1.3465	1.3001	0.7981
	1	—	—	1.5963	1.0967	1.5963
Bessel	∞	1.0000	0.3333	0.8333	0.4800	0.1667
	1	1.5774	0.4227	1.2550	0.5528	0.1922

Table 82.3 gives normalized element values for the various all-pole filter approximations discussed in the previous section up to order 3 and is based on the following normalization:

1. $r_1 = 1$;
2. All the cutoff frequencies (end of the ripple band for the Chebyshev approximation) are $\Omega_c = 1$ rad/s;
3. r_2 is either 1 or ∞ , so that both singly and doubly terminated filters are included.

The element values in Table 82.3 are numbered from the source end in the same manner as in Figure 82.4. In addition, empty spaces indicate unrealizable networks. In the case of the Chebyshev filter, the amount of ripple can be specified as desired, so that in the table only a selective sample can be given. Extensive tables of prototype element values for many types of filters can be found in Reference 4.

The example given above, of a Butterworth filter of order 3, can also be verified using Table 82.3. The steps necessary to convert the normalized element values in the table into actual filter values are the same as previously illustrated.

In contrast to all-pole approximations, the characteristic function of an elliptic filter function is a rational function. The resulting filter will again be a ladder network but the series elements may be parallel combinations of capacitance and inductance and the shunt elements may be series combinations of capacitance and inductance.

Figure 82.5 illustrates the general circuits for even and odd N , respectively. As in the case of all-pole approximations, tabulations of element values for normalized low-pass filters based on elliptic approximations are also possible. Since these tables are quite involved the reader is referred to Reference 4.

Active Filter Design

Active filters are widely used and commercially available with cutoff frequencies from millihertz to megahertz. The characteristics that make them the implementation of choice for several applications are small size for low frequency filters because they do not use inductors; precision realization of theoretical transfer functions by use of precision resistors and capacitors; high input impedance that is easy to drive and for many circuit configurations the source impedance does not effect the transfer function; low output impedance that can drive loads without effecting the transfer function and can drive the transient, switched capacitive, loads of the input stages of A/D converters and low (N+THD) performance for pre-A/D antialiasing applications (as low as -100 dBc).

Active filters use R , C , A (operational amplifier) circuits to implement polynomial transfer functions. They are most often configured by cascading an appropriate number of first- and second-order sections.

The simplest first-order ($N = 1$) active filter is the first-order passive filter of Figure 82.3 with the addition of a unity gain follower amplifier. Its cutoff frequency (Ω_c) is the same as that given in Equation 82.25. Its advantage over its passive counterpart is that its operational amplifier can drive whatever load that it can tolerate without interfering with the transfer function of the filter.

FIGURE 82.7 Second-order active filters can be realized by common filter circuits: (A) Sallen and Key low-pass, (B) multiple feedback bandpass, (C) state variable.

The vast majority of higher-order filters have poles that are not located on the negative real axis in the s -plane and therefore are in complex conjugate pairs that combine to create second-order pole pairs of the form:

$$H(s) = s^2 + \frac{\omega_p}{Q}s + \omega_p^2 \Leftrightarrow s^2 + 2as + a^2 + b^2 \quad (82.30)$$

where $p_1, p_2 = a \pm jb$

$$\omega_p^2 = a^2 + b^2$$

$$Q = \frac{\omega_p}{2a} = \frac{\sqrt{a^2 + b^2}}{2a}$$

The most commonly used two-pole active filter circuits are the *Sallen and Key* low-pass resonator, the *multiple feedback* bandpass, and the *state variable* implementation as shown in Figure 82.7a, b, and c. In the analyses that follow, the more commonly used circuits are used in their simplest form. A more comprehensive treatment of these and numerous other circuits can be found in Reference 20.

The Sallen and Key circuit of Figure 82.7a is used primarily for its simplicity. Its component count is the minimum possible for a two-pole active filter. It cannot generate stopband zeros and therefore is limited in its use to monotonic roll-off transfer functions such as Butterworth and Bessel filters. Other limitations are that the phase shift of the amplifier reduces the Q of the section and the capacitor ratio becomes large for high- Q circuits. The amplifier is used in a follower configuration and therefore is subjected to a large common mode input signal swing which is not the best condition for low distortion performance. It is recommended to use this circuit for a section $Q < 10$ and to use an amplifier whose gain bandwidth product is greater than $100 f_p$.

The transfer function and design equations for the Sallen and Key circuit of Figure 82.7a are

$$H(s) = \frac{1}{R_1 R_2 C_1 C_2} \frac{1}{s^2 + \frac{1}{R_1 C_2} s + \frac{1}{R_1 R_2 C_1 C_2}} = \frac{\omega_p^2}{s^2 + \frac{\omega_p}{Q} s + \omega_p^2} \quad (82.31)$$

FIGURE 82.8 A three-pole Butterworth active can be configured with a buffered first-order RC in cascade with a two-pole Sallen and Key resonator.

from which obtains

$$\omega^2 = \frac{1}{R_1 R_2 C_1 C_2}, \quad Q = \omega_p R_1 C_2 = \sqrt{\frac{R_1 C_2}{R_2 C_1}} \quad (82.32)$$

$$R_1, R_2 = \frac{1}{4\pi f_p Q C_2} \left[1 \pm \sqrt{1 - \frac{4Q^2 C_2}{C_1}} \right] \quad (82.33)$$

which has valid solutions for

$$\frac{C_1}{C_2} \geq 4Q^2 \quad (82.34)$$

In the special case where

$$R_1 = R_2 = R, \text{ then} \quad (82.35)$$

$$C = 1/2\pi R f_p, \quad C_1 = 2QC, \text{ and } C_2 = C/2Q$$

The design sequence for Sallen and Key low-pass of Figure 82.7a is as follows:

For a required f_p and Q , select C_1, C_2 to satisfy Equation 82.34. Compute R_1, R_2 from Equation 82.33 (or Equation 82.35 if R_1 is chosen to equal R_2) and scale the values of C_1 and C_2 and R_1 and R_2 to desired impedance levels.

As an example, a three-pole low-pass active filter is shown in Figure 82.8. It is realized with a buffered single-pole RC low-pass filter section in cascade with a two-pole Sallen and Key section.

To construct a three-pole Butterworth filter, the pole locations are found in Table 82.2 and the element values in the sections are calculated from Equation 82.25 for the single real pole and in accordance with the Sallen and Key design sequence listed above for the complex pole pair.

From Table 82.2, the normalized pole locations are

$$f_{p1} = 1.000, \quad f_{p2} = 1.000, \quad \text{and } Q_{p2} = 1.000$$

For a cutoff frequency of 10 kHz and if it is desired to have an impedance level of 10 k Ω , then the capacitor values are computed as follows:

For $R_1 = 10 \text{ k}\Omega$:

$$\text{from Equation 82.25, } C_1 = \frac{1}{2\pi R_1 r_{p1}} = \frac{1}{2\pi(10,000)(10,000)} = \frac{10^{-6}}{200\pi} = 0.00159 \text{ }\mu\text{F}$$

For $R_2 = R_3 = R = 10 \text{ k}\Omega$:

$$\text{from Equation 82.35, } C = \frac{1}{2\pi R f_{p2}} = \frac{1}{2\pi(10,000)(10,000)} = \frac{10^{-6}}{200\pi} = 0.00159 \text{ }\mu\text{F}$$

from which

$$C_2 = 2QC = 2(0.00159) \text{ }\mu\text{F} = 0.00318 \text{ }\mu\text{F}$$

$$C_3 = C/2Q = 0.5(0.00159) \text{ }\mu\text{F} = 0.000795 \text{ }\mu\text{F}$$

The *multiple feedback* circuit of Figure 82.7b is a minimum component count, two-pole (or one-pole pair), bandpass filter circuit with user definable gain. It cannot generate stopband zeros and therefore is limited in its use to monotonic roll-off transfer functions. Phase shift of its amplifier reduces the Q of the section and shifts the f_p . It is recommended to use an amplifier whose open loop gain at f_p is $> 100Q^2H_p$.

The design equations for the *multiple feedback* circuit of Figure 82.4b are

$$H(s) = -\frac{\frac{s}{R_1 C_1}}{s^2 + \frac{s}{R_3} \left(\frac{1}{C_1} + \frac{1}{C_2} \right) + \frac{(R_1 + R_2)}{R_1 R_2 R_3 C_1 C_2}} = -\frac{\frac{s\omega_p H_p}{Q}}{s^2 + \frac{s\omega_p}{Q} + \omega_p^2} \quad (82.36)$$

when $s = j\omega_p$, the gain H_p is

$$H_p = \frac{R_3 C_2}{R_1 (C_1 + C_2)} \quad (82.37)$$

From Equation 82.36 and 82.37 for a required set of ω_p , Q , and H_p :

$$R_1 = \frac{Q}{C_1 H_p \omega_p}, \quad R_2 = \frac{Q}{\omega_p} \left(\frac{1}{Q^2 (C_1 + C_2)} - H_p C_1 \right), \quad R_3 = \frac{R_1 H_p (C_1 + C_2)}{C_2} \quad (82.38)$$

For R_2 to be realizable,

$$Q^2 (C_1 + C_2) \geq H_p C_1 \quad (82.39)$$

The design sequence for a *multiple feedback* bandpass filter is as follows

Select C_1 and C_2 to satisfy Equation 82.39 for the H_p and Q required. Compute R_1 , R_2 , and R_3 . Scale R_1 , R_2 , R_3 , C_1 , and C_2 as required to meet desired impedance levels.

Note that it is common to use $C_1 = C_2 = C$ for applications where $H_p = 1$ and $Q > 0.707$.

The *state variable* circuit of Figure 82.7c is the most widely used active filter circuit. It is the basic building block of programmable active filters and of switched capacitor designs. While it uses three or four amplifiers and numerous other circuit elements to realize a two-pole filter section, it has many desirable features. From a single input it provides low-pass (V_L), high-pass (V_H), and bandpass (V_B) outputs and by summation into an additional amplifier (A_4) (or the input stage of the next section) a band reject (V_R) or stop band zero can be created. Its two integrator resistors connect to the virtual ground of their amplifiers (A_2, A_3) and therefore have no signal swing on them. Therefore, programming resistors can be switched to these summing junctions using electronic switches. The sensitivity of the circuit to the gain and phase performance of its amplifiers is more than an order of magnitude less than single amplifier designs. The open-loop gain at f_p does not have to be multiplied by either the desired Q or the gain at dc or f_p . Second-order sections with Q up to 100 and f_p up to 1 MHz can be built with this circuit.

There are several possible variations of this circuit that improve its performance at particular outputs. The input can be brought into several places to create or eliminate phase of inversions; the damping feedback can be implemented in several ways other than the R_{Qa} and R_{Qb} that are shown in Figure 82.7c and the f_p and Q of the section can be or adjusted independently from one another. DC offset adjustment components can be added to allow the offset at any one output to be trimmed to zero.

For simplicity of presentation, Figure 82.7c makes several of the resistors equal and identifies others with subscripts that relate to their function in the circuit. Specifically, the feedback amplifier A_1 , that generates the V_H output has equal feedback and input resistor from the V_L feedback signal to create unity gains from that input. Similarly, the “zero summing” amplifier, A_4 has equal resistors for its feedback and input from V_L to make the dc gain at the V_R output the same as that at V_L . More general configurations with all elements included in the equation of the transfer function are available in numerous reference texts including Reference 20.

The *state variable* circuit, as configured in Figure 82.7c, has four outputs. Their transfer functions are

$$V_L(s) = -\frac{R}{R_i(R_f C)^2} \left(\frac{1}{D(s)} \right) \quad (82.40a)$$

$$V_B(s) = \frac{R}{R_i} \left(\frac{\frac{s}{R_f C}}{D(s)} \right) \quad (82.40b)$$

$$V_H(s) = -\frac{R}{R_i} \left(\frac{s^2}{D(s)} \right) \quad (82.40c)$$

$$V_R(s) = \frac{R}{R_i(R_f C)^2} \left(\frac{\left(\frac{R_z}{R} \right) s^2 + 1}{D(s)} \right) \quad (82.40d)$$

where

$$D(s) = s^2 + \frac{a}{R_f C} s + \frac{1}{(R_f C)^2} = s^2 + \frac{\omega_p}{Q} s + \omega_p^2 \quad a = \frac{R_{Qb}}{(R_{Qa} + R_{Qb})} \left(2 + \frac{R}{R_i} \right) \quad (82.41)$$

Note that the dc gain at the low-pass output is

$$V_L(0) = -\frac{R}{R_i} \quad (82.42)$$

from which obtains

$$\omega_p = \frac{1}{R_f C} \quad \text{and} \quad \frac{1}{Q} = \frac{R_{Qb}}{(R_{Qa} + R_{Qb})} \left(2 + \frac{R}{R_i} \right) \quad (82.42)$$

The design sequence for the state variable filter of Figure 82.7c is

Select the values of R_f and C to set the frequency ω_p , the values of R_i for the desired dc gain and R_{Qa} and R_{Qb} for the desired Q and dc gain.

82.5 Discrete-Time Filters

A digital filter is a circuit or a computer program that computes a discrete output sequence from a discrete input sequence. Digital filters belong to the class of discrete-time LTI (linear time invariant) systems, which are characterized by the properties of causality, recursibility, and stability, and may be characterized in the time domain by their impulse response and in the transform domain by their transfer function. The most general case of a discrete-time LTI system with the input sequence denoted by $x(kT)$ and the resulting output sequence $y(kT)$ can be described by a set of *linear difference equations with constant coefficients*.

$$y(kT) = \sum_{\mu=0}^N b_{\mu} x(kT - \mu T) - \sum_{\mu=1}^N a_{\mu} y(kT - \mu T) \quad (82.43)$$

where $a_0 = 1$. An equivalent relation between the input and output variables can be given through the convolution sum in terms of the impulse response sequence $h(kT)$:

$$y(kT) = \sum_{\mu=0}^N h(kT) x(kT - \mu T) \quad (82.44)$$

The corresponding transfer function is given by

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\sum_{\mu=0}^N b_{\mu} z^{-\mu}}{1 + \sum_{\mu=1}^N a_{\mu} z^{-\mu}} \Leftrightarrow H(z) = b_0 \prod_{\mu=1}^N \left(\frac{z - z_{0\mu}}{z - z_{\infty\mu}} \right) \quad (82.45)$$

where $H(z)$ is the z -transform of the impulse response $h(kT)$ and $X(z)$, $Y(z)$ are the z -transform of the input signal $x(kT)$ and the output or the filtered signal $y(kT)$. As can be seen from Equation 82.44, if for at least one μ , $a_{\mu} \neq 0$, the corresponding system is recursive; its impulse response is of infinite duration — **infinite impulse response (IIR) filter**. If $a_{\mu} = 0$, the corresponding system is nonrecursive — **finite**

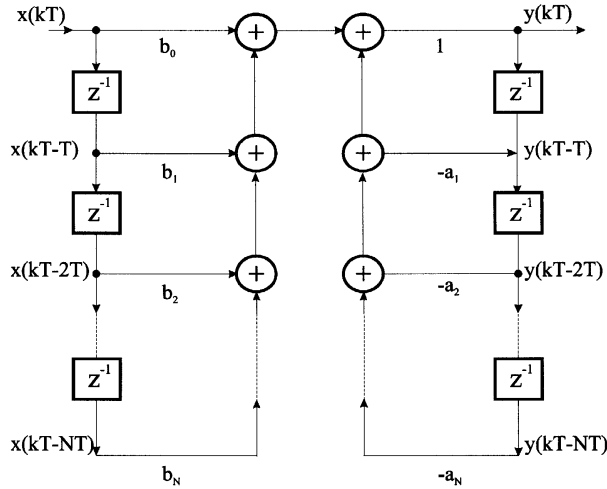

FIGURE 82.9 The difference equation of a digital filter can be realized by a direct-form I implementation that uses separate delay paths for the X and Y summations.

impulse response (FIR) filter; its impulse response is of finite duration and the transfer function $H(z)$ is a polynomial in z^{-1} . The zeros of the polynomial $X(z)$ given by $z = z_{oi}$ are called the poles of $H(z)$ and are commonly referred to as the *natural frequencies* of the filter. The condition for the stability of the filter is expressed by the constraint that all the poles of $H(z)$ should lie inside the unit circle, that is $|z_{oi}| < 1$. The zeros of $Y(z)$ given by $z = z_{ot}$ which are equivalent to the zeros of $H(z)$ are called the *transmission zeros* of the filter. Clearly, at these frequencies the output of the filter is zero for any finite input.

On the unit circle, the transfer function frequency $H(z)$ reduces to the frequency response function $H(e^{j\omega T})$, the discrete-time Fourier transform of $h(kT)$, which in general is complex and can be expressed in terms of magnitude and phase

$$H(e^{j\omega T}) = |H(e^{j\omega T})| e^{j\theta(\omega)} \quad (82.46)$$

The gain function of the filter is given as

$$\alpha(\Omega) = 20 \log_{10} |H(e^{j\omega T})| \quad (82.47)$$

It is also common practice to call the negative of the gain function the attenuation. Note that the attenuation is a positive number when the magnitude response is less than 1.

Figure 82.9 gives a block diagram realizing the difference equation of the filter, which is commonly referred to as the *direct-form I* realization. Notice that the element values for the multipliers are obtained directly from the numerator and denominator coefficients of the transfer function. By rearranging the structure in regard to the number of delays, one can obtain the canonic structure called *direct-form II* shown in Figure 82.10, which requires the minimum number of delays.

Physically, the input numbers are samples of a continuous signal and real-time digital filtering involves the computation of the iteration of Equation 82.43 for each incoming new input sample. Design of a filter consists of determining the constants a_u and b_u that satisfies a given filtering requirement. If the filtering is performed in real time, then the right side of Equation 82.46 must be computed in less than the sampling interval T .

FIGURE 82.10 A direct-form II implementation of the difference equations minimizes the number of delay elements.

82.6 Digital Filter Design Process

The digital filter design procedure consists of the following basic steps:

1. Determine the desired response. The desired response is normally specified in the frequency domain in terms of the desired magnitude response and/or the desired phase response.
2. Select a class of filters (e.g., linear-phase FIR filters or IIR filters) to approximate the desired response.
3. Select the best member in the filter class.
4. Implement the best filter using a general-purpose computer, a DSP, or a custom hardware chip.
5. Analyze the filter performance to determine whether the filter satisfies all the given criteria.

82.7 FIR Filter Design

In many digital signal-processing applications, FIR filters are generally preferred over their IIR counterparts, because they offer a number of advantages compared with their IIR equivalents. Some of the good properties of FIR filters are a direct consequence of their nonrecursive structure. First, FIR filters are inherently stable and free of limit cycle oscillations under finite-word length conditions. In addition, they exhibit a very low sensitivity to variations in the filter coefficients. Second, the design of FIR filters with exactly *linear phase* (constant group delay) vs. frequency behavior can be accomplished easily. This property is useful in many application areas, such as speech processing, phase delay equalization, image processing, etc.

Finally, there exists a number of efficient algorithms for designing optimum FIR filters with arbitrary specifications. The main disadvantage of FIR filters over IIR filter is that FIR filter designs generally require, particularly in applications requiring narrow transition bands, considerably more computation to implement.

An FIR filter of order N is described by a difference equation of the form

$$y(kT) = \sum_{\mu=0}^N b_{\mu} x(kT - \mu T) \quad (82.48)$$

FIGURE 82.11 The sequence of the delays and summations can be varied to produce alternative direct-form implementations.

and the corresponding transfer function is

$$H(z) = \frac{Y(z)}{X(z)} = \sum_{\mu=0}^N b_{\mu} z^{-\mu} \quad (82.49)$$

The objective of FIR filter design is to determine $N \pm 1$ coefficients given by

$$h(0), h(1), \dots, h(N) \quad (82.50)$$

so that the transfer function $H(e^{j\omega T})$ approximates a desired frequency characteristic. Note that because Equation 82.47 is also in the form of a convolution summation, the impulse response of an FIR filter is given by

$$h(kT) = \begin{cases} b_{\mu}, & k = 0, 1, \dots, N \\ 0 & \text{otherwise} \end{cases} \quad (82.51)$$

Two equivalent structures for FIR filters are given in Figure 82.11.

The accuracy of an FIR approximation is described by the following parameters:

- δ_p passband ripple
- δ_s stopband attenuation
- $\Delta\omega$ transition bandwidth

These quantities are depicted in Figure 82.12 for a prototype low-pass filter. δ_p and δ_s characterize the permissible errors in the passband and in stopband, respectively. Usually, the passband ripple and stopband attenuation are given in decibels, in which case their values are related to the parameters δ_p and δ_s by

$$\text{Passband ripple (dB): } A_p = -20 \log_{10}(1 - \delta_p) \quad (82.52)$$

FIGURE 82.12 Tolerance limits must be defined for an FIR low-pass filter magnitude response.

$$\text{Stopband ripple (dB): } A_s = 20 \log_{10}(\delta_s) \quad (82.53)$$

Note that due to the symmetry and periodicity of the magnitude response of $|H(e^{j\omega T})|$, it is sufficient to give the filter specifications in the interval $0 \leq \omega \leq \pi$.

Windowed FIR Filters

Several design techniques can be employed to synthesize linear-phase FIR filters. The simplest implementation is based on *windowing*, which commonly begins by specifying the ideal frequency response and expanding it in a Fourier series and then truncating and smoothing the ideal impulse response by means of a window function. The truncation results in large ripples before and after the discontinuity of the ideal frequency response known as the Gibbs phenomena, which can be reduced by using a window function that tapers smoothly at both ends. Filters designed in this way possess equal passband ripple and stopband attenuation, i.e.,

$$\delta_p = \delta_s = \delta \quad (82.54)$$

To illustrate this method, let us define an ideal desired frequency response that can be expanded in a Fourier series

$$H_d(e^{j\omega T}) = \sum_{k=-\infty}^{\infty} h_d(kT) e^{-jk\omega T} \quad (82.55)$$

where $h_d(kT)$ is the corresponding impulse response sequence, which can be expressed in terms of $H_d(e^{j\omega T})$ as

$$h_d(kT) = \frac{1}{2\pi} \int_{-\pi}^{\pi} H_d(e^{j\omega T}) e^{jk\omega T} d\omega \quad (82.56)$$

The impulse response of the desired filter is then found by weighting this ideal impulse response with a window $w(kT)$ such that

$$h(kT) = \begin{cases} w(kT)h_d(kT), & 0 \leq k \leq N \\ 0, & \text{otherwise} \end{cases} \quad (82.57)$$

Note that for $w(kT)$ in the above-given interval we obtain the rectangular window. Some commonly used windows are Bartlett (triangular), Hanning, Hamming, Blackmann, etc., the definitions of which can be found in Reference 15.

As an example of this design method, consider a low-pass filter with a cutoff frequency of ω_c and a desired frequency of the form

$$H_d(e^{j\omega T}) = \begin{cases} e^{-j\omega NT/2}, & |\omega| \leq \omega_c \\ 0, & \omega_c < |\omega| \leq \pi, \end{cases} \quad (82.58)$$

Using Equation 82.56 we obtain the corresponding ideal impulse response

$$h_d(kT) = \frac{1}{2\pi} \int_{-\omega_c}^{\omega_c} e^{-j\omega TN/2} e^{j\omega kT} d\omega = \frac{\sin[\omega_c(kT - TN/2)]}{\pi(kT - TN/2)} \quad (82.59)$$

Choosing $N = 4$, $\omega_c = 0.6\pi$ and a Hamming window defined by

$$w(kT) = \begin{cases} 0.54 - 0.46 \cos(2\pi kT/N), & 0 \leq k \leq N \\ 0, & \text{otherwise} \end{cases} \quad (82.60)$$

we obtain the following impulse response coefficients:

$$\begin{aligned} h(0) &= -0.00748 \\ h(1) &= 0.12044 \\ h(2) &= -0.54729 \\ h(3) &= 0.27614 \\ h(4) &= -0.03722 \end{aligned} \quad (82.61)$$

Optimum FIR Filters

As mentioned earlier, one of the principal advantages of FIR filters over their IIR counterparts is the availability of excellent design methods for optimizing arbitrary filter specifications. Generally, the design criterion for the optimum solution of an FIR filter design problem can be characterized as follows. The maximum error between the approximating response and the given desired response has to be minimized, i.e.,

$$E(e^{j\omega T}) = W_d(e^{j\omega T}) \left| \left| H_d(e^{j\omega T}) \right| - \left| H(e^{j\omega T}) \right| \right| \quad (82.62)$$

where $E(e^{j\omega T})$ is the weighted error function on a close range X of $[0, \pi]$ and $W_d(e^{j\omega T})$ a weighting function, which emphasizes the approximation error parameters in the design process. If the maximum absolute value of this function is less then or equal ε on X , i.e.,

$$\varepsilon = \max_{\omega \in X} \left| E(e^{j\omega T}) \right| \quad (82.63)$$

the desired response is guaranteed to meet the given criteria. Thus, this optimization condition implies that the best approximation must have an equiripple error function. The most frequently used method for designing optimum magnitude FIR filters is the Parks–McClellan algorithm. This method essentially reduces the filter design problem into a problem in polynomial approximation in the Chebyshev approximation sense as discussed above. The maximum error between the approximation and the desired magnitude response is minimized. It offers more control over the approximation errors in different frequency bands than is possible with the window method. Using the Parks–McClellan algorithm to design FIR filters is computationally expensive. This method, however, produces optimum FIR filters by applying time-consuming iterative techniques. A FORTRAN program for the Parks–McClellan algorithm can be found in the IEEE publication Programs for DSP in Reference 12. As an example of an equiripple filter design using the Parks–McClellan algorithm, a sixth-order low-pass filter with a passband $0 \leq \omega \leq 0.6\pi$, a stopband $0.8\pi \leq \omega \leq \pi$, and equal weighting for each band was designed by means of this program.

The resulting impulse response coefficients are

$$\begin{aligned} h(0) &= h(6) = -0.00596 \\ h(1) &= h(5) = -0.18459 \\ h(2) &= h(4) = 0.25596 \\ h(3) &= 0.70055 \end{aligned} \quad (82.64)$$

Design of Narrowband FIR Filters

When using conventional techniques to design FIR filters with especially narrow bandwidths, the resulting filter lengths may be very high. FIR filters with long filter lengths often require lengthy design and implementation times, and are more susceptible to numerical inaccuracy. In some cases, conventional filter design techniques, such as the Parks–McClellan algorithm, may fail the design altogether. A very efficient algorithm called the interpolated finite impulse response (IFIR) filter design technique can be employed to design narrowband FIR filters. Using this technique produces narrowband filters that require far fewer coefficients than those filters designed by the direct application of the Parks–McClellan algorithm. For more information on IFIR filter design, see Reference 7.

82.8 IIR Filter Design

The main advantage of IIR filters over FIR filters is that IIR filters can generally approximate a filter design specification using a lower-order filter than that required by an FIR design to perform similar filtering operations. As a consequence, IIR filters execute much faster and do not require extra memory, because they execute in place. A disadvantage of IIR filters, however, is that they have a nonlinear phase response. The two most common techniques used for designing IIR filters will be discussed in this section. The first approach involves the transformation of an analog prototype filter. The second method is an optimization-based approach allowing the approximation of an arbitrary frequency response.

The transformation approach is quite popular because the approximation problem can be reduced to the design of classical analog filters, the theory of which is well established, and many closed-form design methods exist. Note that this is not true for FIR filters, for which the approximation problems are of an entirely different nature. The derivation of a transfer function for a desired filter specification requires the following three basic steps:

1. Given a set of specifications for a digital filter, the first step is to map the specifications into those for an equivalent analog filter.
2. The next step involves the derivation of a corresponding analog transfer function for the analog prototype.
3. The final step is to translate the transfer function of the analog prototype into a corresponding digital filter transfer function.

Once the corresponding analog transfer function for the analog prototype is derived, it must be transformed using a transformation that maps $H_a(s)$ into $H(z)$. The simplest and most appropriate choice for s is the well-known bilinear transform of the z -variable

$$s = \frac{2(1-z^{-1})}{T_d(1+z^{-1})} \Leftrightarrow z = \frac{1+(T_d/2)s}{1-(T_d/2)s} \quad (82.65)$$

which maps a stable analog filter in the s -plane into a stable digital filter in the z -plane. Substituting s with the right-hand side of Equation 82.63 in $H_a(s)$ results in

$$H(z) = H_a\left(\frac{2(1-z^{-1})}{T_d(1+z^{-1})}\right) \Rightarrow H(e^{j\omega T})\Big|_{z=e^{j\omega T}} = H_a\left(\frac{2j}{T_d} \tan\left(\frac{\omega T}{2}\right)\right) \quad (82.66)$$

As it can be seen from Equation 82.66, the analog frequency domain (imaginary axis) maps onto the digital frequency domain (unit circle) nonlinearly. This phenomena is called frequency warping and must be compensated in a practical implementation. For low frequencies Ω and ω are approximately equal. We obtain the following relation between the analog frequency Ω and the digital frequency ω

$$\Omega = \frac{2}{T_d} \tan(\omega T/2) \quad (82.67)$$

$$\omega = \frac{2}{T} \arctan(\Omega T_d/2) \quad (82.68)$$

The overall bilinear transformation procedure is as follows:

1. Convert the critical digital frequencies (e.g., ω_p and ω_s for low-pass filters) to the corresponding analog frequencies in the s -domain using the relationship given by Equation 82.67.
2. Derive the appropriate continuous prototype transfer function $H_a(s)$ that has the properties of the digital filter at the critical frequencies.
3. Apply the bilinear transform to $H_a(s)$ to obtain $H(z)$ which is the required digital filter transfer function.

To illustrate the three-step IIR design procedure using the bilinear transform, consider the design of a second-order Butterworth low-pass filter with a cutoff frequency of $\omega_c = 0.3\pi$. The sampling rate of the digital filter is to be $f_s = 10$ Hz, giving $T = 0.1$ s. First, we map the cutoff frequency to the analog frequency

$$\Omega_c = \frac{2}{0.1} \tan(0.15\pi) = 10.19 \text{ rad/s} \quad (82.69)$$

The poles of the analog Butterworth filter transfer function $H_a(s)$ are found using Equation 82.11. As explained earlier, these poles lie equally spaced in the s -plane on a circle of radius Ω_c .

$$H_a(s) = \frac{1}{s^2 + \sqrt{2}\Omega_c s + \Omega_c^2} \quad (82.70)$$

Application of the bilinear transformation

$$s = \frac{2(1 - z^{-1})}{0.1(1 + z^{-1})} \quad (82.71)$$

gives the digital transfer function

$$H(z) = \frac{0.00002 + 0.00004z^{-1} + 0.00002z^{-2}}{1 - 1.98754z^{-1} + 0.98762z^{-2}} \quad (82.72)$$

The above computations were carried out using Reference 9, which greatly automates the design procedure.

Design of Arbitrary IIR Filters

The IIR filter design approach discussed in the previous section is primarily suitable for frequency-selective filters based on closed-form formulas. In general, however, if a design other than standard low-pass, high-pass, bandpass, and stopband is required, or if the frequency responses of arbitrary specifications are to be matched, in such cases it is often necessary to employ algorithmic methods implemented on computers. In fact, for nonstandard response characteristics, algorithmic procedures may be the only possible design approach. Depending on the error criterion used, the algorithmic approach attempts to minimize the approximation error between the desired frequency response $H_d(e^{j\omega T})$ and $H(e^{j\omega T})$ or between the time-domain response $h_d(kT)$ and $h(kT)$. Computer software is available for conveniently implementing IIR filters approximating arbitrary frequency response functions [8,9].

Cascade-Form IIR Filter Structures

Recall that theoretically there exist an infinite number of structures to implement a digital filter. Filters realized using the structure defined by Equation 82.44 directly are referred to as direct-form IIR filters. The direct-form structure, however, is not employed in practice except when the filter order $N \leq 2$, because they are known to be sensitive to errors introduced by coefficient quantization and by finite-arithmetic conditions. Additionally, they produce large round-off noise, particularly for poles closed to the unit circle.

Two less-sensitive structures can be obtained by partial fraction expansion or by factoring the right-hand side of Equation 82.46 in terms of real rational functions of order 1 and 2. The first method leads to *parallel connections* and the second one to *cascade connections* of corresponding lower-order sections, which are used as building blocks to realize higher-order transfer functions. In practice, the cascade form is by far the preferred structure, since it gives the freedom to choose the pairing of numerators and denominators and the ordering of the resulting structure. Figure 82.13 shows a cascade-form implementation, whose overall transfer function is given by

FIGURE 82.13 An IIR filter can be implemented by a cascade of individual transfer functions.

$$H(z) = \prod_{k=1}^M H_k(z) \quad (82.73)$$

where the transfer function of the k th building block is

$$H_k(z) = \frac{b_{0k} + b_{1k}z^{-1} + b_{2k}z^{-2}}{1 + a_{1k}z^{-2} + a_{2k}z^{-2}} \quad (82.74)$$

Note this form is achieved by factoring Equation 82.45 into second-order sections.

There are, of course, many other realization possibilities for IIR filters, such as state-space structures [9], lattice structures [10], and wave structures. The last is introduced in the next section.

82.9 Wave Digital Filters

It was shown earlier that for recursive digital filters the approximation problem can be reduced to classical design problems by making use of the bilinear transform. For wave digital filters (WDFs) this is carried one step farther in that the structures are obtained directly from classical circuits. Thus, to every WDF there corresponds an *LCR* reference filter from which it is derived. This relationship accounts for their excellent properties concerning coefficient sensitivity, dynamic range, and all aspects of stability under finite-arithmic conditions. The synthesis of WDFs is based on the wave network characterization; therefore, the resulting structures are referred to as wave digital filters. To illustrate the basic idea behind the theory of WDFs, consider an inductor L , which is electrically described by $V(s) = sLI(s)$. In the next step we define wave variables $A_1(s)$ and $B_1(s)$ as

$$\begin{aligned} A_1(s) &= V(s) + RI(s) \\ B_1(s) &= V(s) - RI(s) \end{aligned} \quad (82.75)$$

where R is called the port resistance. Substituting $V(s) = sLI(s)$ in the above relation and replacing s in $A_1(s)$ and $B_1(s)$ with the bilinear transform given by Equation 82.65, we obtain

$$B(z) = \frac{(1 - z^{-1})L - (1 + z^{-1})R}{(1 - z^{-1})L + (1 + z^{-1})R} A(z) \quad (82.76)$$

Letting $R = L$, the above relation reduces to

$$B(z) = -z^{-1} A(z) \quad (82.77)$$

Thus an inductor translates into a unit delay in cascade with an inverter in the digital domain. Similarly, it is easily verified that a capacitance can be simulated by a unit delay and a resistor by a digital sink. Figure 82.14 shows the digital realizations of impedances and other useful one-port circuit elements.

FIGURE 82.14 Digital filter implementations use functional equivalents to one port linear filter elements.

To establish an equivalence with classical circuits fully, the interconnections are also simulated by so-called wave adaptors. The most important of these interconnections are series and parallel connections, which are simulated by series and parallel adaptors, respectively. For most filters of interest, only two- and three-port adaptors are employed. For a complete design example consider [Figure 82.15](#).

FIGURE 82.15 Digital wave filters establish equivalence with classical filter circuits by use of wave adaptor substitutions: (A) *LC* reference low-pass; (B) identification of wire interconnections; (C) corresponding wave digital filter.

FIGURE 82.16 A data acquisition system with continuous time inputs and outputs uses antialias prefiltering, an A/D converter, digital signal processing, a D/A converter, and an output smoothing filter.

For a given *LC* filter, one can readily derive a corresponding WDF by using the following procedure. First, the various interconnections in the *LC* filter are identified as shown in Figure 82.15. In the next step the electrical elements in the *LC* filter are replaced by its digital realization using Figure 82.15. Finally, the interconnections are substituted using adaptors. Further discussions and numerical examples dealing with WDFs can be found in Reference 3, 13, and 14.

82.10 Anti-Aliasing and Smoothing Filters

In this section two practical application areas of filters in the analog conditioning stage of a data acquisition system are discussed. A block diagram of a typical data acquisition system is shown in Figure 82.16, consisting of an **antialiasing filter** before the analog-to-digital converter (ADC) and a smoothing filter after the digital-to-analog converter (DAC).

For a complete discrete reconstruction of a time-continuous, band-limited input signal having the spectrum $0 \leq f \leq f_{\max}$, the sampling frequency must be, according to the well-known Shannon's sampling theorem, at least twice the highest frequency in the time signal. In our case, in order to be able to represent frequencies up to f_{\max} , the sampling frequency $f_s = 1/T > 2f_{\max}$. The necessary band limiting to $f \leq f_{\max}$ of the input time-continuous signal is performed by a low-pass filter, which suppresses higher spectral components greater than f_{\max} . Violation of this theorem results in alias frequencies. As a result, frequency components above $f_x/2$, the so-called Nyquist frequency, appear as frequency components below $f_x/2$. Aliasing is commonly addressed by using antialiasing filters to attenuate the frequency components at and above the Nyquist frequency to a level below the dynamic range of an ADC before the signal is digitized. Ideally, a low-pass filter with a response defined by

$$H(j\Omega) = \begin{cases} 1, & |\Omega| \leq \pi/T \\ 0, & |\Omega| \geq \pi/T \end{cases} \quad (82.78)$$

is desired to accomplish this task. In practice, a variety of techniques based on the principles of continuous-time analog low-pass filter design can be employed to approximate this "brick-wall" type of characteristic. Antialiasing filters typically exhibit attenuation slopes in the range from 45 to 120 dB/octave and stopband rejection from 75 to 100 dB. Among the types of filters more commonly used for antialias purposes are the Caier elliptic, Bessel, and Butterworth. The optimum type of filter depends on which kinds of imperfections, e.g., gain error, phase nonlinearity, passband and stopband ripple, etc., are most likely to be tolerated in a particular application. For example, Butterworth filters exhibit very flat frequency response in the passband, while Chebyshev filters provide steeper attenuation at the expense of some passband ripple. The Bessel filter provides a linear phase response over the entire passband but less attenuation in the stopband. The Caier elliptic filter, with its extremely sharp roll-off, is especially useful as an antialiasing filter for multichannel digitizing data acquisition systems. However, the large-phase nonlinearity makes it more appropriate for applications involving analysis of the frequency content of signals as opposed to phase content or waveform shape.

Many considerations discussed above also apply to smoothing filters. Due to the sampling process, the frequency response after the digital-to-analog conversion becomes periodic with a period equal to the sampling frequency. The quantization steps that are created in the DAC reconstruction of the output waveform and are harmonically related to the sampling frequency must be suppressed through a low-

pass filter having the frequency response of Equation 82.78 also referred to as a smoothing or reconstruction filter. While an antialiasing filter on the input avoids unwanted errors that would result from undersampling the input, a smoothing filter at the output reconstructs a continuous-time output from the discrete-time signal applied to its input.

Consideration must be given to how much antialiasing protection is needed for a given application. It is generally desirable to reduce all aliasable frequency components (at frequencies greater than half of the sampling frequency) to less than the LSB of the ADC being used. If it is possible that the aliasable input can have an amplitude as large as the full input signal range of the ADC, then it is necessary to attenuate it by the full 2^N range of the converter. Since each bit of an ADC represents a factor of 2 from the ones adjacent to it, and $20 \log(2) = 6$ dB, the minimum attenuation required to reduce a full-scale input to less than a LSB is

$$\alpha < -20N(6 \text{ dB}) \quad (82.79)$$

where N is the number of bits of the ADC.

The amount of attenuation required can be reduced considerably if there is knowledge of the input frequency spectrum. For example, some sensors, for reasons of their electrical or mechanical frequency response, might not be able to produce a full-scale signal at or above the Nyquist frequency of the system and therefore “full-scale” protection is not required. In many applications, even for 16-bit converters that, in the worst case, would require 96 dB of antialias protection, 50 to 60 dB is adequate.

Additional considerations in antialias protection of the system are the noise and distortion that are introduced by the filter that is supposed to be eliminating aliasable inputs. It is possible to have a perfectly clean input signal which, when it is passed through a prefilter, gains noise and harmonic distortion components in the frequency range and of sufficient amplitude to be within a few LSBs of the ADC. The ADC cannot distinguish between an actual signal that is present in the input data and a noise or distortion component that is generated by the prefilter. It is necessary that both noise and distortion components in the output of the antialias filter must also be kept within an LBS of the ADC to ensure system accuracy.

82.11 Switched Capacitor Filters

Switched-capacitor (SC) filters, also generally referred to as analog sampled data filters, provide an alternative to conventional active- RC filters and are commonly used in the implementation of adjustable antialiasing filters. SC filters comprise switches, capacitors, and op amps. Essentially, an SC replaces the resistor in the more traditional analog filter designs. Because the impedance of the SC is a function of the switching frequency, one can vary the cutoff frequency of the SC filter by varying the frequency of the clock signal controlling the switching. The main advantage of SC filters is that they can be implemented in digital circuit process technology, since the equivalent of large resistors can be simulated by capacitors having small capacitance values.

When using SC filters, one must also be aware that they are in themselves a sampling device that requires antialias protection on the input and filtering on their outputs to remove clock feedthrough. However, since clock frequencies are typically 50 to 100 times f_c of the filter, a simple first or second RC filter on their inputs and outputs will reduce aliases and noise sufficient to permit their use with 12- to 14-bit ADCs. One need also to consider that they typically have dc offset errors that are large, vary with time, temperature, and programming or clock frequency. Interested readers may refer to References 5 and 14.

82.12 Adaptive Filters

Adaptive filtering is employed when it is necessary to realize or simulate a system whose properties vary with time. As the input characteristics of the filter change with time, the filter coefficients are varied with

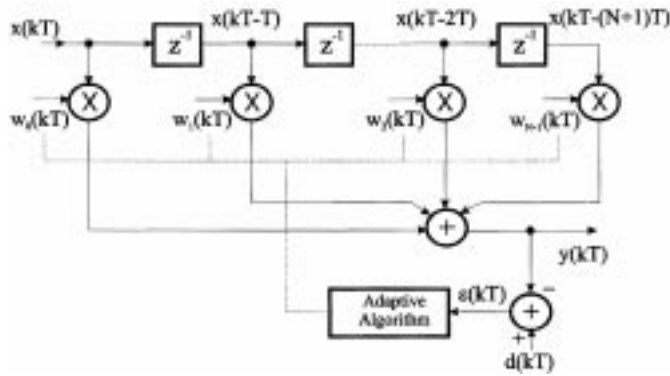

FIGURE 82.17 An adaptive filter uses an adaptive algorithm to change the performance of a digital filter in response to defined conditions.

time as a function of the filter input. Some typical applications of adaptive filtering include spectral estimation of speech, adaptive equalization, echo cancellation, and adaptive control, to name just a few. Depending on the application, the variations in the coefficients are carried out according to an optimization criterion and the adaptation is performed at a rate up to the sampling rate of the system. The self-adjustment capability of adaptive filter algorithms is very valuable when the application environment cannot be precisely described. Some of the most widely used adaptive algorithms are LMS (least-mean square), RLS (recursive least-squares), and frequency domain, also known as block algorithm. The fundamental concept of an adaptive filter is depicted in [Figure 82.17](#).

An adaptive filter is characterized by the filter input $x(kT)$ and the desired response $d(kT)$. The error sequence $\epsilon(kT)$ formed by

$$\epsilon(kT) = \sum_{\mu=0}^{N-1} w_{\mu}(kT)x(kT - \mu T) \quad (82.80)$$

and $x(kT), \dots, x(kT - T(N-1))$ serve as inputs to an adaptive algorithm that recursively determines the coefficients $w_0(kT + T), \dots, w_{N-1}(kT + T)$. A number of adaptive algorithms and structures can be found in the literature that satisfy different optimization criteria in different application areas. For more detailed developments refer to References 1, 15, and 16.

Defining Terms

Antialiasing filter: Antialiasing filters remove any frequency elements above the Nyquist frequency.

They are employed before the sampling operation is conducted to prevent aliasing in the sampled version of the continuous-time signal.

Bandpass filter: A filter whose passband extends from a lower cutoff frequency to an upper cutoff frequency. All frequencies outside this range are stopped.

Equiripple: Characteristic of a frequency response function whose magnitude exhibits equal maxima and minima in the passband.

Finite impulse response (FIR) filter: A filter whose response to a unit impulse function is of finite length, i.e., identically zero outside a finite interval.

High-pass filter: A filter that passes all frequencies above its cutoff frequency and stops all frequencies below it.

Ideal filter: An ideal filter passes all frequencies within its passband with no attenuation and rejects all frequencies in its stopband with infinite attenuation. There are five basic types of ideal filters: low pass, high pass, bandpass, stopband, and all pass.

Infinite impulse response (IIR) filter: A filter whose response to a unit impulse function is of infinite length, i.e., nonzero for infinite number of samples.

Low-pass filter: A filter that attenuates the power of any signals with frequencies above its defined cutoff frequency.

Passband: The range of frequencies of a filter up to the cutoff frequency.

Stopband: The range of frequencies of a filter above the cutoff frequency.

Transition region: The range of frequencies of a filter between a passband and a stopband.

83.1 Spectrum Analysis and Correlation

Ronney B. Panerai

Most sensors and instruments described in previous sections of this handbook can produce continuous measurements in time or sequential measurements at fixed or variable time intervals, as represented in [Figure 83.1](#). The temporal patterns resulting from such measurements are usually referred to as *signals*. Signals can either be *continuous* or *discrete in time* (Figure 83.1). The main objective of *spectral analysis* is to provide an estimate of the distribution of signal power at different frequencies. Spectral analysis and correlation techniques are an aid to the interpretation of signals and to the systems that generate them. These methods are now widely used for the analysis and interpretation of measurements performed in medicine, geophysics, vibration analysis, communications, and several other areas.

Although the original concept of a **signal** involves measurements as a function of time (Figure 83.1), this term has been generalized to include measurements along other dimensions, e.g., distance. In addition, signals can have multiple dimensions — the instantaneous velocity of an airplane can be regarded as a four-dimensional signal since it depends on time and three spatial coordinates.

With the growing availability of signal-processing computer packages and dedicated instruments, most readers will perform spectral analysis and correlation at the “touch of a button,” visualizing results on a screen or as a computer plot. These “black-box” systems are useful for saving time and money, but users should be aware of the limitations of the fundamental techniques and circumstances in which inappropriate use can lead to misleading results. This chapter presents the basic concepts of spectral analysis and correlation based on the **fast Fourier transform (FFT)** approach. FFT algorithms allow the most efficient computer implementation of methods to perform spectral analysis and correlation and have become the most popular option. Nevertheless, other approaches, such as parametric techniques, wavelet transforms, and time-frequency analysis are also available. These will be briefly discussed and the interested reader will be directed to the pertinent literature for applications that might benefit from alternative approaches.

FIGURE 83.1 Examples of continuous and discrete-time signals. (a) Continuous recording of intracranial pressure in a head-injured patient. (b) Intracranial pressure measurements obtained at regular intervals of 50 ms. (c) Non-uniformly spaced measurements of mean intracranial pressure over a period of 30 h following surgery.

Fundamental Concepts

Spectral Analysis

Practical applications of spectral and correlation analysis are performed on discrete-time signals (Figure 83.1). These are obtained either from a sequence of discrete measurements or from the transformation of a continuous signal (Figure 83.1) to digital format using an **analog-to-digital converter (ADC)**.

When the latter is adopted to allow computer analysis of an originally continuous signal, two main characteristics of the ADC need to be considered. The first is the number of bits available to represent each sample, as this will determine the resolution and accuracy of the sampled signal. The second important consideration is the *sampling interval* Δt (Figure 83.1). From the *Nyquist theorem*,¹ the maximum value of Δt must be such that the *sampling frequency* $f_s = 1/\Delta t$ is at least twice the highest frequency of interest in the original signal. If this rule is not followed, spectral and correlation estimations might be considerably distorted by a phenomenon called *aliasing*.² Low-pass filtering before ADC is always recommended to limit the bandwidth of the continuous signal to allow the correct choice of f_s or Δt . In practice, the sampling frequency is usually much higher than the minimum required by the Nyquist theorem to provide a better visual representation of the sampled data.

Let x_n represent a discrete-time signal with samples at $n = 0, 1, 2, \dots, N - 1$. The Fourier theorem^{1,2} states that it is possible to decompose x_n as a sum of cosine and sine waveforms of different frequencies using an appropriate combination of amplitude coefficients. Therefore,

$$x_n = a_0 + \sum_{k=1}^{N-1} a_k \cos\left(\frac{2\pi kn}{N}\right) + \sum_{k=1}^{N-1} b_k \sin\left(\frac{2\pi kn}{N}\right) \quad (83.1)$$

where $k = 1, 2, \dots, N - 1$ determines the frequency of each cosine and sine waveforms as $f_k = k/N\Delta t$. The corresponding coefficients are calculated from

$$a_0 = \frac{1}{N} \sum_{n=0}^{N-1} x_n \quad (83.2a)$$

$$a_k = \frac{1}{N} \sum_{n=0}^{N-1} x_n \cos\left(\frac{2\pi kn}{N}\right) \quad (83.2b)$$

$$b_k = \frac{1}{N} \sum_{n=0}^{N-1} x_n \sin\left(\frac{2\pi kn}{N}\right) \quad (83.2c)$$

Note that Equation 83.2a represents the mean value of x_n and that the argument $2\pi kn/N$ is the same for the *direct* (Equation 83.2) and *inverse* (Equation 83.1) **discrete Fourier transforms (DFT)**.

From Euler's formula,³ it is possible to combine the cosine and sine terms to express the DFT in exponential form:

$$e^{j\theta} = \cos \theta + j \sin \theta \quad (83.3)$$

leading to

$$x_n = \sum_{k=0}^{N-1} c_k e^{j(2\pi kn/N)} \quad (83.4)$$

with

$$c_k = \frac{1}{N} \sum_{n=0}^{N-1} x_n e^{-j(2\pi kn/N)} \quad (83.5)$$

where c_k is now a complex value related to the original cosine and sine coefficients by

$$c_0 = a_0 \quad (83.6a)$$

$$c_k = a_k - jb_k \quad k = 1, 2, \dots, N-1 \quad (83.6b)$$

A graphic representation of the a_k , b_k , or c_k coefficients for each value of k (or f_k) constitutes the frequency spectrum of x_n , expressing the relative contribution of different sinusoidal frequencies to the composition of x_n (Equation 83.4). Since c_k is complex (Equation 83.6b), a more meaningful physical interpretation of the spectrum is obtained with the *amplitude* and *phase* spectra, defined as

$$A_k = \left(a_k^2 + b_k^2 \right)^{1/2} = |c_k| \quad (83.7a)$$

$$\theta_k = \tan^{-1} \left(-\frac{b_k}{a_k} \right) \quad (83.7b)$$

Figure 83.2 shows the amplitude (or magnitude) and phase spectra for the signal in Figure 83.1a, sampled at intervals $\Delta t = 20$ ms. The signal was low-pass-filtered at 20 Hz before ADC. The total duration is given by $T = N\Delta t = 5$ s, corresponding to $N = 250$ samples. Before calculating the spectral coefficients, the mean value of the complete record was removed (dc term) and any linear trends were removed by fitting a straight line to the data (detrending). As will be discussed below, it is also important to apply a window to the data, to minimize the phenomenon of leakage. For $k > N/2$ both spectra present symmetrical values. This can be easily demonstrated from the fact that cosine (and sine²) functions have even symmetry while sine has odd symmetry. From Equation 83.7 it follows that A_k and θ_k have *even* and *odd* symmetry, respectively.⁴ Consequently, only half the spectral components ($k \leq N/2$) are required to give a complete description of x_n in the frequency domain.

The amplitude spectra indicates the combined amplitude of the cosine and sine terms to reconstruct x_n ; the phase spectra reflects the relative phase differences (or time delays) between the sinusoidal waveforms to generate the temporal pattern of x_n . The amplitude spectra also reflects the signal power at different frequencies. For simplicity, the power spectrum can be defined as

$$P_k = A_k^2 = |c_k|^2 \quad (83.8)$$

Direct implementation of Equation 83.8, however, leads to spectral power estimates which are biased and inconsistent. More appropriate procedures for estimating the **power spectrum** (or *power density spectrum*) will be discussed later.

Parseval's theorem⁵ demonstrates that the total signal energy can be computed either in time or frequency domain:

$$\frac{1}{N} \sum_{n=0}^{N-1} x_n^2 = \sum_{k=0}^{N-1} P_k \quad (83.9)$$

If x_n has zero mean, the left-hand side of Equation 83.9 is the biased estimator of signal variance.⁶ Although most applications of spectral analysis concentrate on the characteristics of the amplitude or power spectra, it is important to bear in mind that the phase spectrum is also responsible for the temporal pattern of x_n . As an example, both the Dirac impulse function and white noise have a flat, constant amplitude (or

FIGURE 83.2 Amplitude and phase spectra of the intracranial pressure signal represented in Figure 83.1a after analog-to-digital conversion with a sampling interval of 20 ms. The main peak in the amplitude spectrum corresponds to the frequency of the cardiac cycle in Figure 83.1a. Wraparound of the phase spectrum is apparent in the third and 13th harmonics (arrows). Both spectra have been plotted to 10 Hz only.

power) spectra,⁶ it is the difference in the phase spectra which accounts for the different morphologies in the time domain.

Interpretation of the amplitude and phase spectra of both theoretical functions and sampled data is facilitated by taking into account several properties of the DFT (Equations 83.4 and 83.5), namely, *symmetry*, *linearity*, *shifting*, *duality*, and *convolution*.⁷ To these, a very important property of Equations 83.1 and 83.4 must be added. Since cosine and sine functions are periodic, and exist for $-\infty < t < \infty$, Equations 83.1 and 83.4 will reconstruct x_n not only in the interval of interest ($0 \leq t \leq T$) but also at all other multiple intervals $pT \leq t \leq (p+1)T$ ($p = 0, \pm 1, \pm 2, \dots$). As a consequence, spectral estimations obtained with the DFT inherently assume that x_n is *periodic* with period $T = N/\Delta t$. As discussed in the following sections, this property needs to be taken into account when performing spectral analysis with the DFT and FFT.

Correlation Analysis

The basic concept of the correlation coefficient, as a measure of the strength of linear relationship between two variables⁶ can be extended to signal analysis with the definition of the **cross-correlation function (CCF)** as⁵:

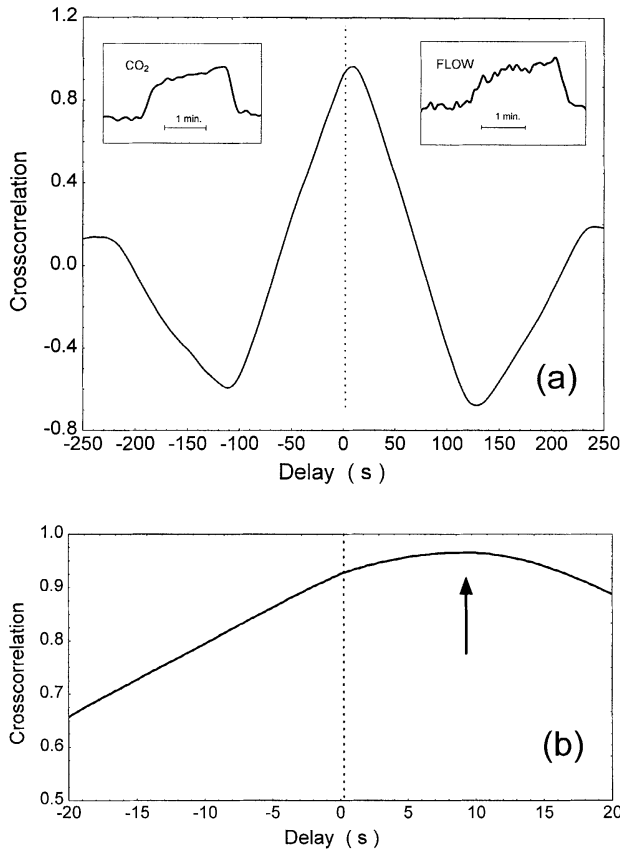

FIGURE 83.3 CCF between changes in arterial CO₂ and blood flow to the brain. Arterial CO₂ was estimated from end-tidal measurements and cerebral blood flow with Doppler ultrasound in the middle cerebral artery. (a) CCF and original signals (inserts). The cross-correlation value of approximately 1.0, observed at time delays near zero, reflects the similar temporal patterns between the two measurements. The negative cross correlations are obtained when either signal is shifted by approximately the duration of the plateau phase, which lasts 2 min. (b) Enlarging the scale around delay = 0 shows that the peak cross correlation occurs at 10 s, reflecting the time it takes for the flow to respond to the CO₂ change (Data kindly provided by Dr. Joanne Dumville, Mr. A. Ross Naylor, and Prof. David H. Evans, University of Leicester, U.K.)

$$r_{xy}(p) = \frac{1}{N} \sum_{n=0}^{N-1} x_n y_{n-p} \quad p = 0, \pm 1, \pm 2, \dots \quad (83.10)$$

where x_n and y_n are zero-mean, discrete-time signals defined in the interval $n = 0, 1, 2, \dots, N - 1$. For each value of p , the cross correlation is computed by shifting y_n by $p\Delta t$ and calculating the average product in Equation 83.10. If x_n and y_n are unrelated, the sum of positive and negative products will tend to zero. Conversely, if y_n tends to follow x_n , but with a time delay D , $r_{xy}(p)$ will show a peak at $p = D/\Delta t$. This property of the CCF is illustration in Figure 83.3. As noted by Bergland,⁸ cross correlation can be viewed as “one signal searching to find itself in another signal.”

For $y_n = x_n$, $r_{xy}(p)$ becomes the **autocorrelation function (ACF)**:

$$r_{xx}(p) = \frac{1}{N} \sum_{n=0}^{N-1} x_n x_{n-p} \quad (83.11)$$

FIGURE 83.4 ACF of the discrete-time version of the signal in Figure 83.1a. The periodicity of the ACF reflects the quasi-periodic pattern of the intracranial pressure signal (Figure 83.1a).

and it is intuitive that the maximum value of $r_{xx}(p)$ occurs for $p = 0$ with

$$r_{xx}(0) = \frac{1}{N} \sum_{n=0}^{N-1} x_n^2 \quad (83.12)$$

which represents the signal variance or total energy. Therefore, for signals with unit standard deviation, the autocorrelation peak is equal to 1.

The Wiener–Khinchine theorem⁹ demonstrates that the autocorrelation function and the power spectrum constitute a Fourier transform pair, that is,

$$S_k = \sum_{p=0}^{N-1} r_{xx}(p) e^{-j(2\pi kp/N)} \quad (83.13)$$

where S_k is usually called the autospectra of x_n .⁶ Equation 83.13 indicates that it is possible to estimate the power spectra from a previous estimate of the autocorrelation function. As a transform pair, the autocorrelation function can also be derived from the autospectra by substituting S_k for c_k in Equation 83.4.

From Equation 83.11 it is clear that $r_{xx}(p)$ has even symmetry, that is, $r_{xx}(+p) = r_{xx}(-p)$. This property is apparent in Figure 83.4, which show the estimated autocorrelation function for the signal in Figure 83.1a. Another characteristic of ACF, which can be visualized in Figure 83.4, is the occurrence of secondary peaks reflecting the presence of an oscillatory component in x_n (Figure 83.1a).

Fast Fourier Transform

The FFT is not a single algorithm but rather a large family of algorithms which can increase the computational efficiency of the DFT. The main ideas behind the formulation of FFT algorithms are discussed below. A detailed description of the different algorithms that have been proposed is beyond the scope of this introduction; this can be found in References 5 through 7 and 10 through 14.

For both software and hardware implementations of Equations 83.4 and 83.5, the computational efficiency is usually expressed by the number of complex multiplications and additions required or, simply, by the *number of operations*.¹⁰ Straight implementation of either Equation 83.4 or 83.5 leads to N^2 operations. Typically, FFT algorithms can reduce this number to $N \log_2 N$. For $N = 1024$ the FFT algorithm is 100 times faster than the direct implementation of Equation 83.4 or 83.5.

The essence of all FFT algorithms is the periodicity and symmetry of the exponential term in Equations 83.4 and 83.5, and the possibility of breaking down a transform into a sum of smaller transforms for subsets of data. Since n and k are both integers, the exponential term is periodic with period N . This is commonly represented by

$$W_N = e^{-j(2\pi/N)} \quad (83.14)$$

and Equation 83.5 can be written as

$$c_k = \frac{1}{N} \sum_{n=0}^{N-1} x_n W_N^{kn} \quad k = 0, 1, 2, \dots, N-1 \quad (83.15)$$

In many applications the terms W_N^{kn} are called **twiddle factors**. Assuming $N = 8$, calculation of the DFT with Equation 83.15 will require 64 values of W_8^{kn} . Apart from the minus sign, a simple calculation can show that there are only four different values of this coefficient, respectively: 1, j , $(1 + j)/\sqrt{2}$, and $(1 - j)/\sqrt{2}$.⁴ Consequently, only these four complex factors need to be computed, representing a significant savings in number of operations.

Most FFT algorithms are based on the principle of **decimation-in-time**, involving the decomposition of the original time (or frequency) sequence into smaller subsequences. To understand how this decomposition can reduce the number of operations, assume that N is even. In this case it is possible to show that Equation 83.15 can be written as^{4,5,7,11}:

$$c_k = \frac{1}{N} \sum_{r=0}^{(N/2)-1} x_r^e \cdot W_{N/2}^{kr} + \frac{1}{N} \sum_{r=0}^{(N/2)-1} x_r^o \cdot W_{N/2}^{kr} \quad (83.16)$$

where x_r^e and x_r^o represent the even- and odd-order samples of x_n , respectively. Comparing Equations 83.15 and 83.16, it is clear that the latter represents two DFTs with dimension $N/2$, involving $2(N/2)^2$ operations rather than the N^2 operations required by Equation 83.15. This process of decimation-in-time can be carried out further to improve computational performance. In the general case, N can be decomposed into q factors:

$$N = \prod_{i=1}^q r_i = r_1 r_2 \dots r_q \quad (83.17)$$

The number of operations required is then⁶:

$$\text{number of operations} = N \sum_{i=1}^q r_i \quad (83.18)$$

In the original algorithm of Cooley and Tukey,¹⁰ $r_i = 2$ and $N = 2^q$. In this case the theoretical number of operations required would be $2Nq = 2N \log_2 N$. As pointed out in Reference 6, further improvements in efficiency are possible because of the symmetry of the twiddle factors. The efficiency gain of most FFT algorithms using radix-2, i.e., $N = 2^q$ is

$$\text{efficiency gain} = \frac{N^2}{N \log_2 N} = \frac{N}{\log_2 N} \quad (83.19)$$

For $N = 1024$, $q = 10$ and the efficiency gain is approximately 100. Specific applications might benefit from other decompositions of the original sequence. Cases of particular interest are radix-4 and radix-8 FFTs.¹⁴ However, as shown by Rabiner and Gold,¹¹ (p. 585), it is not possible to generalize the superiority of radix-8 over radix-4 algorithms.

In general, most FFT algorithms accept complex x_n sequences in Equation 83.5. By limiting x_n to the most common situation of real-valued signals, it is possible to obtain more efficient algorithms as demonstrated by Sorensen et al.¹⁵ Uniyal¹⁶ performed a comparison of different algorithms for real-valued sequences showing that performance is architecture dependent. For machines with a powerful floating point processor, the best results were obtained with Brunn's algorithm.¹⁷

The application of FFT algorithms for spectral and correlation analysis is discussed in the following sections.

FFT Spectral Analysis

For some deterministic signals, x_n can be expressed by a mathematical function and the amplitude and phase spectra can be calculated as an exact solution of Equations 83.5 and 83.7. The same is true for the power spectra (Equations 83.8 and 83.13). Examples of this exercise can be found in many textbooks.^{1,2,4,5,7}

In most practical applications, there is a need to perform spectral analysis of experimental measurements, corresponding to signals which, in general, cannot be described by simple mathematical functions. In this case the spectra has to be estimated by a numerical solution of Equations 83.5 through 83.8, which can be efficiently implemented on a digital computer with an FFT algorithm. For estimation of the power spectrum, this approach is often classified as *nonparametric*, as opposed to other alternatives which are based on parametric modeling of the data such as *autoregressive* methods.¹⁸ Considerable distortions can result from applications of the FFT unless attention is paid to the following characteristics and properties of the measured signal and the DFT/FFT.

Limited Observation of Signal in Time

Limited observation of a signal x_n in time can be seen as the multiplication of the original signal x_n^∞ by a rectangular window of duration $T = N\Delta t$ as exemplified for a single sinusoid in Figure 83.5. The DFT assumes that x_n is periodic, with period T , as mentioned previously. Instead of a single harmonic at the frequency of the original sinusoid, the power spectrum estimated with the FFT will have power at other harmonics as indicated by the spectrum in Figure 83.5c. The spectral power, which should have been concentrated on a single harmonic (Figure 83.5c, dashed line), has "leaked" to neighboring harmonics and for this reason this phenomenon is usually called *leakage*. The morphology of the distorted spectrum of Figure 83.5c can be explained by the fact that the Fourier transform of a rectangular window function (Figure 83.5b is given by a *sinc* function ($\sin x/x$) which presents decreasing side lobes.^{1,2} Multiplication in time corresponds to the convolution operation in the frequency domain.^{1,2} In the general case of signals comprising several harmonics, the *sinc* functions will superimpose and the resulting spectrum is then a distorted version of the "true" spectrum. As the individual *sinc* functions superimpose to produce the complete spectrum, a *picket-fence* effect is also generated.⁸ This means that spectral leakage not only adds spurious power to neighboring harmonics but also restricts the frequency resolution of the main spectral peaks. The effects of spectral leakage can be reduced by (1) increasing the period of observation and (2) multiplying the original signal x_n by a window function with a smooth transition as represented by the dashed line window in Figure 83.5b. The Fourier transform of a window function with tapered ends has smaller side lobes, thus reducing the undesirable effects leakage. A large number of tapering windows have been proposed, as reviewed by Harris.¹⁹ As an example, the four-term Blackman–Harris window, defined as

$$w_n = a_0 - a_1 \cos\left(\frac{2\pi n}{N}\right) + a_2 \cos\left(\frac{4\pi n}{N}\right) - a_3 \cos\left(\frac{6\pi n}{N}\right) \quad n = 0, 1, 2, \dots, N-1 \quad (83.20)$$

FIGURE 83.5 Effect of limited observation time T on the amplitude spectra of a sinusoidal component. (a) Observation of a single harmonic (dashed line) for a limited period of time T is equivalent to the multiplication for the rectangular function represented in (b). The Blackman–Harris window is also represented in (b) (dashed line). (c) Truncating a single harmonic produces spectral estimates smeared by *leakage* (solid line) as compared with the theoretical result (dashed line) with width equal to the frequency resolution ($f_r \approx 0.004$ Hz).

produces side lobe levels of -92 dB if the a_i coefficients are chosen as $a_0 = 0.35875$, $a_1 = 0.48829$, $a_2 = 0.14128$, $a_3 = 0.01168$.¹⁹ Windows also play an important role in the sampling properties of power spectral estimates, as will be discussed later. Windowing attenuates the contribution of signal samples at the beginning and end of the signal and, therefore, reduces its effective signal duration. This effect is reflected by the equivalent noise bandwidth (ENBW) defined as¹⁹

$$\text{ENBW} = \frac{\sum_{n=0}^{N-1} w_n^2}{\left[\sum_{n=0}^{N-1} w_n \right]^2} \quad (83.21)$$

For a rectangular window $\text{ENBW} = 1.0$ and for the Blackman–Harris window (Equation 83.20) the corresponding value is 2.0. The majority of other window shapes have intermediate values of ENBW.¹⁹

Effects of “Zero-Padding”

Most FFT algorithms operate with $N = 2^q$ samples, the choice of q is many times critical. Since frequency resolution is inversely proportional to N , in many circumstances a value of q leading to $2^q > N$ is preferable to the option of limiting the signal to $N' = 2^{q-1}$ samples with $N' < N$. The most common and simple way of extending a signal to comply with the 2^q condition is by **zero-padding**. For signals with zero mean and with first and last values around zero, this can be accomplished by complementing the signal with Q zeros to achieve the condition $N + Q = 2^q$. For signals with end points different from zero, these values can be used for padding. If initial and final values differ significantly, a linear interpolation from the last to the first point is also a practical option. However, with the application of windowing, most signals will have similar initial and final points and these can be used for zero-padding. As discussed in the next section, zero-padding has important applications for the estimation of correlation functions via FFT. For spectral analysis, it is relatively simple to demonstrate that adding Q zeros corresponds to over sampling the N point original spectrum with a new frequency resolution which is $(N + Q)/N$ times greater than the original resolution. Consequently, although zero-padding does not introduce major distortions, it produces the false illusion of higher resolution than warranted by the available N measured signal samples.

Phase Spectrum Estimation

The use of Equation 83.7b to estimate the phase spectrum is fraught with a different kind of problem, resulting from the indetermination of the \tan^{-1} function to discriminate between phase angles with absolute values greater than π . This problem is illustrated in Figure 83.2b showing that phase angles decrease continuously until reaching $-\pi$ and then “jump” to continue decreasing from the $+\pi$ value. This feature of the phase spectrum is called **wraparound**. Methods to “unwrap” the phase spectrum have been proposed,²⁰ but a general satisfactory solution to this problem is not available. In some cases the shifting property of the DFT^{5,7} can be used to “rotate” the original signal in time, thus minimizing the slope of the phase spectrum and, consequently, the occurrence of wraparound.

Sampling Properties of Spectral Estimators

The most straightforward approach to computing the power spectrum is to use Equation 83.8. This method is known as the **periodogram**.⁵ Application is limited to signals which are **stationary**, meaning stable statistical properties (such as the mean and the variance) along time. For measurements performed on *nonstationary* systems, such as speech or systems with time-varying parameters, other methods of spectral estimation are available and will be mentioned later. It is possible to demonstrate that when the period of observation T tends to infinity, Equation 83.8 gives an unbiased estimate of the power spectrum. In practice, due to finite values of T , the phenomenon of spectral leakage described above will lead to power spectral estimates which are *biased*.

The second inherent problem with the periodogram is the *variance* of the resulting spectral estimates. Assuming x_n to follow a Gaussian distribution, it follows that a_k and b_k will also be Gaussian because Equation 83.2 represents a linear transformation. Since Equations 83.7a and 83.8 involve the sum of two squared Gaussian variates, P_k will follow a χ^2 distribution with two degrees of freedom.⁶ In this case the

mean and the standard deviation of the power spectral estimate will be the same, *independently of the frequency considered*. As a consequence, power spectral estimates obtained from Equation 83.8, using a simple sample x_n , should be regarded as highly unreliable. In addition, the variance or standard deviation of this χ^2 distribution does not decrease with increases in sample duration N . This indicates that the periodogram (Equation 83.8) is an *inconsistent* estimator of the power spectrum.

For a χ^2 distribution with m degrees of freedom, the coefficient of variation is given by

$$CV[\chi_m^2] = \frac{\sqrt{2m}}{m} = \sqrt{\frac{2}{m}} \quad (83.22)$$

showing that it is possible to improve the reliability of power spectral estimates by increasing m . This can be achieved by replacing Equation 83.8 by²¹

$$\hat{P}_k = \frac{1}{L} \sum_{l=1}^L c_{k,l}^2 \quad k=0, 1, 2, \dots, N-1 \quad (83.23)$$

with L representing a number of separate samples x_n each with length $T = N\Delta t$. If only one record of x_n can be obtained under stationary conditions, it is possible to break down this record into L segments to obtain an improved estimate of the power spectrum with variance reduced by a factor of L . However, the spectral resolution, given by $f_r = 1/T$, will be reduced by the same factor L , thus indicating an inescapable compromise between resolution and variance.

A *modified periodogram* was introduced by Welch²¹ consisting of the multiplication of x_n by a triangular, or other window shape, before computing the individual spectral samples with Equation 83.5. The application of a window justifies overlapping adjacent segments of data by as much as 50%. For a signal with a total duration of N samples, the combination of overlapping with segmentation (Equation 83.23) can lead to a further reduction of the spectral variance by a factor of 11/18.

Averaging L spectral samples as indicated by Equation 83.23 represents one approach to improve spectral estimation by means of *smoothing*. A similar effect can be obtained with the **correlogram**. Equation 83.13 indicates that it is possible to estimate the power spectrum from the autocorrelation function. Limiting the number of shifts of the autocorrelation function to $p \ll N$ is equivalent to smoothing the original spectrum by convolution with the Fourier transform of a Bartlett (triangular) window.²² As discussed in the next section, the autocorrelation function can also be computed more efficiently with the FFT and it can be shown that in this case it involves a smaller number of numerical operations than the Welch method based on the periodogram.⁵

FFT Correlation Analysis

Before considering the application of FFT algorithms to compute auto- and cross-correlation functions, it is important to discuss their sampling properties using Equations 83.10 and 83.11 as estimators. Assuming that variables x_n and y_n are not defined outside the interval $0 \leq n \leq N-1$, it follows from Equation 83.10 that as p increases and the two functions “slide” past each other, the effective number of summed products is $N - |p|$ rather than N as implied by Equations 83.10 and 83.11. For this reason these equations are often rewritten as

$$r_{xy}(p) = \frac{1}{N - |p|} \sum_{n=0}^{N-|p|-1} x_n y_{n-1} \quad p=0, \pm 1, \pm 2, \dots \quad (83.24)$$

The main justification for this modification, however, is that Equations 83.10 and 83.11 lead to biased estimations of correlation functions while Equation 83.24 is *unbiased*.

Equation 83.24 normally assumes that x_n and y_n are standardized variables with zero mean and unit variance. If the mean values are different from zero, Equation 83.10 and 83.11 will produce distorted estimates with a “pyramid effect” due to the presence of the dc term. However, this effect is compensated for in Equation 83.24 and in this case the effect of the mean value is to add a constant term:

$$r_{xy}(p) = r'_{xy}(p) - m_x m_y \quad (83.25)$$

where $r'_{xy}(p)$ is the cross correlation of variables with mean values m_x and m_y , respectively.

Similarly to the DFT, Equations 83.10 and 83.11 involve N^2 operations and Equation 83.24 slightly less. Since the autocorrelation and the power spectra constitute a Fourier transform pair (Equation 83.13), the computation of correlation functions can also be sped up by means of an FFT algorithm. For the sake of generality, the **cross spectrum** of x_n and y_n can be defined as⁶

$$C_{xy}(f_k) = X(f_k)Y^*(f_k) \quad (83.26)$$

with $X(f_k)$ and $Y(f_k)$ representing the Fourier transforms of x_n and y_n , respectively. The generalized Wiener–Khintchine theorem then gives the cross-correlation function as

$$r_{xy}(p) = \sum_{k=0}^{N-1} C_{xy}(f_k) e^{-j(2\pi kp/N)} \quad (83.27)$$

Therefore, “fast” correlation functions can be computed²³ using the forward FFT to calculate $X(f_k)$ and $Y(f_k)$ and then the inverse FFT to obtain $r_{xy}(p)$ with Equation 83.27. Obviously, when autocorrelation functions are being computed with this method, only one transform is necessary to obtain the autospectra (Equation 83.13) instead of the cross spectra (Equation 83.26).

When correlation functions are computed with the FFT, it is critical to pay attention again to the periodicity of the transformed variables as an intrinsic property of the DFT. When the two functions in either Equation 83.10 and 83.11 are displaced by p samples, for periodic functions there will be nonzero products outside the range $0 \leq n \leq N - 1$, thus leading to significant errors in the estimated auto- or cross-correlation functions. In this case the resulting estimates are called *circular* correlations.⁶ This error can be avoided by zero-padding the original signals from $n = N$ to $n = 2N - 1$ and computing the FFTs with $2N$ points. The resulting correlation functions will be noncircular and, in the range $0 \leq p \leq N - 1$, will agree with correlations computed with the original Equations 83.10 or 83.11. Finally, to remove bias the results of Equation 83.27 should also be multiplied by $N/(N - |p|)$ to agree with Equation 83.24.

Further Information

Software for FFT special analysis is available from multiple sources. Off-the-shelf software ranges from specialized packages for digital signal processing, such as DADiSP, to statistical packages which include FFT analysis of time series. Mathematical and engineering packages such as MATLAB also include routines for FFT spectral and correlation analysis. For a review of available options see Reference 24. For readers who want to implement their own software, FFT routines can be found in Reference 4, 13 through 15, and 18. Additional references are 25 through 27.

Hardware implementations of FFT algorithms are common in areas requiring real-time spectral analysis as in the case of blood flow velocity measurement with Doppler ultrasound. For a review of hardware implementations see References 11 and 28. Developments in this area follow the pace of change in VLSI technology.²⁹

One of the limitations of the FFT is the fact that frequency resolution is the inverse of the signal observation time. Improved resolution can be obtained with *parametric* methods of spectral analysis and

their application is particularly relevant when only short segments of data are available or when it is necessary to discriminate between frequency harmonics which are closely spaced in the spectrum. Broadly speaking, parametric methods assume that the data follow spectral densities with a known pole-zero structure of variable complexity, characterized by a given *model order*. All-zero models correspond to the *moving average* structure while the all-pole version represents the *autoregressive* model. The general case is the autoregressive-moving average model (ARMA). For a comprehensive review of these methods see Reference 30; further information and software implementations can be found in References 18 and 27.

Nonstationary signals present a particular problem. In cases where the signal statistical properties change relatively slowly with time, it is possible to select short segments of quasi-stationary data and to use the DFT or parametric methods to estimate the spectra as mentioned previously. However, when these changes in systems parameters or statistical moments are fast in relation to the phenomenon under observation (e.g., speech or seismic data), this approach is not feasible because of the poor frequency resolution resulting from short observation times. Methods proposed to cope with signal nonstationarity often depend on the underlying cause of nonstationary behavior.^{9,31} More general methods, known as *time-frequency distributions*, are now favored by most investigators.³² The Wigner–Ville and Choi–Williams transforms are some of the more widely used of these time–frequency distributions. In each case the signal is described by a simultaneous function of time *and* frequency and hence is graphically represented by a three-dimensional plot having time and frequency as dependent variables.

A different approach to the analysis of nonstationary data is the application of *wavelets*.³³ This alternative also has advantages in the representation of fast transients and in applications requiring data compression and pattern classification. Similarly to the sine and cosine functions, which are the basis of Fourier analysis, wavelets are orthogonal functions which can be used to decompose and reconstruct signals using a finite set of coefficients obtained by a *wavelet transform* (WT). The main difference between wavelets and sinusoids, however, is that the former are limited in time. In addition, the complete orthogonal set of wavelets can be obtained simply by expansion (or compression) and scaling of a single function, known as the *mother wavelet*. Because of their limited time duration wavelets can provide a much more synthetic decomposition of fast transients, or sharp edges in image analysis, than it is possible to obtain with the DFT. Their property of expansion/contraction of a single mother wavelet can also overcome a major limitation of the DFT, that is, to allow good frequency resolution at both low and high frequencies. For applications of the WT and commercially available software see References 34 and 35.

Defining Terms

Analog-to-digital conversion: The process of converting a continuous signal to a discrete time sequence of values usually sampled at uniform time intervals.

Autocorrelation function (ACF): A measure of longitudinal variability of a signal which can express the statistical dependence of serial samples.

Correlogram: Numerical calculation and graphical representation of the ACF or CCF.

Cross-correlation function (CCF): A measure of similarity between signals in the time domain which also allows the identification of time delays between transients.

Cross-spectrum: The complex product of the power spectra of two different signals.

Decimation-in-time: The process of breaking down a time series into subsequences to allow more efficient implementations of the FFT.

Discrete Fourier transform (DFT): The usual method to obtain the Fourier series of a discrete time signal.

Fast Fourier transform (FFT): Algorithm for the efficient computation of the DFT.

Periodogram: A family of methods to estimate the power spectrum using the DFT.

Power spectrum: The distribution of signal power as a function of frequency.

Signal: Continuous or discrete representation of a variable or measurement as a function of time or other dimension.

Stationarity: Property of signals which have statistical moments invariant with time.

Twiddle factors: Exponential term in the DFT whose periodicity allow repeated use and hence considerable savings of computation time in the FFT.

Wraparound: Overflow of phase spectral estimations above $|\pi|$ due to the uncertainty of the \tan^{-1} function.

Zero-padding: Extension of a signal with zeros, constant values, or other extrapolating functions.

83.2 RF/Microwave Spectrum Analysis¹

A. Ambrosini, C. Bortolotti, N. D’Amico, G. Grueff, S. Mariotti, S. Montebugnoli, A. Orfei, and G. Tomassetti

A *signal* is usually defined by a time-varying function carrying some sort of information. Such a function most often represents a time-changing electric or magnetic field, whose propagation can be in free space or in dielectric materials constrained by conductors (waveguides, coaxial cables, etc.). A signal is said to be periodic if it repeats itself exactly after a given time T called the period. The inverse of the period T , measured in seconds, is the frequency f measured in hertz (Hz).

A periodic signal can always be represented in terms of a sum of several (possibly infinite) sinusoidal signals, with suitable amplitude and phase, and having frequencies that are integer multiples of the signal frequency. Assuming an electric signal, the square of the amplitudes of such sinusoidal signals represent the power in each sinusoid, and is said to be the power spectrum of the signal. These concepts can be generalized to a nonperiodic signal; in this case, its representation (spectrum) will include a continuous interval of frequencies, instead of a discrete distribution of integer multiples of the fundamental frequency. The representation of a signal in terms of its sinusoidal components is called Fourier analysis. The (complex) function describing the distribution of amplitudes and phases of the sinusoids composing a signal is called its Fourier transform (FT). The Fourier analysis can be readily generalized to functions of two or more variables; for instance, the FT of a function of two (spatial) variables is the starting point of many techniques of image processing. A time-dependent electrical signal can be analyzed directly as a function of time with an *oscilloscope* which is said to operate in the *time domain*. The time evolution of the signal is then displayed and evaluated on the vertical and horizontal scales of the screen.

The *spectrum analyzer* is said to operate in the *frequency domain* because it allows one to measure the harmonic content of an electric signal, that is, the power of each of its spectral components. In this case the vertical and horizontal scales read powers and frequencies. The two domains are mathematically well defined and, through the FT algorithm, it is not too difficult to switch from one response to the other. Their graphical, easily perceivable representation is shown in [Figure 83.6](#) where the two responses are shown lying on orthogonal planes. It is trivial to say that the easiest way to make a Fourier analysis of a time-dependent signal is to have it displayed on a spectrum analyzer. Many physical processes produce

FIGURE 83.6 How the same signal can be displayed.

(electric) signals whose nature is not deterministic, but rather stochastic, or random (noise). Such signals can also be analyzed in terms of FT, although in a statistical sense only.

A time signal is said to be band-limited if its FT is nonzero only in a finite interval of frequencies, say $(F_{\max} - F_{\min}) = B$. Usually, this is the case and an average frequency F_0 can be defined. Although the definition is somewhat arbitrary, a (band-limited) signal is referred to as RF (radio frequency) if F_0 is in the range 100 kHz to 1 GHz and as a microwave signal in the range 1 to 1000 GHz. The distinction is not fundamental theoretically, but it has very strong practical implications in instrumentation and spectral measuring techniques. A band-limited signal can be described further as narrowband, if $B/F_0 \ll 1$, or wideband otherwise.

The first step in performing a spectral analysis of a narrowband signal is generally the so-called heterodyne downconversion: it consists in the mixing (“beating”) of the signal with a pure sinusoidal signal of frequency F_L , called local oscillator (LO). In principle, mixing two signals of frequency F_0 and F_L in any nonlinear device will result in a signal output containing the original frequencies as well as difference $(F_0 - F_L)$ and the sum $(F_0 + F_L)$ frequencies, and all their harmonic (multiple) frequencies. In the practical case, a purely quadratic mixer is used, with an LO frequency $F_L < F_0$; the output will include the frequencies $(F_0 - F_L)$, $2F_L$, $2F_0$, and $(F_0 + F_L)$, and the first term (called the intermediate frequency or IF) will be easily separated from the others, which have a much higher frequency. The bandwidth of the IF signal will be the same as the original bandwidth B ; however, to preserve the original information fully in the IF signal, stringent limits must be imposed on the LO signal, because any deviation from a pure sinusoidal law will show up in the IF signal as added phase and amplitude noise, corrupting the original spectral content. The process of downconverting a (band-limited) signal is generally necessary to perform spectral analysis in the very high frequency (microwave) region, to convert the signal to a frequency range more easily handled technically.

When the heterodyne process is applied to a wideband signal (or whenever $F_L > F_{\min}$) “negative” frequencies will appear in the IF signal. This process is called *double sideband* mixing, because a given IF bandwidth B (i.e., $F_L + B/2$) will include two separate bands of the original signal, centered at $F_L + IF$ (“upper” sideband) and $F_L - IF$ (“lower” sideband). This form of mixing is obviously undesirable in spectrum analysis, and input filters are generally necessary to split a wideband signal in several narrowband signals before downconversion. Alternatively, special mixers can be used that can deliver the upper and lower sidebands to separate IF channels. A band-limited signal in the frequency interval $(F_{\max} - F_{\min}) = B$ is said to be converted to baseband when the LO is placed at $F_L = F_{\min}$, so that the band is converted to the interval $(B-0)$. No further lowering of frequency is then possible, unless the signal is split into separate frequency bands by means of filters.

After downconversion, the techniques employed to perform power spectrum analysis vary considerably depending on the frequencies involved. At lower frequencies, it is possible to employ analog-to-digital converters (ADC) to get a discrete numerical representation of the analog signal, and the spectral analysis

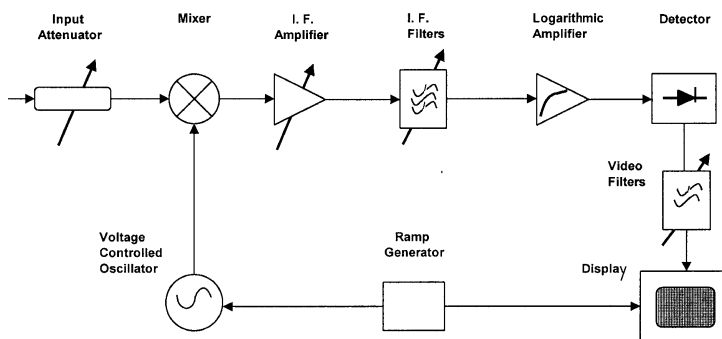

FIGURE 83.7 Block diagram of a commercial spectrum analyzer.

is then performed numerically, either by direct computation of the FT (generally via the fast Fourier transform, FFT, algorithm) or by computation of the signal autocorrelation function, which is directly related to the square modulus of the FT via the Wiener–Khinchin theorem. Considering that the ADC must sample the signal at least at the Nyquist rate (i.e., at twice the highest frequency present) and with adequate digital resolution, this process is feasible and practical only for frequencies (bandwidths) less than a few megahertz. Also, the possibility of a real-time analysis with high spectral resolution may be limited by the availability of very fast digital electronics and special-purpose computers. The digital approach is the only one that can provide extremely high spectral resolution, up to several hundred thousand channels. For high frequencies, several analog techniques are employed.

A Practical Approach to Spectrum Analysis [1]

Spectrum analysis is normally done in order to verify the harmonic content of oscillators, transmitters, frequency multipliers, etc. or the spurious components of amplifiers and mixer. Other specialized applications are possible, such as the monitoring of radio frequency interference (RFI), electromagnetic interference (EMI), and electromagnetic compatibility (EMC). These applications, as a rule, require an antenna connection and a low-noise, external amplifier. Which are then the specifications to look for in a good spectrum analyzer? We would suggest:

1. It should display selectable, very wide bands of the EM radio spectrum with power and frequency readable with good accuracy.
2. Its selectivity should range, in discrete steps, from few hertz to megahertz so that sidebands of a selected signal can be spotted and shown with the necessary details.
3. It should possess a very wide dynamic range, so that signals differing in amplitude six to eight orders of magnitude can be observed at the same time on the display.
4. Its sensitivity must be compatible with the measurements to be taken. As already mentioned, specialized applications may require external wideband, low-noise amplifiers and an antenna connection.
5. Stability and reliability are major requests but they are met most of the time.

Occasionally a battery-operated option for portable field applications may be necessary. A block diagram of a commercial spectrum analyzer is shown in Figure 83.7.

Referring to Figure 83.7 we can say that we are confronted with a radio-receiver-like superhet with a wideband input circuit. The horizontal scale of the instrument is driven by a ramp generator which is also applied to the voltage controlled LO [2].

A problem arises when dealing with a broadband mixing configuration like the one shown above, namely, avoiding receiving the image band.

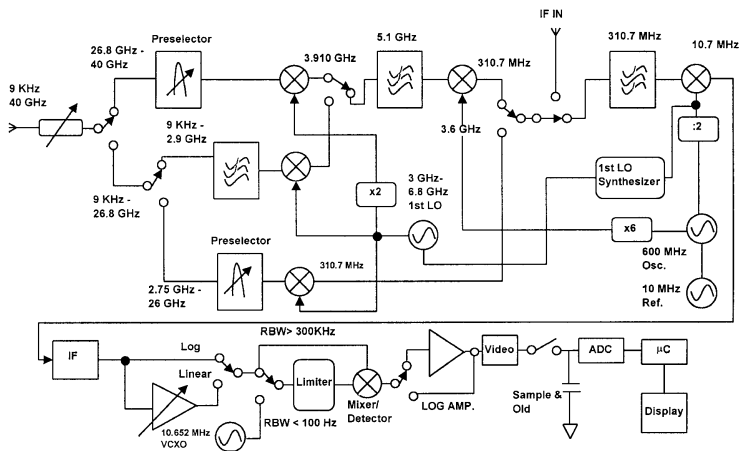

FIGURE 83.8 Standard block diagram of a modern spectrum analyzer.

FIGURE 83.9 Increasing the input bandwidth characteristics.

The problem is successfully tackled here by upconverting the input band to a high-valued IF. An easily designed input low-pass filter, not shown in the block diagram for simplicity, will now provide the necessary rejection of the unwanted image band.

Nowadays, with the introduction of YIG bandpass filter preselectors, tunable over very wide input bands, upconversion is not always necessary. Traces of unwanted signals may, however, show up on the display although at very low level (less than -80 dBc) on good analyzers.

A block diagram of a commercial spectrum analyzer exploiting both the mentioned principles is shown in Figure 83.8. This instrument includes a very important feature which greatly improves its performance: the LO frequency is no longer coming from a free-running source but rather from a synthesized unit referenced to a very stable quartz oscillator. The improved quality of the LO both in terms of its own noise and frequency stability, optimizes several specifications of the instrument, such as frequency determining accuracy, finer resolution on display, and reduced noise in general.

Further, a stable LO generates stable harmonics which can then be used to widen the input-selected bands up to the millimeter region. As already stated, this option requires external devices, e.g., a mixer-amplifier as shown in Figure 83.9a and b.

The power reference on the screen is the top horizontal line of the reticle. Due to the very wide dynamic range foreseen, the use of a log scale (e.g., 10 dB/square) seems appropriate. Conventionally, 1 mW is taken as the zero reference level: accordingly, dBm are used throughout.

The noise power level present on the display without an input signal connected (noise floor) is due to the input random noise multiplied by the IF amplifier gain. Such a noise is always present and varies with input frequency, IF selectivity, and analyzer sensitivity (in terms of noise figure).

The “on display dynamic range” of the analyzer is the difference between the maximum compression-free level of the input signal and the noise floor. As a guideline, the dynamic range of a good instrument could be of the order of 70 to 90 dB.

An input attenuator, always available on the front panel, allows one to apply more power to the analyzer while avoiding saturation and nonlinear readings. The only drawback is the obvious sensitivity loss. One should not expect a spectrum analyzer to give absolute power level readings to be better than a couple of dB.

For the accurate measurement of power levels, the suggestion is to use a power meter. An erratic signal pattern on display and a fancy level indication may be caused by the wrong setting of the “scan time” knob. It must be realized that high-resolution observation of a wide input band requires the proper scanning time. An incorrect parameter setting yields wrong readings but usually an optical alarm is automatically switched on to warn the operator.

The knowledge of the noise floor level allows a good valuation of the noise temperature, T_n (and therefore of the sensitivity), of the analyzer, a useful parameter on many occasions. The relations involved are as follows.

The Nyquist relation states that

$$P = k * T_n * B$$

where P = noise floor power level read on the display (W)

k = Boltzmann constant = 1.38×10^{-23} (J/K)

B = passband of the selected IF (Hz)

therefore,

$$T_n = P / (k * B)$$

Usually engineers prefer to quote the noise figure of receivers. By definition we can write

$$N = (T_n / T_o) + 1$$

where N = noise factor

T_o = 290 K

F (noise figure) = $10 \log N$

A typical F for a good spectrum analyzer is of the order of 30 dB.

It must be said, however, that the “ultimate sensitivity” of the spectrum analyzer will depend not only on its noise figure but also on the setting of other parameters like the video filter, the IF bandwidth, the insertion of averaging functions, the scan speed, the detector used, etc.

As a rough estimate a noise floor level of $-130/-140$ dBm is very frequently met by a good instrument.

Another criterion to select a spectrum analyzer is a good “IMD dynamic range,” that is, the tendency to create spurious signals by intermodulation due to saturation.

This figure is generally quoted by the manufacturers, but it is also easily checked by the operator by injecting two equal amplitude sinusoidal signals at the input socket of the analyzer. The frequency separation between the two should be at least a couple of “resolution bandwidths,” i.e., the selected IF bandwidth. As the input levels increase, spurious lines appear at the sum and difference frequencies and spacing of the input signals.

FIGURE 83.10 (a) Spurious free dynamic range. (b) Higher-order spurious.

The range in decibels between the nonoverloaded input signals on display and the barely noticeable spurious lines is known as the “spurious free dynamic range,” shown graphically in Figure 83.10a, where the third-order “intercept point” is also graphically determined. If input power is increased, higher-order spurious signals appear, as shown in Figure 83.10b. The input connector of most spectrum analyzers is of the $50\ \Omega$ coaxial type. Past instruments invariably used N-type connectors because of their good mechanical and electrical behavior up to quite a few gigahertz. Today SMA or K connectors are preferred.

External millimeter wave amplifiers and converters use waveguide input terminations. As is discussed in the next section, multipurpose analyzers are available where power meter, frequency counter, tracking generator, etc. can all be housed in the same cabinet. The economic and practical convenience of these units must be weighed on a case-by-case basis.

Finally, we mention that spectrum analyzers are available equipped with AM and FM detectors to facilitate their use in the RFI monitoring applications.

What Is the Right Spectrum Analyzer for My Purpose?

Several manufacturers offer a large number of spectrum analyzer models; the choice may be made on the basis of application field (i.e., CATV, mobile telephony, service, surveillance, R&D, etc.), performance (resolution bandwidth, frequency range, accuracy, battery operation etc.), or cost.

In addition, it is important to know that most spectrum analyzers need some accessories generally not furnished as a standard: for example, a connectorized, coaxial, microwave cable is always required; a directional coupler, or power divider, or handheld sampler antenna may be very useful to pick up the signals; and a personal computer is useful to collect, store, reduce, and analyze the data.

There are four main families of RF and microwave spectrum analyzers.

Family 1

The bench instruments are top performance, but also large, heavy, and the most expensive class, intended for metrology, certification, factory reference, and for radio surveillance done by government and military institutions.

The frequency ranges span from few tens of hertz up to RF (i.e., 2.9 GHz), up to microwave region (i.e., 26.5 GHz), or up to near millimeter wavelength (i.e., 40 GHz). This class of instruments includes lower noise figures, approximately 20 dB, and may be decreased down to 10 to 15 dB with an integrated preamplifier. The synthesized local oscillator has a good phase noise (typically 10 dB better than other synthesized spectrum analyzers) for precise, accurate, and stable measurement. Also this class of instruments, by sharing the display unit, can be integrated with plug-in instruments like a power meter (for more accurate power measurements) or a tracking generator (for network analysis and mixer testing).

The interface to a computer (and a printer) such IEEE-488 or RS-232 is standard; it allows remote control and data readings; this class of spectrum analyzer often has a powerful microprocessor, RAM, and disks for storing data and performing statistical and mathematical analysis.

The best known families are the Hewlett-Packard series, 71xxxx [3] and the Rhode & Schwarz series FSxx. [4]. Indicative prices are between \$50,000 and \$90,000.

Family 2

Less-expensive bench instruments, the workhorse class of spectrum analyzers, portable and lightweight, are associated with a synthesized local oscillator, that includes a frequency range from few kilohertz up to RF region (i.e., 2.9 GHz), microwave region (i.e., 26.5 GHz), or near millimeter wavelengths (i.e., 40 to 50 GHz). A typical noise figure of 30 dB is good enough to ensure most measurements. A large number of filters down to few hertz of resolution are offered; digital filters are preferable to analog ones, because they give a faster refresh rate of the trace on the display. This kind of spectrum analyzer nearly always has the capability to extend the frequency range up to millimeter and submillimeter wavelengths with an external mixer. One of the most important features for a spectrum analyzer in this class is the quality of the local oscillator; it should be synthesized (PLL) to achieve stability, precision, accuracy, and low phase noise. Demodulation is also an important feature to listen to AM, FM on the loudspeaker and to display TV pictures or complex modulations onto the screen, which is often required by people working on surveillance, TV, and mobile telephone. The interface to a computer such as IEEE-488 or RS232 is standard in a large number of spectrum analyzers, and allows the remote control and data reading, storing, and manipulation.

This kind of instrument may integrate a tracking generator, a frequency counter, and other instruments that can transform the spectrum analyzer into a compact, full-featured RF and microwave laboratory.

The most popular families are the Hewlett-Packard series 856xx [3, 5], Rhode & Schwarz series FSExxx [4], Anritsu series MS26x3 [6], IFR mod. AN930 [7], and Marconi Instruments series 239x [9]. The Tektronix production should be taken in account. Prices typically span from \$30,000 to \$60,000.

Family 3

The entry level, a more economical class of spectrum analyzer, is intended for field use or for one specific application. If your need is mainly EMI/EMC, CATV, mobile telephone, or surveillance, perhaps you do not need the extreme stability of a synthesized local oscillator, and a frequency range up to 2 GHz may be enough; however, if you need some special functions such as “quasi peak detector” or “occupied bandwidth measurement,” two functions that are a combination of a mathematical treatment with some legislative aspects, these are easily measured with a spectrum analyzer including those functions. As the normatives can change, the capability to easily upgrade the measurement software is important; some models come with a plug-in memory card, some others with 3.5” disks.

A large number of spectrum analyzer models are tailored to meet the specific needs of a customer. This is the case with the HP series 859x [3], Tektronix series 271x [10], IFR series A-xxxx [8], Anritsu MS2651 [6], and Advantest series U4x4x [4]. Costs typically are around \$10, 000 to \$20,000.

Family 4

The most economical class of spectrum analyzer, with prices around \$2,000 to \$6000, includes instruments that perform only the basic functions with a limited frequency range and filter availability and without digital capability. They are intended for service, for general-purpose measurements (i.e., IP₃, harmonic distortion) or for recertification in EMI/EMC measurements. One of the most popular series is the Hameg series HM50xx [11].

In this class are some special spectrum analyzers that come on a personal computer (PC) board. Such spectrum analyzers, generally cheap (typically \$3,000 to \$5,000), with frequency range up to 2 GHz, may include PLL local oscillators, tracking generators, and other advanced characteristics. The input is through a coaxial connector on the board, the output and the control is done by a virtual instrument running on the PC. One model is made by DKD Instruments [12].

Other unusual RF spectrum analyzers working in conjunction with a PC and worth noting are the instruments for EMI/EMC measurements and reduction in power lines and power cords. For this type of instrument, the core is not the hardware but the software that performs the measurement according to international standards and may guide the engineer to meet the required compatibility. An example is given by Seaward Electronic Sceptre [13].

FIGURE 83.11 Block diagram of spectrum analyzer for radioastronomy.

Advanced Applications

New technological approaches and the use of spectrum analysis concepts in radioastronomy constitute some advanced spectrum analysis applications. Autocorrelators, with a typical frequency resolution of $\sim 5/25$ kHz, have been extensively used in radioastronomy. Their performance is well documented; the autocorrelation function is computed online and recorded. Later the FFT of the function is computed off line in order to get the power spectrum. Recently, the Tektronix 3054 Fourier Analyzer, based on a bank of programmable filters, was introduced as an alternative approach. The state of the art in integrated digital signal processors (DSPs) allows an alternative approach to spectrum analysis. By paralleling several of these DSPs, one is able to compute online the FFT directly on a very wide input bandwidth (several tens of megahertz).

By using this technique, high time and frequency resolution can be achieved.

A system based on the Sharp LH9124-LH9320 chip set is described in Figure 83.11. It is based on VME boards: one or two 10-bit, 40-MS/s ADCs and two boards in charge to compute the FFT of the incoming streams of data, in real time [14]. A following block computes the power and averages on board up to 64 K spectra before storing the result on disk or tape. The FFT boards are powered by one of the fastest state-of-the-art DSPs (Sharp LH9124). The overall system is controlled by an embedded FORCE 3 Sparcstation. The LH 9124 DSP works with 24+24 bits (with 6 exponent bit) in block floating point. The system architecture allows expansion of the input bandwidth and the number of channels by paralleling more DSP boards. All the computing core is housed in a VME crate and is able to produce single-sided spectra from 1024 frequency bins to 131072 bins at an input bandwidth of 12 MHz without losing data or with 56% of time efficiency at 20 MHz. Single- or double-channel operation mode is provided. In a single-channel mode the main features of the system are reported as

Input bandwidth	0.5–20 MHz
Time efficiency	100% at 12 MHz (56% at 20 MHz)
FFT size	1K, 2K, 256K (points)
Avg's out format	<256 averages \rightarrow integer 24 bits >256 averages \rightarrow float 32 bits
Windows	Hanning, Hamming, Kaiser Bessel

This spectrometer was developed (1993) as a cost-effective system for both the NASA-SETI (Search for Extraterrestrial Intelligence) program [15,16] and for radioastronomical spectroscopy [17] at the CNR Institute of Radio Astronomy of Bologna. The digital spectrometer was first used to investigate the effects of the Jupiter/SL9 comet impacts (July 1994) [18,19]. In this application, the high time resolution of the spectrometer (a 16K points FFT every 1.3 ms) was exploited to compensate for the fast planet rotational velocity Doppler shift.

The system has been successfully used at the 32-m dish radiotelescope near Bologna in many line observations with unique results. Note that the use of such a high time and resolution system in radio astronomy may help to observe the molecular line in a very precise and unusual way. The whole pattern (a couple of megahertz wide) of a NH_3 molecule line coming from the sky was obtained in flash mode with a frequency resolution high enough to distinguish the different components. The same machine can be used for high-time-resolution observations of pulsar and millisecond pulsar. In those cases, the possibility of performing the FFT of the RF signal on line allows coherent dedispersion of the pulses. This new technological approach in computing the FFT may be successfully addressed to many different fields, such as image processing, medical diagnostic systems, radio surveillance, etc.

84.1 Introduction

For a variety of reasons the signal that comes from the output of a sensor will usually need to be processed as has been explained elsewhere. This may be needed for a single sensor alone, as found in the conversion from an electronic resistance temperature sensor into the equivalent digital display number.

Alternately and increasingly so, as is now discussed, the outputs from several sensors need to be combined into a single signal to form a mapping of those sources from “many to one.” An example of this would be when a set of sensors measuring many different variables is used to determine if a machine tool is correctly making a component.

There are now many ways that can be used to combine signals, each having its own features that make it the best to use in a given circumstance.

Signal-processing methods range from the well-proven and mostly used method using processing based on mathematical relationships that are very precise — these are explained elsewhere. These are generally executed using digital computation and are often referred to as digital signal processing (DSP) methods.

Alternately, it has now been shown conclusively that less quantitative methods can be also used to great effect despite their lack of complete formal mathematical formulation. These are here called the (applied intelligence) methods, a convention developed to distinguish man-made systems from the very broad, and oversold, use of the term *artificial intelligence*.

Many seemingly different methods exist in the latter group but, as will be shown here, they are a part of a continuum of ways that range from use of subjective to exactly objective procedures. These are not well explained as a group because they are presented in the literature as different methods used in isolation of each other. This account shows how they all tie together, thus making it easier to decide which is appropriate in a given application. They are particularly useful for handling highly nonlinear situations where algorithms cannot be realized.

While we appear to prefer the total objectivity of a mathematically formulated method of signal processing, it is now well proven that the AI methods often are better choices to use in terms of better speed of performance and often lower cost of processing. Often they are the only solution since the algorithmic approach cannot be deployed because of the lack of a suitable mathematical formulation or powerful enough processor to run the algorithm.

Signal processing in the modern instrument, therefore, will often make use of many different methods. This account is an introduction to the characteristics of the various forms and is written to assist selection. Space limitations prevent presentation of each kind in detail.

84.2 Overview of Algorithmic Methods

Traditionally the most popular method used to develop mapping models is that of mathematical modeling. The mathematical model is usually what is sought, as it provides the highest level of understanding about the subject and the most precise representation of the behavior. The major disadvantage of mathematical models is that they can quickly become so complex that implementation of these models in measurement systems is often impractical.

In this class, the single, or set of multiple, input signal(s) to the data processor is converted to the output form using tightly formulated mathematical description. This relationship is called the algorithm. Strict relationships hold; the relationship is said to be *formal*, meaning that for any given input the output will always be the same. The algorithm supports only one interpretation.

This method of signal processing is the most highly developed method and is certainly one to aim for because it is devoid of ambiguity. All will agree on how it will respond. It carries a comforting level of understanding and, thus, acceptance.

Algorithmic methods can be very accurate, traceable, and can be calibrated with relative ease and agreement. They are the basis of many instrumentation systems. The origin of their use in instrumentation goes back to the early days of computing using, first, mechanical computational machines (late 1800s to around 1930) and then analog electric devices (early 1900s to 1960s), all of which were mostly replaced by the use of digital computers commencing around 1950. All of these algorithmic methods of processing can be simplistically regarded as embodiments of a mathematical equation inside a suitable technological machine.

As the demanded complexity and performance requirements grew over time, so did the demands on the detail of the algorithm and the means to model it inside a computational machine. Mathematical description eventually reaches limits of definition as the models push the boundaries of mathematical methods and human development. Too often, this arises before adequate detail is able to be built into the model. The algorithm is then an inadequate model of the need.

As the algorithm increases in complexity, the processing power needed must be increased to maintain both fidelity and speed of processing.

Despite great advances being made in algorithm development and in computer power, the algorithmic methodology eventually encountered mathematical and technological barriers in many fields. The method is seen to not always be the best to use because of lack of an adequate algorithm or the high cost of computing.

In instrumentation, another factor also arises. Fast, detailed processing brings with it the need for increasing electrical bandwidth requirements in signal transmission. This increases implementation costs and also eventually reaches technological constraints.

84.3 Overview of Applied Intelligence Methods

Fortunately, the solutions that may overcome these limiting constraints in many circumstances were developing in other fields under the general name of artificial intelligence (now called applied intelligence in engineering), as new forms of mathematics and in other fields, such as decision theory.

Principally, a key limitation of the algorithmic method is that its unforgiving level of formalism carries with it a depth of processing exactitude that is often not warranted.

Other methods have emerged that allow vaguely subjective, as opposed to tightly objective, processing to be applied to good effect.

These AI methods have gradually gained acceptance to the degree that many are now routinely used and are supported by dedicated applications software and electronic integrated circuitry.

At first, these many alternatives were seen to be isolated methods. Gradually, the literature has shown trends to merge them in pairs. Their use in a more widely mixed form is still limited. This account seeks to give a comprehensive appreciation of the commonly met AI processing methods by placing them into relative perspective.

It is interesting to contemplate that natural world computing in animals does not appear to make much use of algorithmic methods, but does make extensive use of the methods presented here in the AI class.

The paradigm invoked here is that experience has shown that informal methods based on knowledge-based systems (KBS) can produce mappings of many inputs to one by use of less than completely formal description.

The AI methods can yield surprisingly efficient solutions to previously unsolved needs. They often can outperform algorithmic methods or carry out a similar task with far less computing power. They are all associated with multiple input processing and can be applied to forming decisions from data supplied by sensors. Each situation has to be judged on the balance between use of computing effort and effective processing.

On the downside, they lack formality and thus may be very hard to calibrate and authenticate. They, not having adequate scientific foundation and a solid formal base of operation, are not easily accepted as “sound.” They are often hard to comprehend by a second party, for their description is not always adequately documented or done to any agreed convention. As their principles vary widely, they must be well understood before application is developed.

For all of these negative factors, they often are able to provide “more performance for less cost” and thus will be increasingly adopted.

Their rising level of use should not suggest the algorithmic methods will become obsolete, but more that the instrument designer now has a much larger set of processing tools available.

84.4 Mapping, in General

The high-level purpose of most signal processing is to yield knowledge of a situation so that decisions can be made.

For example, consider a health-monitoring system installed on an aircraft engine. A set of sensors of different measurand types and locations is installed at various critical points on the engine — temperatures, pressures, flow rates, metal content of the lubricating oil, and more. The data from these are collected and transmitted to a central processor using a common digital bus. The many inputs then need to be combined in some way to decide such conditions as emergency states, when to change the oil, and engine efficiency. This combination is a “mapping of many to a few.”

These are not always simple mappings, for there is no adequate algorithm available to give a mathematical description for such things as degradation of oil condition. However, human intuition can be used quite effectively to obtain answers — the human mind is very capable of carrying out such mapping functions. This form of natural processing makes use of what are technically called “heuristics” — but more commonly known as “rules of thumb.”

Consider the question, “How could we decide, using an automated measurement system, when loaves being made in a bakery are satisfactory to sell?” As the way to decide this almost all people asked would suggest that the weight, size, crustiness, appearance and softness inside would be the parameters that must all be satisfactory (that is, lie within a small range of values for each) to be declared suitable. Weight

and size are easily measured; the others are not for they are really heuristics, as is the choice of the set of parameters.

The thought process implemented here is that the designer starts with a desire to know something about a situation. Consider how we could automatically monitor the “risk of working in a hazardous place” in order to give an alarm at set levels. In this kind of situation a study of the problem will lead to identification of key parameters. These parameters can each be assigned safety functions that express how each parameter varies with system changes. With this framework it is then possible to set up a signal-processing system that continuously calculates the risk level. This form of solution is based on ideas embodied in the wide field of decision-making theory.

The heart of application of AI methods of signal processing in instrumentation lies with appreciation of decision theory methods.

A range of multivariable mappings methods using AI ideas have emerged. Those well established in instrumentation are

- Representational measurement theory and ways sets are mapped into other sets (whose usefulness is still emerging);
- Rule and frame representation of heuristic knowledge and ways they are used to form expert systems and other KBSs;
- Binary Boolean trees as crisp logical mappings; which is the foundation of the
- Fuzzy logic method based on fuzzy set theory.

Another class of AI methodology that does not fit the same sequence, yet includes powerful methods, is those that assist optimization of the mapping setup. There are two main methods in use;

- Genetic algorithm and its use to optimize fuzzy logic and other multisensor setups, and the
- Artificial neural net, a mapping method that learns by itself, from experience, how to achieve an optimal mapping in a given situation that it has been taught to work in.

84.5 Basics of Decision Theory

Rules about a Decision-Making Process

Before entering into the detail of the AI signal-processing methods, it is necessary to develop a foundation about the ways in which decisions can be made by computers using sensed information. It is not that well appreciated, but setting up a mapping-type signal-processing situation is actually implementing a decision-making information system. General appreciation of decision making can be found in the introductory work of Kaufmann [3] .

Unlike the human brain decision maker which carries out smart thinking with ease to build a machine counterpart, an engineered object needs effective externalization of the process involved. This begins by developing appreciation of the basic rules that always apply about a decision-making situation. These have been summarized by Baker et al. [1] and condense to

1. There must be a clearly expressed criterion for making a judgment of the options available, which must be such that others will understand how the judgment was made.
2. All decisions will involve choosing alternative strategies to arrive at the best one to use. This will involve assigning score numbers to the selected parameters and deciding how to process the set of numbers.
3. A decision is made by a choice of competing alternatives in the face of given restraints. Decisions can only rarely be made in the general sense but will be made for a given set of circumstances. The complexity of a problem rises rapidly as the number of parameters rises.
4. The process used attempts to achieve some payoff as a value added or lost. It aims to rank the various mapping alternatives to advise the apparently best to use. Note that once a decision-making

mapping is built, the information about alternatives is no longer available as it will only usually embed one set of parameters as a single process.

5. A decision matrix carrying the competing parameters results. A method of combining the matrix constituents is needed, and, again, there is no singularly definitive, absolutely correct way to process the matrix.

In setting up a signal-processing mapping, these rules will need to be addressed. They will be embedded in the software of the hardware processor as its operational strategy. Considerable creativity is needed by the designer of the processor, for much of the setup of decision-making methods requires subjective human interpretation in several steps of the process. Decision making is really only needed when there is no exact and obvious answer. The devices built to mimic the human process will never be perfect. There will be much debate about which are the best methods and parameters to use. Engineers must live with this situation and make machines that will make good decisions, that are as close to perfect as possible.

Extracting Parameters

The first step in setting up a decision mapping is to understand the need. That means researching it by observation and from literature on the topic. This sets up the specific knowledge base to allow one to progress to the next step.

Then comes the need to define the key parameters of the situation. There is no organized way to develop these. They arise from inventive and innovative thought processes that seem to be based on prior learning.

To streamline this intuitive step, it is useful to apply some ordered processes that assist in externalizing appropriate parameters. Three methods are now briefly described.

Slip Writing

A group of people familiar with the problem area are read a brief statement of the problem by a person independent from the problem. An example could be “What do you think are the main parameters that a person uses to decide if a loaf of bread is fresh?”

Without much time to reflect the group is then asked to write down the key parameters that come to mind immediately as they work without talking about the problem as a group. They write down each parameter on a separate piece of paper, doing this as fast as ideas come to them. This only happens for a few minutes. The slips of paper are then collected and classified. The whole process takes around 10 min and is known as slip writing.

It will usually be found that there is common agreement about the majority of parameters with some quite unexpected ones also arising.

Slip writing a good way to find consensus. It probes the mind well and can bring out appreciation of factors that open discussion might easily inhibit. It is important in this method to decouple the thoughts of each person during the process; otherwise the real parameters may not be externalized because some people may exert influence on others of the group.

Brainstorming and Think Tanks

If participants are shown what others are thinking and are encouraged to debate issues, it is possible to gain consensus and also allow group participants the opportunity to help each other be innovative at the same time. This method works best when the participants are prepared to go into open discussion. Several similar processes are those known as brainstorming or carrying out a think-tank session.

Here a problem in need of solution is written down as a well-prepared statement by the session organizer. A team of experts, each covering the expected aspects of the problem area, are selected and sent the statement along with any supporting exhibits. Each person considers, over a few days, how he or she might contribute a solution.

FIGURE 84.1 Knowledge trees allow facts and their relationships to be captured in pictorial form.

The group is then assembled. The problem is first reviewed by the session leader and each person is then asked for ideas. As ideas are externalized they are recorded in very brief form — large sheets of butcher paper are suitable. These sheets must be readable by all in the group and be prepared instantly to keep up with the thoughts of the group.

It will be found that innovative ideas will arise as candidate solutions are put up and seen by others in the group. This method encourages group-driven inventiveness.

Gradually the group will settle on a few solutions that it feels have a good chance of succeeding. This list is then ordered in priority of likelihood of success. The session leader then writes up the outcomes, ready for further investigation.

Knowledge Trees

The final method to be described here for developing parameters of a decision, called knowledge trees, has the merit of ordering the relative place of parameters as well as encouraging inventiveness of solutions. It also provides a mapping structure. This procedure is based on age-old realization that we think problems through by breaking them down into ever smaller subproblems until we feel able to solve them. Overall solution is then very much a matter (but not entirely so in practice) of implementing the solution of all subproblems and combining them by a process called integration.

The need is first written down. For example, “How would we measure the quality of loaves of bread?” or in a shorter form “Is the loaf OK?”

This forms the top-level parameter of the tree given as [Figure 84.1](#). Consideration of the situation at hand then leads to realization of the collection of parameters relevant to get this answer. These might be weight, size, crustiness, appearance, and softness. They may have been externalized by a group process, such as slip writing, or created by the individual.

Each branch on the tree is then visited to see how that parameter might be measured. Only one of these can be measured as it stands — it is reasonable to assume that weight can be measured with scales.

Size is not so easy to measure as it is expressed for there is inadequate definition. More thought will yield another level to the tree — length, width, and height — for this parameter. As linear measurements, these can also be measured with ease.

When building the branching downward, a thought process has decided how the parameters map upward and downward. Size dictates the mapping of three parameters into one, so there must also be a defined mapping model for that mapping.

Note also that to branch downward, the thought process used has actually been driven by some heuristics. Each branching has been driven by rules of some kind — but more on that in the rule-based decision-making method covered below.

<u>Size</u>	<u>Crustiness</u>	<u>Appearance</u>	<u>Softness</u>	<u>Parameters</u>
$\Rightarrow \frac{Si}{W}$	$\Rightarrow \frac{C}{W}$	$\Rightarrow \frac{A}{W}$	$\Rightarrow \frac{So}{W}$	<u>Weight</u>
	$\Rightarrow \frac{C}{Si}$	$\Rightarrow \frac{A}{Si}$	$\Rightarrow \frac{So}{Si}$	<u>Size</u>
		$\Rightarrow \frac{A}{C}$	$\Rightarrow \frac{So}{C}$	<u>Crustiness</u>
			$\Rightarrow \frac{So}{A}$	<u>Appearance</u>

Scores (number of times preferred)

<u>Si</u>	<u>C</u>	<u>A</u>	<u>So</u>	<u>W</u>
2	2	1	3	2

FIGURE 84.2 Triangle of pairs assessment is a simple way to decide which choice to make. This table gives the workings for the grading of bread as in the example of Figure 84.1

It is also easy to see why the other parameters could be measured with automated instrumentation. Softness could be assessed in terms of the squeeze factor, which is actually measurable as the compliance of the loaf at the center point of a side of the loaf. Appearance would map down the tree into color, texture, and graininess of the image. It is left to the reader to think up and draw a complete tree.

When all branch ends have been reticulated down to the point where they can be measured, the system mapping can be implemented with a human-made sensing system. The parameters are externalized and the mapping process is largely decided.

Use of tree-based thinking is a simple, yet powerful, way of keeping track of decision making for a complex situation. The recorded form also allows others to see the thought process used.

Two Examples of Decision Assistance Methods

Triangle of Pairs

Having now seen how to externalize parameters and how they might be interrelated using trees, we can move on to investigate how to set up a suitable decision-making process.

Knowing the parameters is not enough yet to design a multisensor mapping processor. The relative importance of the parameters is also a key factor. Furthermore, the tree is not the only way to combine sensor signals.

Two, of many, examples of decision assistance methods are now outlined to illustrate these points.

The first, the triangle of pairs (TOP) method, allows parameters to be ranked against others on the binary-only basis of which is preferred of each two compared. In the bread example, compare some of the parameters for their relative importance. Crustiness is preferred to weight. Softness is preferred to size and so on until all pairs have been considered. If all combinations are carried through and recorded as a matrix, a triangle of pairs results, as in [Figure 84.2](#).

Having formed a matrix of competing parameters, the next step is to decide how the matrix can be processed. This is where much debate can occur. For the TOP method, however, the binary nature of the choices means a simple count of first preferences gives the ordered preference of parameters — at least as that person assessed it!

We will see later how the idea is extended by giving parameters a varying degree of “preference” rather than the simple binary choice allowed here.

Utility Analysis

A more fully developed method for making decisions in complex and subjective situations is one called utility analysis (UA). This is a process that can be applied to find the usefulness of a design, piece of equipment, or any similar situation where one can externalize and prioritize a set of measurable parameters. Although mostly applied to decision making as a paper study, the process is amenable to the creation of a multisensor mapping processor.

Appreciation of this process is easily obtained by working through an example. Consider the need to set up a method for grading the quality of bread made in an automated bakery.

The first step is to decide the parameters that will affect the choice finally made. We select weight, size, and appearance as the key parameters to illustrate the method. (More parameters might be needed in a real situation.) We also decide that these are important according to the relative weighting ratios of 1.0:0.2:0.8.

Next utility curves must be set up, one for each parameter. These show how the usefulness of the parameter changes as the parameter ranges.

The simplest way to obtain these graphs is to use one's own intuition, but a better way is to make use of some form of consensus-forming procedure as discussed above. [Figure 84.3](#) shows what these three functions might look like. As a guide to their construction, if the weight of the loaf is too low, it fails to comply with legal requirements and thus has zero utility as a product below the allowed uncertainty of weight. The size factor depends on the type of bread. Here it is assumed it is for sandwich making, in which case the size can be too small for sliced meats or too big for a toaster. Appearance can only be measured by mapping downward to a set of measurands; it is convenient to plot the function in more vaguely defined terms in this method.

Note that the weighting ratios have already been incorporated into the utility charts by setting their best values at the correct percentage.

It is necessary to reinforce the fact that the set of graphs is needed for the parameters, not for each case to be considered. With the charts set up, the selection process can begin.

A matrix is now created, as also shown in [Figure 84.3](#). The actual measured weight value (960 g) for loaf 1 (under automatic inspection) is compared with the graph of weight to yield a utility of 0.4. The size is done likewise, using the size graph to get 0.2, and the appearance sensor set tells us it is between poor and good to give us 0.4. Each loaf is subjected to the same process. The other two loaves have different sets of scores.

The combined usefulness of a given loaf is now to be decided by processing the set of numbers for that loaf. Here is where some difficulty arises, because there are many ways to combine the three scores for each loaf. One way often used is simply to sum the values, as is done in the example. Note that this can be satisfactory unless a zero or other unacceptable value arises, in which case more mapping processing is needed. Assume that an acceptable combined score has been determined to be 1.8 or higher (with the best, due to the weightings, 2.0).

Having carried out the processing of the matrix, we find that the first loaf is not acceptable and the other two are equally acceptable.

What we have done is to form an automatic measuring system that can make assisted and graded decisions. There is certainly a degree of human subjectivity inherent in the method, but by recording what is taking place the task can be automated and it can also be evaluated in the light of experience, correcting choices of parameters and weightings.

Other decision-making methods exist: they use elements of the above concepts in a variety of assemblages.

The above has been a very rapid introduction to decision-making methods. These are rarely taught as the foundation of the now popularized AI signal-processing methods given next. They are, however, the conceptual basis of the AI processes.

FIGURE 84.3 Utility analysis is a more-detailed way to automate loaf inspection with a set of sensors. Here are shown three of the utility functions for the example in Figure 84.1 along with the scoring matrix for loaves passing the inspection point.

Parameter Object Under Assessment	Weight (g)	Size (m ³ 10 ⁻³)	Appearance (grade)	Score (Σ)
Loaf 1	(960) 0.4	(4) 0.2	(poor/good) 0.4	1.0
Loaf 2	(1000) 1.0	(3.5) 0.2	(good/excellent) 0.8	2.0
Loaf 3	(1100) 1.0	(4.9) 0.1	(excellent) 0.8	1.9

84.6 Principal AI Methods

Measurement Theory

Sensors observe a finite number of variables associated with real-world events. Measurement systems are required to convert the information from these sensors into knowledge. This process often involves what is known as mapping.

Depending on the loss or preservation of information, the mapping process can be classified as either

1. transformation, or
2. abstraction.

If a rule exists that assigns every element of x in the set X (written $x \in X$) to precisely one element $y \in Y$, we say that a function exists that maps the set X to the set Y , and this is represented as [Figure 84.4](#) and symbolically by

$$y = f(x) \quad (x \in X)$$

A transformation defines a one-to-one mapping on the set of all elements of x into y , in which for all $x \in X$ there exists a unique value in Y ; therefore the inverse transformation is guaranteed, i.e., $x = f^{-1}(y)$.

An abstraction differs from a transformation in that it can map a number of elements $x_i \in X$ into the same y , or a many-to-one mapping; hence, no inverse operator can exist such that the inverse image of X can be uniquely retrieved from Y . Therefore, abstraction is usually characterized by a loss of information.

It is possible to define the set theoretical relationship as a formal mathematical model and then embed that in the signal processor. Although this is a clearly useful method of formalizing mappings, this approach is not commonly used at the time of writing but can be expected to find more favor in the future.

FIGURE 84.4 Pictorial representation of the set theoretical mapping process.

FIGURE 84.5 Part of a design knowledge tree for improving the performance of an audio speaker system.

Rule and Frame-Based Systems

In early stages of problem solving, we seem naturally to look to rules of thumb to get the solution started. Even the algorithmic methods start with this form of thinking, for one has to decide what the elements of the decision are and how they might be assembled into a strategy for implementation in the signal processor. As the rules are externalized one's thought patterns also usually build knowledge trees that show the relationship between the rules.

Consideration of the knowledge supporting the structure of a tree will reveal that the decision needed about which way to branch as one moves through a tree is actually the implementation of a rule that has relevance at that junction. Rules link parameters together.

Figure 84.5 is a tree giving some of the design options for improving the performance of an audio speaker system. This tree has been built by applying a designer's knowledge of speaker system design. The heuristic rule set for the top branch is stated as

IF speaker output (W) increases
 AND distortion (D) is reduced

AND positioning (L) improved
THEN audio output (O) is improved

No part of the rule set could be first realized using formal mathematical or algorithmic thinking. Intuition, leap, common sense, and other terms that describe the human intelligence process must be applied to commence a solution.

At some stage a rule may become describable by an algorithm — when that occurs a formal mathematical expression can be used to embed relationships. However, this is often not the case and so methods have been developed in computers to process heuristics.

The full set of AI techniques were originally all rolled into what became known as KBSs but this term is so overused that it has lost specific meaning.

Among the first AI processing methods were special computing ways to process the logic of a set of rules. These became known as expert systems (ES). In the example above, the rule tree is very sparse; a practical system for decision making is likely to have from 100 to several thousand rules.

The rules are considered by an inference engine (a software program) that is able to carry out Boolean logical operations of AND, OR, etc. to yield the outcome appropriate to the set of rules relevant to the problem at hand.

Trees can be traversed from the top down (downward chaining) or from the bottom up (upward chaining) and modern ES software applications carry out these operations with great sophistication.

KBS methods generally suffer from the feature that they seem to give answers all too easily, for they use only a few of the many rules available to come to a solution in a given situation. To help users feel more confident in their application, features are often offered that include plotting of the chaining used to get the solution or stating the rule set used.

Rule-based software applications are sold as empty shells. The user fills the shells with the rule set to make the application specific. These applications are now commonly used. They are relatively easy to use without the need for a competent computer programmer.

Rules are a primitive way to express knowledge. A better form of representation is the frame. This has the ability to hold more knowledge than a single rule and is a small database about a limited area of the system of interest. Frames are like objects in object oriented programming. Advanced ES shells operate with frames.

ES shells are now very capable entities for decision making. They are a significant tool in the instrument signal processor's toolbox. Space restricts more explanation but enough has been stated here to allow further development of AI methods.

Some basic characteristics about rule- and frame-based processing are as follows (these apply variously):

- The software program is often self-explanatory as the rules can be read as (almost) normal language;
- They need considerable computer power as the rule number increases;
- They are relatively slow to yield a solution but are best used for cases where slow outcomes are applicable;
- They need special software;
- They are not that well known, so their application may be slow to find favor.

ESs soon run out of usefulness if the problem becomes complex. The computer search becomes too slow because the number of rules needed rapidly rises with problem complexity. The approach used today for large-problem-solving systems is to build an ES for each facet of the problem. These small-problem AI units are called agents. A set of agents is then combined using a conceptual software-based blackboard that calls on the agents to investigate a problem put to the system.

The chaining operation basically only carries out simple Boolean algebra operations using system parameters represented by a description called a rule. The system has no understanding of the wording of the rule. Thus, it is only processing as through the tree branching is either one way or the other. In its simplest form, it contains no concept of making that branching decision with a graded concept of which way to go.

FIGURE 84.6 A simple comfort index measurement system uses temperature and humidity variables.

FIGURE 84.7 Conventional crisp set for the measurement system of Figure 84.6.

Real life is full of unclear logical operations. The outcome of a decision will be clearly this way or that, but just where the change arises is problematic. The changeover point is unclear because the variables of the rule are fuzzy. It is desirable to process rules with regard of their likelihood of relevance depending on the state and selection of other rules. As is explained below, the fuzzy logic method of carrying out a mapping is another way that allows the rule to have more variability than the two-state exactness of binary logic.

Fuzzy Logic

This explanation is not intended to be a rigorous mathematical examination of fuzzy sets and fuzzy logic but rather explain, through example, the application of fuzzy techniques in measurement systems, specifically in respect to mapping models. For more detail, see Mauris et al. [4].

The simple example used here is a measurement system, Figure 84.6, that maps two input sensors (temperature and humidity) into one output value (comfort index). Clearly there is no formally accepted definition of comfort index as it is a subjective assessment. One of the advantages of fuzzy sets is that they are usually intended to model people's cognitive states.

In the mid 1960s Professor Lofti Zadeh recognized the deficiencies of Boolean logic, in that its TRUE/FALSE nature did not deal well with the shades of gray that exist in real life situations.

Boolean logic uses classical set theory where an element is either viewed as entirely true or completely false $A = \{0,1\}$. These are often referred to as a crisp sets, Figure 84.7. In a crisp set the transition between sets is instantaneous, i.e., 36.9°C is considered warm whereas 37.1°C is considered hot. Hence, small changes in the input values can result in significant changes in the model output. Clearly, the real world is not like this.

Fuzzy logic uses a multivalued set where degrees of membership are represented by a number between 0 and 1 $A = [0,1]$ $\mu_A:U \rightarrow [0,1]$, where μ_A is the membership function. With fuzzy logic the transition between sets is gradual and small changes in input values result in a more graceful change in the model output, Figure 84.8.

Fuzzy Expert Systems

A fuzzy expert system, Figure 84.9, combines fuzzy membership functions and rules, in place of the often all-too-crisp Boolean logic, to reason about data. The fuzzy expert system is usually composed of three processing sections:

FIGURE 84.8 Fuzzy set representation temperature regimes in the comfort controller example.

FIGURE 84.9 A fuzzy inference system combines rules in a way that allows them to be fuzzy in nature, that is, not crisp.

- Step 1. Fuzzification
- Step 2. Rule evaluation
- Step 3. Defuzzification

Step 1 — Fuzzification.

In fuzzification crisp inputs from input sensors are converted into fuzzy inputs using the membership functions in the knowledge base. A fuzzy input value is generated for each linguistic label of each input. For example, in Figure 84.8, for an input temperature of 37°C the fuzzy input is COLD(0.0), COOL(0.0), MILD(0.0), WARM(0.15), HOT(0.80). A similar set of fuzzy inputs are generated for the humidity sensor, Figure 84.10.

FIGURE 84.10 Humidity membership function for the controller example.

TABLE 84.1 The Fuzzy Associative Matrix Links Inputs and Outputs

Hum/Temp	Cold	Cool	Mild	Warm	Hot
Low	uncomfort.	uncomfort.	uncomfort.	uncomfort.	uncomfort.
Medium	uncomfort.	acceptable	comfortable	acceptable	uncomfort.
High	uncomfort.	acceptable	acceptable	acceptable	uncomfort.
Very High	uncomfort.	uncomfort.	uncomfort.	uncomfort.	uncomfort.

Step 2 — Rule Evaluation.

Rules provide a link between fuzzy inputs and fuzzy outputs. Rules are usually expressed in the form of IF ... AND/OR ... THEN ... statements.

For example,

- 'IF' the TEMPERATURE is HOT 'AND' the HUMIDITY is HIGH 'THEN' it is UNCOMFORTABLE.
- 'IF' the TEMPERATURE is MILD 'AND' the HUMIDITY is MEDIUM 'THEN' it is COMFORTABLE.
- 'IF' the TEMPERATURE is WARM 'AND' the HUMIDITY is LOW 'THEN' it is UNCOMFORTABLE.

Rules can also be expressed in the form of a table or matrix, called the Fuzzy Associative Matrix. This matrix, Table 84.1, provides a complete description of the system performance for all combinations of inputs.

The function of the rule evaluation step is to evaluate the relative strengths or truth of each of the rules in order to determine which rules dominate. In this example the rules contain AND relationships and therefore the overall rule strength must be the minimum (MIN) value of the two strengths of the input values.

For example, at a temperature of 37°C and a humidity of 65% the rule strengths of the three example rules are

- 'IF' the TEMPERATURE is HOT(0.8) 'AND' HUMIDITY is HIGH(0.68) 'THEN' it is UNCOMFORTABLE (Rule Strength = $\text{MIN}(0.8,0.68) = 0.68$).
- 'IF' the TEMPERATURE is MILD(0.0) 'AND' the HUMIDITY is MEDIUM(0.0) 'THEN' it is COMFORTABLE (Rule Strength = $\text{MIN}(0.0,0.0) = 0.0$).
- 'IF' the TEMPERATURE is WARM 'AND' the HUMIDITY is LOW 'THEN' it is UNCOMFORTABLE (Rule Strength = $\text{MIN}(0.15,0.0) = 0.0$).

All rules must be evaluated (in this case all 20 in the matrix) to determine each rule strength. If two rule strengths exist for one fuzzy output label, then the maximum (MAX) rule strength is used because this represents the rule which is most true; that is, in the previous example the fuzzy output for UNCOMFORTABLE is the $\text{MAX}(0.68,0.0) = 0.68$.

Step 3 — Defuzzification.

Now that rule strengths exist for all the output fuzzy labels, a crisp output value can be determined from the fuzzy output values. The most common method used to defuzzify the fuzzy output value is the center of gravity (COG) method. The fuzzy rule strengths determined from rule evaluation are used to truncate the top of the output membership functions. Given this area curve, the COG or balance point can then be calculated. For example, in Figure 84.11, for fuzzy output values of

- UNCOMFORTABLE = 0.68
- ACCEPTABLE = 0.2
- COMFORTABLE = 0

the COG or crisp "Comfort Index" evaluates to 25.

Fuzzy logic signal processing is now a well-developed method. It is supported by copious teaching material including those on internet and on CD ROMs provided by manufacturers of this form of special integrated circuit chip sets and setup software. Possibly its best known application has been in clothes washing machines where the wash parameters are set to suit the load. Although there are still limitations, this method can be considered to be a mature procedure.

FIGURE 84.11 Output membership functions for controller. Each type of shaded area represents the three states of comfort.

Genetic Algorithms

The methods discussed thus far all have required the user to advise the system about the parameters to use. That is, they need to be taught efficient mappings.

In sharp contrast to these types of systems, there also exist other AI methods that possess the ability to learn, by themselves, what are the more optimal mapping configurations. Two main techniques are used — genetic algorithms (GAs) and artificial neural networks (ANNs). These self-learning processes both work well in certain situations and are now commonly used in signal processing. On the face of it, both seem to possess magical properties because they defy logical thought processes and a clear understanding of how they actually operate.

We begin with an overview of GAs. These make use of the basic principles by which natural selection found in living things, that is, from genetics, is able to improve gradually the fitness of species. That the genetic principles found in nature can be used in human-made applications is accredited to pioneering work of John Holland in the mid 1970s. Today, it is large field in algorithm optimization research; see Tang et al. [7]. A very simplistic description now follows to give some insight.

The concept starts with the selection of a set of features, [Figure 84.12](#), (these can take a wide range of forms and are not just measurement parameters), that represent the essential features of a system of interest. As examples, the DNA molecule carries the code of the characteristics of living beings and a computer string can carry a coded message that represents the features of the behavior of some human-devised system.

Various types of events (crossover, mutation, inversion are commonly encountered methods) can slightly alter the code of any particular string. When this happens, the new string then represents another closely similar, but different system having new properties. Consider, next, that a number of slightly different code strings have been formed.

When a change takes place in the code of a string, it is assessed against the other strings using rules for a predecided fitness test. If improvement has occurred in the overall properties, then it is adopted as one of the full set. If not better, then it is discarded. In this way the set of strings, and thus the total system capability, gradually improves toward an optimal state.

The operational aspects of such systems are beyond description here. Suffice to say that the technique is well established — but highly specialized — and is undergoing massive international research effort in hope of alleviating certain limitations.

The first limitation is that although it is generally agreed each adopted change for the better takes the overall system capability closer to the goal being sought, there is, as yet, no theory that can be applied to show the state of maximum optimization. GAs, therefore, always have doubt associated with their solutions as to how much more improvement might be possible.

FIGURE 84.12 In the GA method sets of code strings are first modified by some form of genetic operations. They are then intercompared using fitness functions to select a better code to use in the subsequent set of strings. This iterative process is continued until some event disrupts it.

The second limitation becomes obvious when the computational demands are considered in terms of the number of comparison operations needed to be run in the improvement process. This number can be truly huge, especially as the range of options rises with increase in string length. This kind of operation usually needs very large and fast computing power. In cases where there is plenty of time to determine

an improvement, this is not a major limitation. An example of effective use would be finding how best to operate a wide range of functions in a complex system when the task is then fixed; this method was used to set up more optimal use of power supplies in a space vehicle. In cases where the variables in a code string are fast changing, the method may not be applicable.

When running this form of computer program, it is essential to have a measure of the speed — the dynamic behavior — at which this highly iterative process is moving toward the optimization goal: the user can then decide if it is a viable method for obtaining improvement.

With this background, it is probably obvious why GAs are sometimes used to set up the membership functions of fuzzy logic systems. As explained above, the membership functions each are part of a set of individual functions that form the mapping for a multisensor system. The choice of the membership function is largely heuristic and thus may not be the best function to use. By setting up several sets of functions it is then possible to apply GA computing methods iteratively to select a better set to use. Such systems have been used where the time of currency of a function set is longer than the time needed to improve the functions. Obviously, use of GAs increases system set up and operational complexity, but once implemented may yield worthwhile gains.

Artificial Neural Networks

The AI basket of potentially useful methods in signal processing is full of surprises. Attention is now directed to another method, which can learn, after an initial training period, how to better operate a given mapping process.

Neurocomputing or use of ANNs is another AI technique well suited to make a mapping processor in some circumstances. (These are sometimes called NNs but should not be used for human-devised systems as that leads to confusion with life sciences research on living neural networks.) ANNs are particularly useful when mapping complex multidimensional information to a simpler representation. Because of their ability to deal with nonlinear relationships, they find application in areas where traditional statistical techniques are of limited use. Some application areas include pattern recognition and classification, categorization, function approximation, and control.

Biological Neuron

The ANN has been inspired by the biological structure of the brain, and it is an attempt to mimic processes within the biological nervous system. The neuron is an information-processing cell in the brain, [Figure 84.13](#). It consists of

1. A body or *soma*
2. Input branches or *dendrites*
3. Output branch or *axon*

The neuron receives signals through its dendrites, and then transmits signals from its cell body along the axon. The neuron will generate an output (or fire) when the aggregation of the inputs reaches a threshold level. At the terminals of the axon are *synapses*. The synapse couples the signals from the axon of one neuron to the dendrites of another neuron. The strength with which these signals are transferred from the axon to the dendrite is controlled by the synapse and can be altered; hence the synapses can learn from experience.

Desirable characteristics of neural systems include

- Massive parallelism
- Learning ability
- Ability to generalize
- Adaptability
- Fault tolerance

It is the attempt to construct machines that exhibit these characteristics that has led to the ANN methods of signal processing.

FIGURE 84.13 A biological neuron.

FIGURE 84.14 This neuron model is commonly used.

Artificial Neural Network

In 1943 McCulloch and Pitts proposed the first model of an artificial neuron. This has formed the basis for the generally accepted form of synthetic neuron model or processing element (PE); see [Figure 84.14](#).

The output of the processing element y is given by

$$y = g \left[\left(\sum_i w_i \bullet x_i \right) - b \right]$$

where x_i are the PE inputs with weights (synaptic strengths) w_i , b the PE bias, and g the activation or transfer function. Many types of function have been proposed but the most popular is the sigmoid function, defined by

$$g(h) = \frac{1}{\left(1 + e^{(-\beta h)} \right)}$$

where β is the slope parameter.

By themselves the processing elements are very simple; however, when the individual elements are joined into large interconnected networks, complex relationships can be represented. Although a number of network architectures [2] exist, one of the most commonly discussed architectures found in the literature is the feed-forward multilayered perceptron. [Figure 84.15](#) provides a simple illustration of how a multilayered ANN maps a multidimensional input vector x_0, \dots, x_{N-1} in an input space to a vector y_0, \dots, y_{M-1} in an output space.

FIGURE 84.15 A typical three-layer neural network as is commonly used to create an optimal mapping from sensors to outputs.

Learning

A fundamental characteristic of the ANN, once it has been set up as an operational tool in software form, is that it does not need to be programmed for the application. ANNs appear to learn rules from a representative set of examples, rather than having rules programmed in by an expert. The knowledge acquired by the system that controls how the system maps input to output is held within the connection weights of the network.

The focus of extensive ongoing research is the search for optimal training techniques. These techniques tend to fall into two broad categories — supervised and unsupervised learning.

In supervised learning, a representative set of inputs is presented to the network which then modifies its internal weights in order to achieve a desired output. With unsupervised learning, the input data only are presented to the network, following which the network organizes itself through self-modification of its internal weights so that it responds differently to each input stimulus.

It is beyond the scope of this text to review all the current learning techniques for ANNs. This is well documented in the literature [8]. One popular training algorithm — backpropagation — will be discussed as an example.

Backpropagation

Backpropagation is an example of a supervised learning paradigm commonly used with multilayer perceptron network architectures. Backpropagation follows the error-correction principle and uses the error signal $\{d$ (desired output) $- y$ (actual output) $\}$ to modify the connection weights to reduce this error. The backpropagation algorithm is implemented as follows:

1. Initialize network weights to small random values.
2. Present an input vector x_0, \dots, x_{N-1} and the corresponding desired output vector d_0, \dots, d_{M-1} .
3. Calculate the actual output vector y_0, \dots, y_{M-1} by propagating the input through the network.
4. Use a recursive algorithm starting at the output layer and adjust the weights backward by

$$w_{ij}(t+1) = w_{ij}(t) + \eta \delta_j x'_i$$

where $w_{ij}(t)$ = the weight from an input to node j at time t
 x'_i = either the output of node i or an input
 η = a gain term ($0.0 < \eta < 1.0$)
 δ_j = an error term for node j

For the output layer $l = L$ the error is calculated:

$$\delta_j^L = g'(h_j^L) [d_j - y_j]$$

where h_j^L = the net input to the j th unit in the L layer
 g' = the derivative of the activation function g

For hidden layers $l = (L - 1), \dots, 1$, the error is calculated:

$$\delta_j^l = g'(h_j^l) \sum_i w_{ij}^{l+1} \delta_j^{l+1}$$

where h_j^l = the net input to the j th unit in the l th layer.
 g' = the derivative of the activation function g

5. Return to Step 2 and repeat for the next pattern until the error reaches a predefined minimum level.

Unfortunately, no method exists that allows the ANN to create or learn information that is not contained in the training data; that is, the ANN can only reproduce based on experience. Under certain conditions, however, the network can generalize, that is, approximate, output values for data not contained in the training set.

The neural network can be considered as a universal approximator. During supervised learning, the output eventually approximates a target value based on training data. While this is a useful function, the ability to provide output data for test cases not in the training data is more desirable. Loosely, generalization can be viewed in terms of interpolation and extrapolation based on training data. If a test case is closely surrounded by training data, then (as with interpolation) the output accuracy is generally reliable. If, however, the test case is outside of, and not sufficiently close to, training data then (as with extrapolation) the accuracy is notoriously unreliable. Therefore, if the training cases are a sufficiently large sample of the total population of possible input data so that each test case is close to a training case, then the network will adequately generalize.

While multilayer feed-forward networks are finding increasing application in a wide range of products, many design issues such as determining an optimal number of layers, units, and training set for good generalization are research topics. Current theory provides loose guidelines and many of these design issues are resolved by trial and error. Another disadvantage of ANNs is the high demand that many training algorithms can put on computing resources because of their recursive nature.

The ANN, then, provides another alternative for development of suitable mapping models for measurement systems. They can be used to describe complex nonlinear relationships using a network of very simple processing elements. The attraction of the ANN lies in its ability to learn. As long as there exists a sufficiently representative sample of input-to-output data available, the mathematical relationship of the mapping function need not be known. It is effectively taught to the network during a learning process.

Again, there exist important limitations. The worst is the time it might take to adjust the system nodes and weights to a nearly final state. This can often require considerably more time than the time-varying properties of the inputs allow. In many potential applications, they take too long to learn and are not effective. Again computational speed and power are governing factors.

Despite their shortcomings in some applications, ANNs are now a commonly used procedure to set up sensor mapping systems. Examples are banknote image detection and the increased sensitivity of the detection of aluminum in water.

84.7 Problems in Calibration of AI Processing Methods

Calibration of a measurement system is the result of using an agreed upon, often legally binding, process by which it is proven to possess a declared level of accuracy in its measurement outcome. In conventional

instrument terms this implies the system can be set up and compared with a measurement method of superior performance to give its error of accuracy plus its variance from the agreed value determined with a level of uncertainty. This kind of instrument system is then accepted to have a known behavior that could be explained by the laws of physics as causal and unique in performance. The prime example, the physical standard apparatus for a parameter, can and is defined such that it will always give very closely the same outcome, even if built in different laboratories. It will have predictable behavior. At the heart of this acceptability is that it can be modeled in terms of an algorithm. All parts in it follow formal laws and have the same outcomes from implementation to implementation.

Most of this notion has to be put aside because, as explained above, AI-based instrument signal processors are built on a raft of transformations that convert subjective situations into objective ones or they carry out unexplained processes. It is, therefore, not hard to see that calibration is a major issue with this type of processor.

Processes make use of heuristics to at least start them going. The designer, when invoking any of the decision-making methods, will almost certainly not select the same rules, processes, and parameters that another designer will choose. There is a lack of consistency in AI processors. The outcomes are fuzzy, not crisp as in instrumentation that complies with a physical law. They act like humans do in that they provide a range of solutions to the same problem.

At first sight this seems to imply that we should ignore the AI possibilities for they cannot be calibrated according to long-standing metrological practices. However, their performance is often very worthy and will be workable where algorithmic methods are not. This calibration constraint must be considered in terms of human thinking, not so much in terms of physics and mathematical models.

At present, AI processing methods have been well proved in many fields, these tending to be fields in which performance does not need calibration with regard to the standards regime. Examples are the use of fuzzy logic in clothes washing machines to improve the wash by varying the wash cycle parameters, in neural network methods to aid the recognition of banknotes, and in rule-based controllers in industrial process plant controls. Genetic algorithms have been used to schedule power supply and usage in space shuttles — said to be an impossible task by any other known means. These all are typified as being needs where much experience can be devoted to ensuring they work satisfactorily.

They should normally not be the critical processing element in safety-critical situations. They can certainly be used in routine management situations where they can outperform algorithmic methods, but there they should be backed up with conventional alarms. They are often used in off-line plant control where the human and alarms are still the final arbiter. This, however, seems to be only a cautious step in our slow acceptance of new ideas.

The process of calibration here is more akin to that of conducting evaluation and validation. Does the system give the range of outcomes expected in given circumstances? Are the outcomes better than those without the processor? Could it be done as well or better by algorithmic-based processing? Is the speed it gives worth the problems it may bring? Problems in their testing, and thus calibration, are discussed by Sizemore [6]. The issues that need to be considered in the calibration of conventional instrumentation [5] are relevant to the calibration of AI-based processing but need much more care in their execution.

Such questions require consideration of the very same elements of decision theory upon which they are based to test them. They have been set up to think like humans so it is expected they will have to be calibrated and evaluated like humans — that is not at all easy.

At present, the calibration and validation of AI systems are not standardized well enough. This impedes acceptance, but standardization will improve as world knowledge of this relatively new method of processing develops to greater maturity inside instrumentation.

There will be opposition to the use of AI methods, but the performance gain they bring will ensure they are used. The forward-thinking academic measurement community is showing signs of addressing AI signal processing — but it will take time.

National Instruments

85.1 Introduction

Almost every modern instrumentation system includes some form of digitizer, or *analog-to-digital converter (ADC)*. An ADC converts real-world signals (usually voltages) into digital numbers so that a computer or digital processor can (1) acquire signals automatically, (2) store and retrieve information about the signals, (3) process and analyze the information, and (4) display measurement results. A digitizing system can do these jobs with greater speed, reliability, repeatability, accuracy, and resolution than a purely analog system normally can.

The two main functions of an ADC are *sampling* and *quantization*. These two processes convert analog signals from the time and voltage continuums (respectively) into digital numbers having discrete amplitudes, at discrete times. To represent changing signals at every instant in time or at every possible voltage would take an infinite amount of storage. So for every system there is an appropriate *sampling rate* and degree of quantization (*resolution*) so that the system retains as much information as it needs about the input signals while keeping track of manageable amounts of data. Ultimately, the purpose of sampling and quantization is to reduce as much as possible the amount of information about a signal that a system must store in order to reconstruct or analyze it meaningfully.

85.2 Sampling

To prevent having to digitize an infinite amount of information, an analog signal must first be sampled. Sampling is the process of picking one value of a signal to represent the signal for some interval of time. Normally, digitizers take samples uniformly in time, e.g., every microsecond. It is not necessary to sample uniformly, but doing so has some interesting and convenient mathematical properties, which we will see later.

Sampling is done by a circuit called a *sample-and-hold (S/H)*, which, at a sampling instant, transfers the input signal to the output and holds it steady, even though the input signal may still be changing. An S/H usually consists of a signal buffer followed by an electronic switch connected to a capacitor. At a sampling instant, the switch briefly connects the buffer to the capacitor, allowing the capacitor to charge to the input voltage. When the switch is disconnected, the capacitor retains its charge and thus keeps the sampled input voltage steady while the ADC that follows does its job. Quite often, sampling is actually done by a circuit called a *track-and-hold (T/H)*, which differs from an S/H only slightly. Whereas the S/H holds the analog signal until the next sampling instant, the T/H holds the analog signal still only until the ADC has finished its conversion cycle. After the ADC is through, the T/H reconnects the buffer to the capacitor and follows the input signal until the next sampling instant. The result is more accurate sampling, because the buffer has more time to charge the capacitor and “catch up” with (track) the input signal, which has changed since the last sampling instant. Nearly every modern ADC chip has a built-in S/H or T/H, and virtually all data acquisition systems include them.

Of course, sampling necessarily throws away some information, so the art of sampling is in choosing the right sample rate so that enough of the input signal is preserved. The major pitfall of *undersampling* (sampling too slowly) is *aliasing*, which happens whenever the input signal has energy at frequencies greater than one-half the sample rate. In [Figure 85.1a](#), a signal (the fast sine wave) is sampled at a rate

FIGURE 85.1 A demonstration of aliasing. An ADC sampling at rate F_s cannot distinguish between a $0.8F_s$ sine wave and a $0.2F_s$ sine wave. (a) A time-domain illustration. (b) A frequency-domain illustration. Theoretically, a sampler aliases an infinite number of $0.5F_s$ -wide frequency bands into the baseband (0 to $0.5F_s$). Practically, finite analog bandwidth eventually limits how far out in frequency aliases can come from.

F_s , shown by the hash marks at the bottom of the graph. The sine wave has a frequency of $0.8F_s$, which is higher than one half the sample rate ($0.5F_s$). Notice that sampling the lighter sine wave of $0.2F_s$ produces the same set of samples. The resulting sampled data is ambiguous in that we cannot tell from the data what the frequency of the incoming sine wave actually is. In fact, even though the data set appears to represent a sine wave of $0.2F_s$, the actual signal could be any sine wave having a frequency of $(n)F_s \pm 0.2F_s$, where n is any integer, starting with 0. So the original signal could be $0.2F_s$, $0.8F_s$, $1.2F_s$, $1.8F_s$, $2.2F_s$, etc. (or even more than one of those). We say that $0.2F_s$ is the *alias* of a signal that may actually be at another frequency entirely. During interpretation of sampled data, it is customary to treat signals as though they occurred in the baseband (0 to $0.5F_s$), whether or not that is the case. In general, in a system sampling at F_s , a signal at a frequency F will alias into the baseband at

$$F_a = \text{abs}\left[\left(n\right)F_s - F\right], \quad (85.1)$$

where abs denotes absolute value, $n \geq 0$, and $(n)F_s$ is the closest integer multiple of F_s to F .

Everyone has seen a demonstration of aliasing at the movies, in the form of “wagon-wheeling.” As the stagecoach or wagon takes off, the wheels begin to turn, slowly at first, then faster. As the wagon speeds up, the spokes suddenly appear to be turning backward, even though the wagon is moving forward. Sometimes the spokes appear to be standing still. The reason for this is that a motion picture camera shooting film at 24 frames/s is a sampling system operating at 24 samples/s. The turning wagon wheel is a periodic signal that the camera undersamples. When the wheel begins turning just fast enough that one spoke travels at least half the distance to the next spoke in $1/24$ th of a second, the spokes begin to appear to move backward, and the system is aliasing. When the wheel is turning so that a spoke moves exactly the distance between two spokes in $1/24$ th of a second, the spokes appear to be standing still, since they all look the same to the camera.

It follows from Equation 85.1 that if we put into a sampler a signal with no energy at frequencies greater than one half the sample rate ($0.5F_s$), then aliasing will not occur. This is the essence of the Shannon sampling theorem [1], which states that, with mathematical interpolation, the complete input waveform can be recovered *exactly* from the sampled data, at all times at and in between the sampling instants, as long as the sample rate is at least twice as high as the highest frequency content in the signal. Sometimes we refer to $0.5F_s$ as the *Nyquist frequency*, because Nyquist was concerned with the maximum bandwidth of signals [2]. Similarly, twice the highest frequency content of a signal (i.e., the minimum nonaliasing sample rate) is sometimes called the *Nyquist rate*. Sample rates are specified in samples/s, or S/s, and it is also common to specify rates in kS/s, MS/s, and even GS/s.

It is not always necessary to worry about aliasing. When an instrument is measuring slow-moving dc signals or is gathering data for statistical analysis, for instance, getting frequencies right is not important. In those cases we choose the sample rate so that we can take enough data in a reasonable amount of time. On the other hand, if the instrument is a spectrum analyzer, where frequency does matter, or an oscilloscope, where fine time detail is needed, aliasing certainly is an issue. When aliased signals from beyond the frequency band of interest can interfere with measurement, an instrument needs to have an *antialias filter* before the S/H. An antialias filter is a low-pass filter with a gain of 1 throughout most of the frequency band of interest. As frequency increases, it begins to attenuate the signal; by the Nyquist frequency it must have enough attenuation to prevent higher-frequency signals from reaching the S/H with enough amplitude to disturb measurements. An efficient antialias filter must attenuate rapidly with frequency in order to make most of the baseband usable. Popular analog filters with rapid cutoff include elliptic and Chebyshev filters, which use zeros to achieve fast cutoff, and Butterworth filters (sixth order and above), which do not attenuate as aggressively, but have very flat passband response. A good book about filters is Reference 3.

Some ADCs do not need a S/H or T/H at all. If the ADC is converting a slow-moving or dc signal and precise timing isn’t needed, the input may be stable enough during conversion that it is as good as

FIGURE 85.2 The ideal three-bit quantizer has eight possible digital outputs. The analog input-to-digital output transfer function is a uniform staircase with steps whose width and height are 1 LSB exactly. The bottom graph shows the ideal transfer function (a straight line) subtracted from the staircase transfer function.

sampled. There are also *integrating ADCs* (discussed later), which average the input signal over a period of time rather than sampling it. However, internally they actually sample the average.

85.3 Quantization

What sampling accomplishes in the time domain, quantization does in the amplitude domain. The process of digitization is not complete until the sampled signal, which is still in analog form, is reduced to digital information. An ADC quantizes a sampled signal by picking one integer value from a predetermined, finite list of integer values to represent each analog sample. Each integer value in the list represents a fraction of the total analog input range. Normally, an ADC chooses the value closest to the actual sample from a list of uniformly spaced values. This rule gives the *transfer function* of analog input-to-digital output a uniform “staircase” characteristic. Figure 85.2 represents a three-bit quantizer, which maps a continuum of analog input values to only eight (2^3) possible output values. Each step in the staircase has (ideally) the same width along the x -axis, which we call *code width* and define as 1 *LSB* (*least*

significant bit). In this case 1 LSB is equal to 1 V. Each digital code corresponds to one of eight 1-LSB intervals making up the analog input range, which is 8 LSB (and also 8 V in this case).

Of course, we would like our measurement system to have a transfer function that is a straight line and has no steps at all. The bottom graph in Figure 85.2 is the ideal transfer function (a straight diagonal line) subtracted from the staircase function, or the *quantization error*. In an ideal ADC, the quantization error is bounded by $\pm\frac{1}{2}$ LSB, and, over the input range, the average error is 0 LSB and the standard deviation of error is $1/\sqrt{12}$ LSB. As the bottom graph shows, the quantization error at any point is a deterministic function of the input signal.

85.4 ADC Specifications

Range and Resolution

The *input range* of an ADC is the span of voltages over which a conversion is valid. The end points at the bottom and the top of the range are called *-full-scale* and *+full-scale*, respectively. When *-full-scale* is 0 V the range is called *unipolar*, and when *-full-scale* is a negative voltage of the same magnitude as *+full-scale* the range is said to be *bipolar*. When the input voltage exceeds the input range, the conversion data are certain to be wrong, and most ADCs report the code at the end point of the range closest to the input voltage. This condition is called an *overrange*.

The *resolution* of an ADC is the smallest change in voltage the ADC can detect, which is inherently 1 LSB. It is customary to refer to the resolution of an ADC by the number of binary bits or decimal digits it produces; for example, “12 bits” means that the ADC can resolve one part in 2^{12} (= 4096). In the case of a digital voltmeter that reads decimal digits, we refer to the number of digits that it resolves. A “6-digit” voltmeter on a 1 V scale measures from -0.999999 V to $+0.999999$ V in 0.000001 V steps; it resolves one part in 2 000 000. It is also common to refer to a voltmeter that measures from -1.999999 to $+1.999999$ as a “6½ digit” voltmeter. Figure 85.3 compares the resolutions of common word lengths for ADCs.

Coding Conventions

There are several different formats for ADC output data. An ADC using *binary* coding produces all 0s (e.g., 000 for the three-bit converter) at *-full-scale* and all 1s (e.g., 111) at *+full-scale*. If the range is bipolar, so that *-full-scale* is a negative voltage, binary coding is sometimes called *offset binary*, since the code 0 does not refer to 0 V. To make digital 0 correspond to 0 V, bipolar ADCs use *two’s complement* coding, which is identical to offset binary coding except that the *most significant bit (MSB)* is inverted, so that 100 ... 00 corresponds to *-full-scale*, 000 ... 00 corresponds to 0 V (*midscale*), and 011 ... 11 corresponds to *+full-scale*. All of the figures in this chapter depicting three-bit ADC transfer functions use two’s complement coding.

Decimal-digit ADCs, such as those used in digital voltmeters, use a coding scheme call *binary-coded decimal (BCD)*. BCD data consists of a string of four-bit groups of binary digits. Each four-bit group represents a decimal digit, where 0000 is 0, 0001 is 1, and so on, up to 1001 for 9. The other six combinations (1010 through 1111) are invalid, or can be used for special information, such as the sign of the conversion.

Linear Errors

Linear errors are the largest and most common errors in an ADC and are easily corrected by simple calibrations or by additions with and multiplications by correction constants. Linear errors do not distort the transfer function; they only change somewhat the input range over which the ADC operates.

Figure 85.4 shows the transfer function of an ideal three-bit ADC with some *offset error*. The straight line joining the centers of the code transitions is raised, or offset, by 0.6 LSB, and the bottom graph shows the resulting error. Figure 85.5 shows an ideal three-bit ADC with a *+25% gain error*. The slope of the

line through the code transitions is 1.25 times the ideal slope of 1.00. If the slope of the line were 0.75 instead, the gain error would be -25% . The bottom graph shows the error resulting from excessive gain. Offset errors can be compensated for simply by adding a correcting voltage in the analog circuitry or by adding a constant to the digital data. Gain errors can be corrected by analog circuitry like potentiometers or voltage-controlled amplifiers or by multiplying the digital data by a correction constant.

Nonlinear Errors

Nonlinear errors are much harder to compensate for in either the digital or analog domain, and are best minimized by choosing well-designed, well-specified ADCs. Nonlinearities are characterized in two ways: differential nonlinearity and integral nonlinearity.

Differential nonlinearity (DNL) measures the irregularity in the code step widths by comparing their widths to the ideal value of 1 LSB. [Figure 85.6](#) illustrates the three-bit ADC with some irregular code widths. Most of the codes have the proper width of 1 LSB and thus contribute no DNL, but one narrow code has a width of 0.6 LSB, producing a DNL of -0.4 LSB, and one wide code has a width of 1.8 LSB, producing a DNL of $+0.8$ LSB at that code. This converter would be consistent with a DNL specification of ± 0.9 LSB, for example, which guarantees that all code widths are between 0.1 and 1.9 LSB.

It is possible for a code not to appear at all in the transfer function. This happens when the code has a width of 0 LSB, in which case we call it a *missing code*. Its DNL is -1 LSB. If an ADC has a single missing code, the step size at that point in the transfer function is doubled, effectively reducing the local resolution of the ADC by a factor of two. For this reason it is important for an ADC specification to declare that the ADC has *no missing codes*, guaranteeing that every code has a width greater than 0 LSB. Even if an

FIGURE 85.4 An ideal three-bit quantizer, only with +0.6 LSB of offset error.

ADC has missing codes, no code can have a width less than 0 LSB, so the DNL can never be worse than -1 LSB.

Integral nonlinearity (INL) measures the deviation of the code transitions from the ideal straight line, providing that the linear errors (offset and gain) have been removed. Figure 85.7 depicts an ADC with an INL error of +0.7 LSB. The offset and gain errors have been calibrated at the end points of the transfer function.

Relative accuracy (RA) is a measure of nonlinearity related to INL, but more useful. It indicates not only how far away from ideal the code transitions are, but how far any part of the transfer function, including quantization “staircase” error, deviates from ideal (assuming offset and gain errors have been calibrated at the end points). In a noiseless ADC, the worst-case RA always exceeds the worst-case INL by ± 0.5 LSB, as demonstrated in Figure 85.7. In an ADC that has a little inherent noise or has noise (called *dither*) added at the input, the RA actually improves because the addition of noise to the quantizer tends to smooth the *averaged* transfer function. Figure 85.8 shows the average of the digital output data as a function of the input voltage when 0.1 LSB rms of Gaussian random noise is intentionally added to the input. The RA improves to ± 0.3 LSB from ± 0.5 LSB in the noiseless case. If about 0.5 LSB rms of Gaussian noise is added, the quantization staircase becomes nearly straight. This improvement in linearity

FIGURE 85.5 An ideal three-bit quantizer, only with a gain of 1.25 instead of 1.00. This represents a +25% gain error.

comes at the expense of the random error in each individual conversion caused by the noise. Adding more noise to the ADC does not improve the average quantization error much more, but it does tend to smooth out local nonlinearities in the averaged transfer function. For a good discussion of noise and dither, see Reference 4.

Aperture Errors

Aperture errors have to do with the timing of analog-to-digital conversions, particularly of the S/H. *Aperture delay* characterizes the amount of time that lapses from when an ADC (S/H) receives a convert pulse to when the sample is held as a result of the pulse. Although aperture delay (sometimes called *aperture time*) is usually specified as a few nanoseconds for an ADC or S/H by itself, this delay is usually much more than negated by the group delay in any amplifiers that precede the S/H, so that the convert pulse arrives at the S/H quite some time before the analog signal does. For instance, a typical 1 MHz bandwidth amplifier has 160 ns of delay; if the ADC or S/H it was connected to had an aperture delay of 10 ns, the effective aperture delay for the system would be -150 ns.

FIGURE 85.6 A three-bit quantizer with substantial DNL errors. The bottom graph illustrates the resulting INL errors.

Jitter (or *aperture jitter*) characterizes the irregularity in times at which samples are taken. If the nominal period between samples in an ADC is $1 \mu\text{s}$, the actual time may vary from $1 \mu\text{s}$ by as much as a few hundred picoseconds or even as much as a nanosecond from cycle to cycle. Contributions to these variations can come from the crystal clock source (if included under the jitter specification), digital clock circuitry, or the S/H. Jitter is usually specified in picoseconds peak-to-peak or picoseconds rms.

Jitter interferes with measurements (particularly spectral analysis) by effectively frequency modulating the input signal by the jitter profile. A jittery ADC sampling a pure sine wave would scatter energy from the sine wave all throughout the spectrum, perhaps covering up useful spectral information. In a typical ADC, however, most of the interference from jitter tends to occur at frequencies very close to the main signal.

Noise

Noise, whether inherent in an ADC or introduced intentionally (see dither above), limits the resolution of an ADC by adding an interfering waveform to the input signal as the data is converted. Noise comes

FIGURE 85.7 A three-bit quantizer with substantial INL errors. Here, the DNL error is still significant; but, for example, a 12-bit converter with 0.7 LSB of INL from a smooth error “bow” like the one above could have negligible DNL because it would have so many more steps over which to accumulate error.

from many places. The most common kind of noise is *thermal noise*, which is caused by the random nature of electric conduction in resistors and transistors. Thermal noise is worse at higher temperatures and higher resistances. Most other ADC noise is coupled electromagnetically from nearby circuitry, such as clock or logic circuits, or from routing of other input signals. Noise is usually specified in volts rms or peak-to-peak, or LSBs rms or peak-to-peak.

Quantization error (see above) can sometimes be thought of as *quantization noise*. Although quantization error is perfectly predictable with respect to the input signal, when a signal is fairly “busy” (i.e., busy enough that consecutive conversions do not tend to repeat data) the quantization error becomes chaotic, and it can be thought of it as another source of random noise, whose statistical distribution is uniform from -0.5 LSB to $+0.5$ LSB and whose standard deviation is $1/\sqrt{12}$ LSB. This is sometimes the dominant source of noise in spectral analysis applications.

Once noise gets into an ADC, there are ways to process out the noise if it is independent of the signal. Acquisitions of DC signals can be quieted by collecting a number of points and averaging the collection. If the noise is *white random noise*, which has equal energy density at all frequencies, averaging can reduce

FIGURE 85.8 An ideal three-bit quantizer with 0.1 LSB rms Gaussian random noise (dither) added at the input. The relative accuracy has improved to ± 0.3 LSB rms from the ± 0.5 LSB expected from a noiseless quantizer. With the application of 0.5 LSB rms Gaussian noise, the transfer function becomes almost perfectly straight. Larger amounts of dither produce essentially no improvement in linearity.

the amount of noise by the square root of the number of samples averaged. The noise interfering with a repetitive waveform can be quieted by acquiring many waveforms using a level trigger and averaging the collection to produce an average waveform. Most digital oscilloscopes have waveform averaging. Quantization noise, as described above, cannot be averaged out unless other random noise is present.

The noise specifications for an ADC are for quiet, low-impedance signals at the input, such as a dead short. To preserve the noise performance of the ADCs, the user must carefully connect signals to the input with tidy cabling that keeps away from sources of electromagnetic noise. For more information on noise sources and treatment and prevention of noise, see References 5 and 6.

Dynamic Range

The *dynamic range (DR)* of an ADC is the ratio of the largest to the smallest signals the converter can represent. The largest signal is usually taken to be a full-scale sine wave, and the smallest signal is usually

taken to be the background noise level of the ADC. It can be expressed simply as a ratio, but it is more common to express it in decibels (dB):

$$DR = 20 \log(S/N), \quad (85.2)$$

where DR is dynamic range in dB, S is the rms amplitude of the largest signal, and N is the rms amplitude of the smallest signal, the noise. The noise must include the quantization noise of the ADC, which for a perfect, noiseless converter is $1/\sqrt{12}$ LSB rms. For an n -bit converter, a full-scale sine wave has a peak amplitude of 2^{n-1} LSB, which corresponds to an rms amplitude of $2^{n-1}/\sqrt{2}$ LSB, or $2^{n-1.5}$ LSB rms. Hence a perfect ADC had a dynamic range of

$$\begin{aligned} DR &= 20 \log(2^{n-1.5} * \sqrt{12}) \\ &= 20 \log(2^n) + 20 \log(2^{-1.5} * \sqrt{12}) \\ &= (n) [20 \log(2)] + 20 \log(\sqrt{1.5}) \\ &\approx 6.0206n + 1.7609. \end{aligned} \quad (85.3)$$

Equation 85.3 can be used to determine the *effective number of bits (ENOB)* of an imperfect ADC. ENOB may take only noise into account, or it may include noise and harmonic distortion products of the input signal. It is computed as

$$ENOB = (DR - 1.7609) / 6.0206. \quad (85.4)$$

For example, a 16-bit ADC with a dynamic range of 92 dB has an ENOB of 14.988 bits.

85.5 Types of ADCs

The fundamental building block of analog-to-digital conversion is the *comparator*. Every type of ADC has at least one comparator in it, and some ADCs have many. The comparator itself is a one-bit ADC; it has two analog voltage inputs and (usually) one digital output. If the voltage at the + input is greater than the voltage at the – input, the output of the comparator is a digital 1. If the voltage at the + input is less than the voltage at the – input, the output is a digital 0 (see [Figure 85.9](#)).

Another piece that all ADCs have in common is a linearity reference. This is what a comparator in an ADC compares the input signal with in the process of conversion. It directly determines the differential and integral nonlinearities of the ADC. Examples of linearity references include capacitors (in integrating ADCs) and DACs (found in successive-approximation ADCs).

The third piece that every ADC has is a voltage reference. The reference(s) determine the full-scale input range of the ADC and are usually part of or closely associated with the linearity reference.

Flash

Flash converters are the fastest ADCs, achieving speeds near 1 GS/s and resolutions of 10 bits and below. The flash converter with n bits of resolution has $2^n - 1$ high-speed comparators operating in parallel (see [Figure 85.10](#)). A string of resistors between two voltage references supplies a set of uniformly spaced voltages that span the input range, one for each comparator. The input voltage is compared with all of these voltages simultaneously, and the comparator outputs are 1 for all voltages below the input voltage and 0 for all the voltages above the input voltage. The resulting collection of digital outputs from the

(a)

(b)

FIGURE 85.9 The comparator is the essential building block of all ADCs. (a) Comparator symbol. (b) Comparator input/output transfer function.

comparators is called a “thermometer code,” because the transition between all 1s and all 0s floats up and down with the input voltage. Fast logic converts the thermometer codes to normal n -bit binary numbers.

Because of their simplicity, they are fast, but flash converters are limited to resolutions of 10 bits and below because the number of comparators and resistors goes up exponentially with resolution. Because the string resistor values typically vary only a few percent from each other in practical devices, the differential linearity of the flash ADC is quite good. But the same resistor variations can accumulate error across the input range and cause integral nonlinearity of a few LSB.

Successive-Approximation Register

Successive-approximation register (SAR) ADCs are the most common ADCs, having resolutions of 8 to 16 bits and speeds of 1 MS/s and below. They are generally low in cost, and they typically have very good integral linearity. The n -bit SAR ADC contains a high-speed n -bit DAC and comparator in a feedback loop (see [Figure 85.11](#)). The successive-approximation register sequences the DAC through a series of n “guesses,” which are compared with the input voltage ([Figure 85.12](#)). As the conversion progresses, the register builds the n -bit binary conversion result out of the comparator outputs. By the end of the sequence the register has converged to the closest DAC value to the input voltage.

The speed of an SAR ADC is limited by the speed of the DAC inside the feedback loop. The DAC must settle n times to within $1/2^{-n}$ of full-scale within the conversion time of the ADC. Current SAR technology achieves 12-bit resolution at 1 MS/s and 16-bit resolution at 200 kS/s. Faster conversion at these resolutions requires multistage architectures.

Multistage

To achieve higher sample rates than SAR ADCs at resolutions of 10 to 16 bits, *multistage* ADCs (sometimes called *subranging* or *multipass* ADCs) use the iterative approach of SAR ADCs but reduce the number

FIGURE 85.10 A flash converter has $2^n - 1$ comparators operating in parallel. It relies on the uniformity of the resistors for linearity.

FIGURE 85.11 A successive-approximation converter has only one comparator and relies on an internal, precision DAC for linearity.

of iterations in a conversion. Instead of using just a comparator, the multistage ADC uses low-resolution flash converters (4 to 8 bits) as building blocks. [Figure 85.13](#) illustrates an example of a 12-bit two-stage ADC built out of two flash ADCs and a fast DAC. The 6-bit flash ADC converts the residual error of the 8-bit flash ADC. The two digital outputs are combined to produce a 12-bit conversion result.

FIGURE 85.12 (a) Decision tree shows all the possible digital “guesses” of a four-bit successive-approximation converter over time. (b) Decision tree for conversion of four-bit code 1011.

FIGURE 85.13 An example of a 12-bit multistage ADC built out of two flash ADCs and a fast DAC. The 8-bit flash ADC takes a first “guess” at the input signal and the 6-bit flash ADC converts the error in the guess, called the “residue.” The 12-bit DAC actually needs to have only 8 bits, but it must be accurate to 12 bits. If the 8-bit flash ADC were perfect, the second flash ADC would only need 4 bits. But since the first flash actually may have some error, the second flash has 2 bits of “overlap.”

If each flash ADC has a T/H at its input, then each stage can be converting the residual error from the previous stage while the previous stage is converting the next sample. The whole converter then can effectively operate at the sample rate of the slowest stage. Without the extra T/Hs, a new conversion cannot start until the residues have propagated through all the stages. This variation of the multistage ADC is called a *pipelined* ADC.

Integrating

Integrating converters are used for low-speed, high-resolution applications such as voltmeters. They are conceptually simple, consisting of an integrating amplifier, a comparator, a digital counter, and a very stable capacitor for accumulating charge (Figure 85.14). The most common integrating ADC in use is the dual-slope ADC, whose action is illustrated in Figure 85.15. Initially, the capacitor is discharged and so has no voltage across it. At time 0, the input to the integrator is switched to the analog input and the capacitor is allowed to charge for an amount of time, T_1 , which is always the same. Its rate of charging

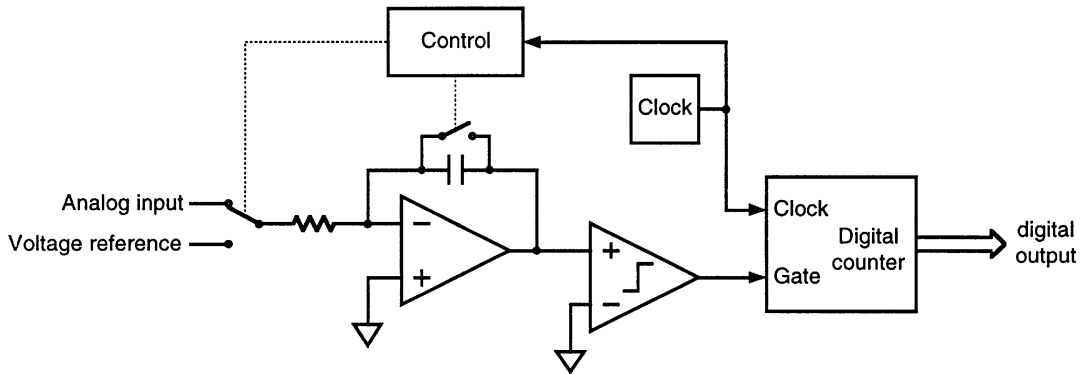

FIGURE 85.14 A dual-slope integrating converter uses a comparator to determine when the capacitor has fully discharged and relies on the capacitor for linearity.

FIGURE 85.15 Charge on the integrating capacitor vs. time. At time 0, the input is switched to analog input and the switch across the capacitor opens. The capacitor integrates charge until fixed time T1. The input is then switched to the voltage reference to discharge the capacitor, and the counter begins counting a known clock. The comparator turns off the counter when the capacitor charge reaches 0 again, at time T2. The resulting count is proportional to the average input voltage over the time interval 0 to T1.

and thus its voltage at T1 are proportional to the input voltage. At time T1 the input switch flips over to the voltage reference, which has a negative value so that the capacitor will begin to discharge at a rate proportional to the reference. The counter measures how long it takes to discharge the capacitor completely. If the capacitor is of high quality, the ratio of the discharge time to the charge time is proportional to the ratio of the input voltage to the voltage reference, and so the counter output represents the analog input voltage.

An elaboration of the dual-slope ADC is the *multislope* integrating ADC. It achieves even higher resolution than the dual-slope ADC by discharging the capacitor at several progressively slower rates. At each rate, the counter is able to resolve finer increments of accumulated charge.

An important distinction between integrating converters and other ADCs is the way they sample the input voltage. Integrating converters do not sample the voltage itself; they *average* the voltage over the integration period and *then* they sample the average that is accumulated on the capacitor. This tends to reject noise that conventional sampling cannot, especially periodic noises. Most integrating ADCs operate with an integration period that is a multiple of one AC line period ($1/60$ or $1/50$ s) so that any potential interference from stray electric or magnetic fields caused by the power system is canceled.

Integrating converters are gradually being replaced in the marketplace with low-speed, high-resolution sigma-delta converters, which see. Sigma-delta converters are generally more flexible than integrating ADCs, and they are easier to use because they do not require an external charging capacitor. The resolution and speed of the two types are comparable, although integrating converters still have the highest linearity.

FIGURE 85.16 Spectrum of a 64-times oversampling SD ADC before the digital decimation filter. The modulator loop samples at 3.072 MS/s and the data comes out of the filter at 48 kS/s. The filter cuts off sharply at $F_s/2$, or 24 kHz, leaving only the small amount of noise left below 24 kHz.

Sigma-Delta ADCs

The *sigma-delta* (SD) ADC is quickly becoming one of the most popular types of ADC. DS ADCs typically have resolutions of 16 to 24 bits and sample rates of 100 kS/s down to 10 S/s. Because of their high resolution at 48 kS/s, they are the most common type of converters in modern digital audio equipment. DS ADCs defy intuition by quantizing initially with *very* low resolution (often one bit) at very high rates, typically 64× to 128× the eventual sample rate (called *oversampling*). The high-rate, low-resolution quantizer operates inside a feedback loop with an analog lowpass filter and a DAC to force the large amount of otherwise unavoidable quantization error (noise) to frequencies higher than the band of interest. The resulting spectral redistribution of the quantization noise is called *noise shaping*, illustrated in [Figure 85.16](#). The low-resolution digital output of the ADC loop is fed into a digital filter that increases the resolution from the resolution of the ADC loop to the output resolution, reduces the data rate from the rate of the ADC loop to the output sample rate, and applies a low-pass digital filter, leaving only the signals in the frequency band of interest and a little inherent electronic noise.

[Figure 85.17](#) shows how a one-bit sigma-delta ADC works. The comparator *is* the ADC, and its output is processed digitally, so that no further analog errors can accumulate. The comparator is in a feedback loop with a low-pass filter (typically third to fifth order) and a one-bit DAC. The one-bit DAC can take on only one of two values, +full-scale and -full-scale, so it is perfectly linear. The low-pass filter causes the loop gain to be high at low frequencies (the signal band of interest) and low at high frequencies. Since the error in a feedback loop is low when the gain is high and high when the gain is low, the errors dominate at high frequencies and are low in the band of interest. The result is a one-bit output whose duty cycle is proportional to the input signal. Together, the elements of the feedback loop are called a *sigma-delta modulator*.

[Figure 85.18](#) illustrates the operation of a simple discrete-time (switched-capacitor) SD ADC. In this first-order example, the low-pass filter is just an integrator. The loop tries to force the input to the comparator back to the baseline, and the figure shows how the duty cycle of the resulting digital output reflects input signal. The digital data here have undesirable patterns which tend to repeat, called *limit cycles*. They can appear in the band of interest and interfere with the signal. Higher-order loop filters (third and above) make the bit activity so chaotic that it has no substantial limit cycles.

FIGURE 85.17 A SD modulating ADC uses a comparator simply as a one-bit quantizer. The linearity of a SD ADC is theoretically perfect because the one-bit DAC can only assume two values, and thus is linear by definition. Modern SD ADCs are made with switched-capacitor circuits which operate at KFs , where F_s is the output data sample rate and K is the oversampling ratio.

FIGURE 85.18 Behavior of a discrete-time (switched-capacitor) first-order SD modulator, where the low-pass filter is simply an integrator. In each graph, the x -axis represents time, and the y -axis represents signal level. (a) The input waveform. (b) Input to the comparator. (c) The one-bit digital comparator output. The duty cycle of this waveform corresponds to the input waveform. The digital filter and decimator recover the original waveform from this one bit.

The chief advantage of a SD converter is that it has a built-in antialias filter, and a darn good one at that. Most DS parts have a *finite-impulse response (FIR)* digital filter, which has an extremely flat frequency response in the passband and an extremely sharp cutoff, properties impossible to implement in analog

filters. The ADC still needs an antialias filter to reject signals above one half the oversampling rate. But this filter is simple to build, since it has to be flat only up to one half the output sampling rate and has many octaves (all the way to near the oversampling rate) to fall off. The combination of the two filters provides watertight protection from aliases, often 96 dB of attenuation over the entire spectrum.

An important improvement of the one-bit SD is the multibit SD, wherein the comparator is replaced by a flash converter with as much as four bits of resolution. This improves the ENOB of the whole converter by several bits.

Voltage-to-Frequency Converters

Voltage-to-frequency converters (VFCs) are versatile, low-cost circuits that convert analog voltages to periodic waveforms whose frequency is proportional to the analog input voltage. A VFC is conceptually similar to an integrating converter (see above) except that the digital counter is missing and is replaced with a short-pulse generator that quickly discharges the capacitor. The voltage reference is not connected intermittently to the input; instead, it appears all the time at the minus input of the comparator instead of ground. The capacitor charges at a rate proportional to the input voltage until the voltage is equal to the voltage reference. Then the comparator trips the pulse generator, which quickly discharges the capacitor, and the cycle begins again. The periodic pulse at the comparator output can be used as the digital output.

The advantage of the VFC over conventional ADCs is that the one-bit output can be transmitted digitally, through isolation transformers, through fiber-optic cable, or through any other isolating, nonisolating, long-distance, or short-distance transmission medium. All that is needed at the receiving end to complete the analog-to-digital conversion is a digital counter, which does not need to be synchronized to the VFC itself. Sometimes, the digital conversion is not needed; a VFC can be used with an isolating transformer and a *frequency-to-voltage converter (FVC)* to create an isolation amplifier. For a good discussion of VFCs, see Reference 7.

85.6 Instrumentation and Components

Integrated Circuits

[Table 85.1](#) lists several popular high-quality ADCs in integrated circuit form. The prices given are approximate for small quantities and for the lowest grade of part, as of mid-1996. By no means exhaustive, the list is sampling of a few of the most popular or best-performing chips of each type of ADC. [Table 85.2](#) contains addresses, phone numbers, and internet sites for the manufacturers in [Table 85.1](#).

Instrumentation

Plug-in data acquisition cards are becoming increasingly popular as personal computer prices come down and processor performance goes up. These cards typically contain one or more ADCs (with S/H), instrumentation amplifiers with gain and differential input, and multiplexers to switch to different inputs. Some have DACs on-board, and some have digital data and timing functions as well. Once considered low performance and hard to use, data acquisition cards have improved dramatically, equaling and in some cases exceeding capabilities of stand-alone instruments. Most come with drivers that interface to user-friendly software packages for creating easy-to-use yet custom-built computer instrumentation. [Table 85.3](#) lists a few popular plug-in data acquisition boards and [Table 85.4](#) lists how their manufacturers may be contacted.

86.1 Introduction

Computers are an essential feature of most instrumentation systems because of their ability to supervise the collection of data and allow information to be processed, stored, and displayed. Many modern instruments are capable of providing a remote user with access to measurement information via standard computer networks.

86.2 Computer-Based Instrumentation Systems

The main features of a computer-based instrumentation system are shown in [Figure 86.1](#). The actual implementation of such systems will depend on the application. Many commercially produced instruments such as spectrophotometers or digital storage oscilloscopes are themselves integrated computer-based measurement systems. These “standalone” instruments may be fitted with interfaces such as IEEE-488 or RS-232 to allow them to be controlled from personal computers (PCs) and also to support the transfer of data to the PC for further processing and display. Alternatively, the instrumentation system may be based around a PC/workstation or an industrial bus system such as a VME or Multibus, allowing the user the ability to customize the computer to suit the application by selecting an appropriate set of add-on cards. Recently, the introduction of laptop and notebook PCs fitted with PCMCIA interfaces with input/output capability has provided opportunities for the development of highly portable instrumentation systems.

The Single-Board Computer

The simplest form of a computer is based around the single-board computer (SBC) which contains a microprocessor, memory, and interfaces for communicating with other electronic systems. The earliest

FIGURE 86.1 Elements of a computer-based instrumentation system.

form of personal computers simply comprised an SBC together with a keyboard, display, disk drives, and a power supply unit. Today, the SBC still offers a solution for the addition of limited intelligence to instrumentation systems as well as forming an element of most computer systems, e.g., as the motherboard of a PC.

An overview of a simple SBC is shown in Figure 86.2. The microprocessor, which contains the central processor unit, is responsible for executing the computer program and for controlling the flow of data around the SBC. The random access memory (RAM) acts as a temporary (i.e., volatile) storage area for both program code and data. On the motherboard of a PC the read only memory (ROM) is largely used for storing the low-level code used to access the input/output hardware, e.g., the BIOS (basic input output system). The operating system and applications software are loaded into RAM from the disk unit. In small, dedicated systems such as an oscilloscope the ROM may be used to store the program code to avoid the need for a disk drive. For small production runs or development work erasable programmable ROM (EPROM) is used as an alternative to ROM, allowing the code to be upgraded without the high cost of commissioning a new ROM chip from the manufacturers.

Data are transferred around the SBC on its data bus, which will be typically 8, 16, or 32 bits wide (corresponding to the number of bits that can be transmitted at the same time). SBCs with 8-bit data buses are less complex and consequently of lower cost than 32-bit systems and may well be the optimum solution for those process control applications which require minimal processing of 8-bit data, e.g., from temperature and position sensors. However the 32-bit bus width of most modern PCs and workstations is essential to ensure the fast operation of Windows-based applications software.

The address bus is used to identify the destination of the data on the data bus. Data transfer is usually between the microprocessor and the memory or interfaces. However, some SBCs support DMA (direct memory access) which allows data to be transferred directly between interfaces and memory without the need the information to pass through the processor. DMA is inherently faster than program-driven data transfer and is used for moving large blocks of data, e.g., loading programs from disk or the transfer of digitized video images.

FIGURE 86.2 An overview of a single board computer.

SBCs are fitted with interfaces to allow them to communicate with other circuits. Interfaces carry out two main functions. First, they serve to ensure that the signals on the internal buses of the SBC are not affected by the connection of peripheral devices. Second, they ensure that signals can pass into and out of the computer and that appropriate voltage levels and current loading conditions are met. A well-designed interface should also provide adequate electrical protection for the SBC from transients introduced via the external connection. Parallel interfaces allow data to be transferred, usually 8 or 16 bits at a time, and contain registers that act as temporary data stores. Serial interfaces must carry out the conversion of data from the parallel format of the internal SBC data bus to and from the serial format used by the interface standard (e.g., RS-232 or RS-422). Some SBCs may contain additional interfaces to support communication with a VDU, local area network (LAN), or a disk drive. Interfaces can range in complexity from a single parallel interface chip to a LAN controller which may require a significant fraction of the SBC board area.

Computer Bus Architectures

All but the simplest computer systems contain several circuit board cards which plug into a printed circuit board backplane. The cards will include at least one SBC and a number of “add-on” cards providing functions such as interfaces to peripherals (e.g., a LAN, graphics display, disk unit) or additional memory. The actual structure of bus architectures is quite variable but the simple model shown in [Figure 86.3](#) contains the essential features. A group of tracks will carry the data and address information with a second group of tracks being used to control the flow of data and to ensure its reliable transfer. Other tracks are reserved for the signals which provide arbitration between SBC cards to ensure that only one such card has control of the bus at any given moment. There will also be tracks which provide utility functions such as clock signals and the transmission of event or interrupt signals.

The main advantage of bus-based systems is that they help one build a complex computerized system using standard cards. By conforming to agreed standard buses (see [Table 86.1](#) for typical examples), the system integrator can minimize problems of incompatibility and keep system costs to a minimum. The

FIGURE 86.3 A simplified model of a computer bus.

TABLE 86.1 Typical Microprocessor Bus Standards

Bus Standard	STE	G96	VME	Multibus II
Data width (bits)	8	8/16	8/16/32	8/16/32
Max address (bytes)	1 M	32 M	4 G	4 G
Synchronous/asynchronous	Async	Async	Async	Sync
Connectors	64 pin	96 pin	96 pin	96 pin + 32 pin

complexity of many bus systems is such that a significant fraction of the area of each card is dedicated to providing the logic required to interface to the bus, adding appreciably to the cost. In addition, data transfer between cards, even using DMA, is relatively slow compared with transfers between chips on the same SBC. There is, therefore, a trade-off between integrating functions on a single SBC and a lack of flexibility in customising the system. An alternative to bus-based systems is to utilize processors such as transputers which are designed to be connected together directly into multiprocessor structures.

Most modern computerized systems adopt some form of distributed intelligence strategy in order to free the central processor unit to run the main application. Graphics controller cards generally employ a dedicated graphics processor able to handle the creation of the basic features such as line drawing or scaling the size of objects. LAN controller cards require intelligence to handle the network protocols and buffer the data flow to and from the network. Disk controller cards relieve the central processor of the need to handle the processes of reading and writing to the disk.

The use of a bus system with more than one SBC allows the designer to dedicate an SBC to the process of data acquisition and temporary data storage in order to ensure that the main SBC can concentrate on data processing and communication with the user. Such a strategy enables the data acquisition SBC to maintain a real-time response to making measurements while allowing the user access to processed data. In most systems one of the SBCs acts as a system controller, which has ultimate control over the use of the bus and will normally contain the bus arbitration hardware. Only one SBC at a time can obtain the authority of the controller to act as a bus master and initiate data communication. The other cards will be configured as slaves allowing them to respond to requests for information from the master. In some systems, e.g., Multibus II, bus arbitration is distributed throughout the intelligent cards.

Industrial Computers

Many instrumentation systems utilize standard PCs or workstations either fitted with add-on cards or linked to intelligent instruments via standard protocols such as IEEE-488 or RS-232. In many industrial environments there is a need to provide protection against hazards such as dust, damage by impact or vibration, and unauthorized access. The systems may have to fit more stringent electromagnetic compatibility (EMC) requirements. Industrial or ruggedized versions of desktop computers are available to meet this market. Cardframes designed to accommodate the standard industrial bus systems such as VME and Multibus can be readily customized to meet the demands of the industrial environment and

ruggedized versions of PCs are also available. In designing industrial computers, care must be paid to the specification of adequate power supplies, both to provide sufficient current for the add-on cards and also to provide protection against fluctuations in the mains supply. It may also be necessary in safety-critical applications to use an uninterruptable power supply that will guarantee the operation of the system during short failures in the mains supply.

Software

All but the simplest computer systems require an operating system to support the operation of applications software. The operating system will allocate areas of memory for use by the applications programs and provide mechanisms to access system resources such as printers or displays. Some operating systems, such as MS DOS, are single-tasking systems, meaning that they will only support the operation of one program or task at a time. Instrumentation systems which simultaneously take measurements, process data, and allow the user to access information generally require a multitasking operating system, such as OS-9, UNIX, or Windows 95. In such instrumentation systems the applications software may well comprise a single program, but it may generate software processes or tasks each with their own local data and code. The multitasking operating system will allow the actual execution of these tasks to be scheduled and also provide mechanisms for communication of information between tasks and for the synchronization of tasks.

Instrumentation systems are real-time environments, i.e., their operation requires that tasks be carried out within specified time intervals; for example, the capture of data must occur at specified moments. Operating systems adopt a range of strategies for determining the scheduling of software tasks. Round-robin scheduling, for example, provides each task with execution time on a rota basis, with the amount of time being determined by the priority of the task. Operating systems which support preemptive scheduling allow high-priority tasks to become active if a specified event such as trigger signal occurs. The speed at which an operating system can switch from one task to another (i.e., context switch) is a important metric for real-time systems.

The extent to which an operating system can respond to a large number of events is extremely limited, as low-priority tasks will have a poor response time. If an instrumentation system needs to make a large number of measurements and also support other activities, such as information display, the solution is generally to use a distributed system with dedicated SBCs operating as microcontrollers to capture the data. These microcontrollers will not usually require an operating system and will each operate a single program which will be either downloaded from the master SBC or located in ROM.

Commercial packages (for examples, see [Table 86.2](#)) are readily available to support PC/workstation based instrumentation systems. A typical system will provide a Windows-type environment to control measurements and store, process, and display data and increasingly make use of the virtual-instrument concept which allows the user to configure instrumentation systems from an on-screen menu. Most packages will allow stand-alone instruments to be controlled using interface cards supporting standards such as IEEE-488 or RS-232. Some packages also support the use of add-on cards for analog-to-digital conversion or a range of control functions such as channel switching and waveform generation; however, their main restriction is the limited range of hardware configurations supported by the software supplier. Each stand-alone instrument and add-on card requires a piece of code called a device driver so that the operating system can access the hardware resources of the card and instrument. Therefore, the development of device drivers requires an intimate knowledge of both the hardware and the operating system.

System Development

The software component of any computerized instrumentation system can form a significant percentage of its total cost. This is especially true of on-off systems which require software to be developed for a specific application, where the cost of the implementation of the software and its maintenance can considerably exceed the hardware costs. In such circumstances the ability to reuse existing code and the

access to powerful development systems and debugging tools are of crucial importance. Some debug software only provides support for stepping through the operation of code written at the assembly code level. When developing device drivers, for example, access to a source-level debugger which can link the execution of code written in a high-level language to the contents of processor registers is useful.

Many SBCs that are intended for operation as stand-alone microcontrollers, instead of in bus-based systems, are often supported by a high-level language such as C or FORTH and a development environment. A common practice is to utilize a PC to develop the code which can be downloaded via a serial link to the microcontroller. Some debugging support for the execution of the code on the microcontroller is also provided. The development of powerful compact Intel 486 or Pentium microcontroller cards running operating systems such as MS DOS can greatly reduce software development time because of the ready access to PC-based software. The implementation of systems based on dedicated microcontrollers may require the use of a logic analyzer to view data on system buses.

86.3 Computer Buses

The VMEbus (IEEE P1014)

The VMEbus [1–3], utilizes a backplane fitted with two 96-pin connectors (called P1 and P2). The P1 connector provides access to all the bus signals with the exception of bits 16 to 31 of the data bus and bits 24 to 31 of the address bus, which are provided on the P2 connector. The location of cards in a VME system is important, as slot 1 must contain the system controller and the priority of the SBCs is determined by their proximity to the system controller SBC. As only 32 of the pins on the P2 connector are defined, the remaining 64 tracks on the P2 backplane may be specified by the user. VME cards may be single height (fitted with a P1 connector only) or double height (fitted with both P1 and P2 connectors). Single-height

FIGURE 86.4 VMEbus arbitration daisy chain.

boards are 100 mm high and 160 mm deep and fit 3U height cardframes. Double-height boards are 233.35 mm high and 160 mm deep and fit 6U height cardframes.

VMEbus Signals

The VMEbus can be described as having four distinct groups of signals.

Data Transfer Bus (DTB).

The DTB provides 32-bit data transfer with 32-bit address information using a nonmultiplexed asynchronous approach. Transfer is supported by a simple handshake mechanism with the bus master initiating the transfer providing an address strobe (AS) signal to tell the destination card to read the address information. The master also controls two data strobe (DS1 and DS2) lines which in a write operation indicate the presence of valid data on the data bus and in a read operation that the master is ready to receive data from the slave. The slave card uses the data acknowledge signal (DTACK) in a read operation to indicate that it has placed valid data on the bus and in a write operation to confirm that it has read the data. There is clearly a danger that the bus will hang up if the slave does not respond to a request for a data transfer, so in most VME systems a watchdog timer is provided to produce a signal on the bus error (BERR) line if a DTACK signal is not detected within the time-out period.

Revision C of the VME bus specification will support 8-, 16-, and 32-bit data transfers, whereas revision D supports 64-bit transfers by making use of the address bus to transfer the additional 32 bits. Data may also be transferred in blocks of up to 256 bytes without the need to retransmit the address information. Most SBCs have both master and slave interfaces allowing their memory to be accessed from other SBCs in the system. The VME bus also supports three types of addressing mode, short (16 bit), standard (24 bit), and extended (32 bit), allowing the memory decoding circuitry of cards to be minimized for small systems or for input/output cards. Six address modifier lines (AM0 to AM5) are used to indicate the addressing mode and also to give information about the mode of transfer (e.g., block transfer and whether the transfer is in privileged, supervisor, or nonprivileged mode).

Arbitration Bus.

The arbitration bus provides a mechanism for deciding which master is allowed to gain control of the bus. The arbitration bus provides four bus request lines (BR0 to BR3) and four bus grant lines. The SBC in slot 1 of the VME bus acts as a bus controller which provides arbitration using a number of scheduling algorithms. In a simple priority-based algorithm each of the bus request lines is assigned a priority, whereas in a round-robin system access to the bus cycles around the bus request lines. Each of the four bus grant lines is in fact allocated two pins on the P1 connector (see Figure 86.4). The bus grant signal therefore passes through each card (called daisy chaining); thus, in Figure 86.4 the signal enters via BG1IN and exits via BG1OUT. This scheme allows a card to intercept the bus grant signal, giving cards nearer the system controller a higher priority. A consequence of daisy chaining is that any unused card slots must be fitted with jumpers between the bus grant pins.

Priority Interrupt Bus.

The priority interrupt bus provides seven interrupt request lines (IRQ1 to IRQ7) with IRQ7 having the highest priority. The interrupt requests may be handled by several SBCs, provided that all interrupts of

the same level are handled by the same master. The interrupt acknowledge line is daisy chained though the cards in a similar way to the bus grant lines (the pins are called IACKIN and IACKOUT). Again, any unused card slots must be fitted with jumpers between these pins.

Utility Bus.

The utility bus provides the power supply tracks, the system reset, a 16-MHz clock and two system failure lines, SYSFAIL, which allows a card to indicate that it has suffered a failure, and ACFAIL, which is generated by the power supply monitor. Both failure lines are handled by the system controller SBC.

Associated with the VMEbus is VXI (VMEbus extensions for instrumentation). This blends the IEEE 1014 VMEbus standard with the IEEE-488 instrumentation bus using the uncommitted pins on the P2 connector to form the IEEE P1155 standard.

Multibus II (IEEE 1296)

Multibus II [3] is a synchronous bus system which is implemented on a single 96-track backplane. Cards conform to the Eurocard format of 220×233.65 mm; however, the bus requires only a single 96-pin DIN 41612-type connector. A second connector may be used to support a local bus or merely provide mechanical stability for a double-height card.

Unlike VME, the Multibus II standard has the following features:

1. A synchronous bus; i.e., data transfer is linked to the bus clock rather than the strobe/acknowledge control lines of the asynchronous VME system;
2. A 32-bit multiplexed address and data bus;
3. A message-passing strategy as an alternative to interrupt request lines;
4. Distributed bus arbitration rather than a central system controller (each card contains a message-passing controller, MPC, chip which participates in implementing the message passing algorithm);
5. Only intelligent cards (i.e., fitted with microprocessors) that can interface to the main bus; simple input/output (I/O) cards should make use of a local bus (e.g., the iLBX bus) using the second DIN connector.

Multibus Signals

Multibus II may be described as having five distinct groups of signals.

Central Control.

The central services module (CSM) in slot 0 is responsible for the generation of this group of signals. The CSM may be implemented on a dedicated card or incorporated onto a SBC. The CSM produces the 10-MHz bus clock as well as a range of reset signals to support both a cold and warm start as well as recovery from power supply failure.

Address/Data.

Multibus II supports a 32-bit multiplexed address/data bus (AD0 to AD31) with four parity lines (PAR0 to PAR3) providing parity information for each data byte. As in all synchronous systems, data are only sampled on an edge of the system clock, a feature that enhances noise immunity.

System Control.

There are ten system control lines (SC0 to SC9) which provide basic handshake information to assist data transfer, e.g., requester is ready or replier is not ready. In addition, these lines are used to convey information such as data width, data error indication, and whether the bus is in the request or reply phase.

Exception Signals.

Two exception signals, bus error (BUSERR) and time-out (TIMOUT), are provided. Any card detecting a data integrity problem must report this to all other cards using BUSERR. The CSM generates a TIMOUT when it detects a data communications hang up on the bus.

Arbitration Group.

The arbitration signals, which determine which card gains control of the bus, consist of a single bus request line (BREQ) and six Bus Arbitration lines (ARB0 to ARB5). To request exclusive use of the bus, a card asserts the BREQ line and provides its arbitration ID on ARB0 to ARB4. It also uses ARB5 to indicate whether the request has high priority or whether “fairness mode” is acceptable. In this latter mode the card will not make another request until after all other requesters have used the bus. Each card has the same bus arbitration logic within its MPC chip. If several cards make high-priority requests, the order of access is determined by the numerical value of the arbitration ID.

Message Passing on Multibus II

Multibus II uses message passing to implement block data transfers and interrupt requests. Each MPC chip contains a first-in first-out (FIFO) buffer, which ensures that the full bandwidth of the bus can be utilized by storing data immediately before or after transfer. In “solicited” transfers, the MPCs cooperate by warning each other that a message is to be sent. These messages may be sent as 32-byte packets in a manner that is analogous to the block transfer mechanism in VME. “Unsolicited” packets not expected by the receiving MPC are used to set up a block transfer or to act as the equivalent of interrupt request signals.

System Configuration

Multibus II employs a software configuration approach in which information such as the base memory address and arbitration ID are sent down the bus rather than by the use of jumpers or dip switches. Some information such as card type and serial number are coded on the cards themselves.

Other System Buses for Small-Scale Systems

The G64/G96 and STE standards [3] are examples of buses well suited to small industrial real-time instrumentation and control systems because of their relatively simple and hence lower-cost bus interfaces, compared with VME and Multibus. Both buses support DMA, have multiprocessor bus arbitration, and use single-height Eurocard (100 × 160 mm) cards. Prototyping cards fitted with bus interfaces are readily available and may be used to develop custom designed I/O cards. Power is supplied on the buses at +5 and ±12 V. In addition, the real-time multitasking operating system OS-9 has been ported onto SBCs which operate with these buses. Development systems that support the use of MS-DOS are also available, thus providing access to a wide range of PC-based software especially for graphics applications.

The G64 bus, which was defined by the Swiss company Gespac in 1979, specifies 64 bus lines which are mapped to rows of a DIN41612 connector. The bus has a 16-bit nonmultiplexed data bus and a 16-bit address bus; 32-bit transfers may be achieved by multiplexing the upper 16 bits of the data bus with the address bus. The G96 standard adds a further 32 bus lines by making use of the third row of a DIN41612 connector to extend the address bus width to 24 bits and provide additional interrupt request lines. The STE bus provides an unmultiplexed 8-bit data and 20-bit address bus using 64-pin DIN41612 connectors.

86.4 Personal Computer Buses

There are three main bus standards for personal computers — industry standard architecture (ISA), extended ISA (EISA), and the microchannel architecture (MCA). In addition, the Personal Computer Memory Card International Association (PCMCIA) architecture has been developed primarily for use in laptop and notebook computers.

ISA and EISA are pin compatible and are both synchronous buses with a clock rate of 8 MHz regardless of the clock rate of the main processor, whereas the MCA bus is an asynchronous bus. Slow slave add-on cards can utilize the ISA and EISA buses by using an appropriate number of wait states. The MCA architecture will not be covered in this chapter. Further details of these bus architectures are given in References 4 through 6.

ISA Bus

The original IBM PC and its clones used the standard PC bus which supported 8 data bus and 20 address bus lines and employed a 62-pin printed circuit card edge connector. When IBM introduced the PC-AT, a second 36-pin connector was added to the motherboard backplane slots to provide a 16-bit data bus and increase the number of address lines to 24. This new bus subsequently became known as the ISA bus and is capable of supporting both cards designed for the original PC bus, and cards with two connectors providing full 16-bit data access. The bus master line allows a card to take over control of the bus; however, this is generally only suited to long-term takeovers. The ISA bus supports 8-bit and 16-bit DMA transfers allowing efficient transfer of blocks of data, e.g., while loading software from disk into RAM. The ISA bus supports the I/O addressing mode of the Intel 80 × 86 range of processors with an I/O address space of 768 locations in addition to the 256 locations reserved for the motherboard.

EISA Bus

The EISA bus provides full 32-bit data and 32-bit address bus lines. ISA cards can fit into EISA bus connectors; however, cards designed for the EISA standard have bilevel edge connectors, providing double the number of contacts as an ISA card. The presence of a notch in the EISA cards allows them to be inserted farther into the motherboard socket than the ISA cards and thus mate with the additional contacts. The EISA standard increases the maximum ISA data width in DMA transfer to 32 bits and also provides a much-enhanced bus master. The following features of EISA are worthy of note.

Bus Arbitration

All EISA systems have a central arbitration control (CAC) device on the motherboard. The CAC uses a multilevel rotating priority arbitration scheme. The top-priority level rotates around three customers, the DMA controller, the dynamic memory refresh controller, and, alternately, either the main CPU or one of the bus master cards. A device that does not make a request is skipped over in the rotation process. The bus masters take it in turns to gain access to the top-priority level. Whereas ISA supported a single bus request line, the EISA standard provides a dedicated pair of request lines (MREQ0 to 14) and acknowledge lines (MAK0 to 14) for each bus master. (*Note:* Although this allows 15 bus masters to be used, in many systems the chip set which implements the CAC supports bus masters in a limited number of the EISA sockets.) The CAC supports preemption, i.e., it allows a device making a request to capture control from another device if it is next in turn. A bus master card must release the bus within 64 bus clock cycles, whereas a DMA controller has 32 clock cycles to surrender the bus.

Input/Output

The EISA bus provides 768 additional I/O locations for each slot in addition to the 768 ISA I/O locations that may be accessed from any slot. EISA cards contain nonvolatile memory to store configuration information (see below), and a minimum of 340 bytes of the I/O address space of each slot is reserved for this purpose.

System Configuration

The EISA system provides support for automatic system configuration to replace the use of jumpers and dip switches to specify parameters such as the base memory address, interrupt request line number, or DMA channel number used by each add-on card. Information on the product type and manufacturer are stored on each EISA add-on card is read by the CPU during system start-up, making it possible to identify the slots that are fitted with full EISA cards. Manufacturers of both ISA and EISA cards should supply a configuration file containing information on the programmable options that are available. When a system configuration program is run, an optimum configuration of the boards will be determined, and the configuration information written into the I/O space of each EISA card. For ISA cards, the user can be informed of the required jumper settings.

PCMCIA

The PCMCIA architecture was developed by the Personal Computer Memory Card International Association and the Japan Electronics Industry Development Association for removable add-on cards for laptop and notebook computers. Each PCMCIA socket has its own host bus adapter (HBA), which acts as an interface to the main computer bus. Cards may be plugged into PCMCIA sockets either before or after the computer has been powered up. There are three types of PC card all with the same planar dimensions (54.00×85.6 mm) but with differing thicknesses, namely, 3.3 mm for type I, 5.0 mm for type II, and 10.5 mm for type III. Cards and sockets are keyed to prevent them from being inserted the wrong way round. The PCMCIA standard supports cards that operate at several possible voltage levels, i.e., 5.0 V cards, 3.3 V cards, or dual-voltage 5.0 V/3.3 V cards.

Configuration

PC cards contain configuration information called the card information structure (CIS) which is stored in nonvolatile memory. Cards may be configured either on system power-up or on insertion of the card into the socket (i.e., plug and play). Configuration is carried out using a form of device driver called an enabler. The enabler may make use of two additional software services called card services and socket services. Socket services, which may be contained in ROM on the PC or loaded from disk during power-up, provide function calls to allow the HBA to be configured to cooperate with the PC card. Card services, which may be an extension to the operating system or an installable device driver, act as a server for the enabler, which performs as a client. Card services provide a range of functions such as accessing the CIS of the card, requesting system resources required by the card, and telling the enabler that a card has been inserted or removed from the socket. Enablers may be classified as dedicated to one particular card or generic, i.e., designed for a range of cards. Note that early PCMCIA cards were not designed for use with card services.

The PCMCIA Socket Interface

The PCMCIA socket comprises a 68-pin connector with 26 address lines providing access to 64 MB of memory space and a 16-bit data bus. Two V_{cc} pins and four ground pins are supplied. The maximum current that can be supplied to the card is 1.0 A with a maximum of 0.5 A from each of the two power supply pins. Release 2.x sockets apply 5.0 V to the V_{cc} pins on power-up and reduce this to 3.3 V if the card has dual-voltage capability. Cards that operate at 3.3 V only are keyed so they cannot fit into this type of socket and only into low-voltage sockets. The supply voltage provided by low-voltage sockets depends on the logic state of its voltage sense inputs. A PCMCIA socket can be configured either as a *memory only* socket or as a *memory or I/O socket*. Initially, the socket acts as a memory only socket but is converted by the enabler to a memory or I/O socket if the card is required to support I/O functions. In this mode the card can generate an interrupt request via a single IRQ pin and support both 8-bit and 16-bit I/O data transfers. DMA may be supported but not by Release 2.x systems.

PC/104

The enormous popularity of PC architecture resulted in its use in embedded systems. A need then arose for a more compact implementation of the ISA bus that could accommodate the reduced space and power requirements of embedded applications. The PC/104 specification (1992) was adopted as the base for an IEEE draft standard called the P996.1 Standard for Compact Embedded PC Modules. The key features of the PC/104 are

- Size reduced to 90×96 mm (3.550×3.775 in.);
- Self-stacking bus allowing modules to be “piggy-backed” and eliminating backplanes or cardframes;
- Rugged 64-contact and 40-contact male and female headers replacing the PC edge connectors ($64 + 40 = 104$, hence PC/104);
- Lower power consumption (<2 W per module).

PC/104 CPU modules range from a basic 9.6-MHz, 8088 compatible XT with one serial port and a keyboard connector to a 100-MHz, 80486DX4 with four serial ports, parallel port, IDE disk controller, display controller, Ethernet adapter, keyboard port, and up to 64 MB of on-board RAM. Pentium-based systems are also available. Systems can be customized from a wide range of modules, including data acquisition boards, solid-state disk modules, and LAN support, all in the same 3.6 by 3.8 in. stackable format.

The wide availability of software development tools for the PC, the large number of software developers familiar with the PC environment, and the ease of transferring software developed on a conventional PC to the PC/104 make this an increasingly popular format.

[Table 86.3](#) lists some manufacturers and suppliers of bus-based systems and industrial computers.

86.5 Peripherals

Computer peripherals fall conveniently into two categories. The first category may be considered to be internal to the computer system and comprises cards plugged directly into a computer bus slot. The

TABLE 86.4 Typical Internal Peripherals

Card Type	Facilities Offered
Display adapter	Provides video and graphics facilities
Serial communications adapter	Serial communication to a similar device using the RS232, RS422, or RS485 standard
IEEE-488 Adapter	Communication with intelligent instruments using the IEEE-488 bus (GPIB)
Digital input/output (I/O)	Individual I/O lines, normally grouped as an 8-bit byte, which may be used to provide logic high and low signals (output) or sense logic high or low signals (input); inputs and outputs may be optically isolated; outputs may drive relays.
Counter/timer	Hardware counter timer allowing external pulses to be counted, digital waveforms generated or pulse widths measured; counter/timers are often available as an additional facility on digital I/O cards
Analog input	Converts an analog input voltage to an integer value which may be read by the computer; resolution typically 8, 10, 12, or 16 bits; input voltage range may be fixed or may be user selectable; conversion times vary from several seconds to tens of nanoseconds
Analog output	Produces an analog output voltage proportional to a digital input; resolution typically be 8, 10, 12, or 16 bits

second category comprises instruments external to the computer but controlled by it. These external instruments are usually themselves “intelligent,” being controlled by their own CPU, and are linked to the main computer by a serial (RS-232) line or the IEEE-488 bus (GPIB). Such instruments may normally be operated in a stand-alone mode in response to their front panel controls without the requirement of an external computer.

Internal Cards

Internal cards are available to perform a wide range of functions. [Table 86.4](#) provides a brief list of representative types. Note that both the serial interface and the IEEE-488 adapter required for the control of external “intelligent” peripherals will be fitted as internal cards. Almost all internal peripherals need to be configured before use to set up such parameters as the base address, the interrupts, and/or DMA channels used. This may involve setting jumpers or switches on the card or may be accomplished under software control using a configuration file supplied by the manufacturer. To operate the cards, bytes are written or read from appropriate addresses on the cards by the controlling SBC. The mechanism for doing this is discussed further in the section concerned with software for data acquisition. Further detail on some of the card types is given below.

Display Adapter

While graphics support is normally available as standard on a PC-based system, this is not the case with other bus-based systems such as VME or Multibus. These systems are provided with a serial port that may be connected to a terminal to provide a text-only dialogue with the operating system running on the SBC. In such circumstances the choice of display adapter will be determined by the user requirements, taking into account the support for the device provided by any software packages that are to be used. If the user intends to write custom graphics software, it is essential to ensure that a graphics library is available from the vendor providing as a minimum line drawing, arc drawing, and block color fill facilities.

IEEE-488 Adapter

This device provides support for communications across the IEEE-488 bus or GPIB (general purpose-interface bus). The bus itself comprises eight data lines, five interface management lines and three handshake lines. Transfers are parallel, synchronous, and at rates up to 1.5 MB/s. The IEEE-488 bus and its applications are discussed further in the section on external instruments.

Serial Communications Adapter

This device provides support for serial communications using the RS-232, RS-422, or RS-485 standards. It is used to provide a text-based terminal for systems based on Multibus or VME and to communicate

with “intelligent” instruments such as position controllers, multimeters, or storage oscilloscopes fitted with similar interfaces.

Serial adapters convert parallel data to and from a bit stream in which each data byte (5, 7, or 8 bits) is framed by a start bit, an optional parity bit and one or more stop bits. The bit stream may be sent via a circuit consisting of only two wires at rates of up to 115,200 bits per second (commonly referred to as 115200 baud). Common bit rates are 300, 600, 1200, 2400, 4800, 9600, 19200, 28800, 38400, 57600, 115200 baud. Both the transmitting and receiving adapters must be configured, normally by software, for the same baud rate, number of data bits, stop bits, and parity. Some form of flow control to prevent a receiver from being overloaded with incoming data is essential. This is accomplished either by separate handshake lines (e.g., those denoted by RTS and CTS in the standard) or by software where the receiver sends a special control byte (XOFF) back to the transmitter telling it to stop sending until it receives a second control byte (XON) to reenable it. For historical reasons the RS-232 standard does not define a bidirectional handshake procedure, and manufacturers have been forced to implement their own schemes which are not always compatible with each other.

Serial communication between devices may be

Full duplex, where either device may transmit or receive data at any time;

Half duplex, where both devices are capable of transmission or reception but only one may transmit at any instant;

Simplex, where one device is a transmitter, one is a receiver, and data can only flow in a single direction.

RS-232, developed by the Electronics Industries Association (EIA), is the oldest standard, originally developed in the early 1960s, to allow mainframe computers to communicate with terminals via modems and telephone lines. This is the origin of the names of some of the connections (e.g., RI ring indicator, DCD data carrier detect), which have no relevance in the applications considered here. A related problem is that the standard expects that the devices being connected are data terminal equipment (DTE), at one end of the link, and data communication equipment (DCE) at the other. Computers and terminals are DTE, while modems are DCE. The most commonly used revision of the standard, RS-232-C (revisions D and E also exist), was made in 1969 and is still widely used. Serial communication is made using voltage levels in the region of ± 12 V, over distances up to 15 m (50 ft) at speeds up to 20000 baud.

RS-422, also developed by the EIA, is an enhancement of the RS-232 standard. Differential transmitters and receivers are employed which allow one transmitter to drive up to ten receivers, using a twisted-pair connection for each circuit, at bit rates up to 10 MBaud at distances up to 12 m (40 ft) or 100 kBaud at distances up to 1200 m (4000 ft). The RTS and CTS lines (defined in the standard) are used for flow control, while the RXD and TXD lines are used to transmit and receive data. Thus, a two-twisted-pair cable is required for duplex connection without hardware handshaking. A four-twisted-pair cable is required if hardware handshaking is used.

RS-485 is based on RS-422 and allows up to 32 driver/receiver pairs to be connected to a common data bus (two twisted pairs). Clearly, only one device can be allowed to transmit at any one time. The RTS circuit is used to disable the other transmitters connected to the bus if a device is required to transmit data. Handshaking is performed using software.

The serial interfaces on instruments are usually configured as DTE devices. We are faced with the problem of connecting one DTE device (the computer serial interface) to another (the instrument), which is not what the RS-232 standard was designed for. Furthermore, since the standard does not define a bidirectional handshake to control data flow, several incompatible handshaking schemes exist. A comprehensive survey of these is presented in Reference 7. A common solution to the DTE to DTE connection problem is the so-called *null modem*, which nothing more than a specially wired cable. [Figure 86.5](#) shows two such connection schemes. One requires the software handshaking procedure and the other implements a bidirectional hardware handshake. The reader should refer to Reference 7 for details of other schemes and for the definitions of the mnemonics used to label the connections.

FIGURE 86.5 Two null modems for connecting DTE to DTE. In (a) all handshaking must be in software. The DTR line “fools” the serial interface that it is connected to the handshake lines of another device. Scheme (b) implements a hardware handshake. The DTR–DSR connection shows each device that the other is present. The RTS lines, connected to the DCD of the other device, which it can monitor, are used to control the flow of data in either direction.

Some common problems encountered in practice are

1. The received data are garbage. This is almost always due to the baud rate, parity, and number of stop bits not being the same at both ends of the link.
2. Data initially correct, but parts in the middle are missing. This is probably a handshake problem. The transmitting device is sending data faster than the receiver can process it.
3. No communications at all. Probably a handshake problem where the transmitter does not sense that the receiver is ready.

Digital Input and Output

These cards provide I/O lines, normally in groups of eight, which may be used to sense or generated digital signals for devices outside the computer. A group of eight input lines is referred to as an (8-bit) input port and a group of eight output lines as an (8-bit) output port. Input and output levels vary from card to card and it is best to consult the appropriate data sheet. Typically, voltages between 2.5 and 5.0 V are considered as high logic levels, whereas voltages between 0.0 and 0.5 are considered as low logic levels. These levels are sometimes referred to loosely as TTL (transistor transistor logic) levels. Note that the actual logic levels used by the various TTL families differ from these slightly. The “high” and “low” ranges may be slightly different for input and output lines. Output lines often have limited current sourcing and sinking abilities compared with TTL, and it is therefore often necessary to buffer them. It is important that voltages exceeding the maximum rated values do not appear on inputs or outputs (e.g., attempting to switch an inductive load might produce a dangerously high transient voltage at an output); otherwise, the device may be damaged. Where this is likely to be a problem, inputs and outputs should be suitably buffered or even optically isolated, which provides protection up to a few kilovolts. Outputs may also drive appropriately connected relays. I/O cards with these facilities on board are readily available.

As a minimum, an I/O card may be expected to support a control register, two I/O ports each with an associated data register, and some handshake lines. Handshake lines may sometimes be used to generate interrupts on the controlling SBC. A byte written to the control register is used to configure the I/O ports, i.e., to determine if they are to behave as input or output ports as well as to select the function, if any, of the handshake lines. It may not be possible to select the direction of optically isolated or buffered ports. Writing a byte to an output port causes a pattern of high and low voltages to appear on the lines reflecting the pattern of zeros and ones in the binary representation of the byte written. Similarly, when a byte is read from an input port, the number read is specified in binary representation by the pattern of high and low logic levels on the input lines. The following example illustrates this.

The Intel 8255 Programmable Peripheral Interface (PPI) is commonly used in digital I/O cards for the PC. Data for this device are readily available [8]. The 8255 provides three ports, denoted A, B and

C, and a control register. Ports A and B may be designated as an 8-bit input port or an 8-bit output port. Port C may be considered as two independent four-bit ports, which may be chosen independently as input or output. Port C may also provide handshake functions. There are three modes in which the chip may operate. The simplest, mode 0, which provides basic input and output without automatic handshaking, is used in our example. Note that the 8 bits of an I/O port are conventionally labeled bits 0 to 7. This is because bit 0 is weighted 2^0 , bit 1 weighted 2^1 , etc. in the binary representation of the number read from or written to the port.

To configure the PPI to operate in mode 0 with port A as an input port and port B as an output port the bit pattern 10011001 must be written to the control register. This number is equivalent to 99 in hexadecimal or 153 in decimal. Suppose now that switches connected to port A hold bits 2 and 7 high and the remaining bits low. The resulting binary pattern will be 10000100, which is equivalent to hexadecimal 84 or decimal 132. When port A is read, the number 132 (decimal) will therefore be obtained. To hold the lines connected to bits 2, 3, and 5 of port B high while leaving the remaining lines low, we see that the binary pattern 00101100 must appear at port B. 00101100 binary is equivalent to 2C hexadecimal or 44 decimal. We therefore write the decimal number 44 to port B.

Counter/Timers

These devices typically provide software programmable event counting, pulse, and frequency measurement. As output devices, they may generate a single pulse (one-shot) when a programmable number of input pulses have been counted and produce square waves of arbitrary frequency and complex duty cycles. Frequencies generated are normally based on an on-board crystal clock to provide independence from the internal clock speed of the computer. Counter/timer cards commonly support at least three independent 16-bit counters.

Common applications include:

1. Alarms. The counter is in one-shot mode and generates a single pulse on timeout. This is connected to interrupt the computer and alert the user in the middle of the currently executing task.
2. Watchdog timer. This is used to detect problems, particularly in systems which are intended to operate without operator intervention. It is similar to the Alarm described earlier except that the interrupt is used to reset the computer. In normal operation this will never occur as all software tasks executing are designed to update the counter constantly so that it never reaches its terminal count. Only if a problem develops, e.g., a software “crash,” will the counter time out and the system be reset.
3. The generation of complex waveforms, e.g., for pulse width modulation. This application uses two counters in cascade, one (T1) to provide regular pulses at the carrier frequency triggering another (T2), in one-shot mode, to provide the variable duty cycle as shown in [Figure 86.6](#).

Analog Input

An analog input card uses an analog-to-digital converter (ADC) that accepts an input voltage and supplies an integer proportional to that voltage to the computer. Many cards now are produced with on-board signal conditioning circuits that provide for variable gain either by means of switches or under program control. Cards with specialized signal conditioning circuits for common applications such as thermocouple linearization or interfacing to strain gages and other bridge sensors, are available. Signal conditioning to protect cards destined to be used in hostile electrical environments is also available. Cheaper cards may provide fixed gain and require additional signal conditioning circuits to be provided external to the computer. Many cards also feature multiplexed inputs where one of several inputs may be selected under program control to be fed to the ADC. Some important parameters to consider in selecting an analog input board are given in [Table 86.5](#).

At rates above a few tens of kilohertz, interrupt-driven data capture is essential to maintain speed. Faster data rates require on-board memory to avoid degrading the performance of the controlling SBC. In this case DMA may be used to transfer data to main memory and increase performance further.

FIGURE 86.6 Using two timers to produce pulse-width modulation under software control. Both timers receive input pulses at a constant frequency from an external clock, as shown at A. Timer T1 operates in continuous mode. The trigger has no effect in this mode. The output of T1 is a single positive-going pulse when it has counted the specified (by software) number of input pulses, as shown at B. Timer T2 operates in one-shot mode. Each time it receives a trigger pulse, its output goes high for a specified (again by software) number of counts, as shown at C. In this way the frequency of the output at C is controlled by the count specified for T1 and the width of the positive-going part of C is controlled by the count specified for T2.

TABLE 86.5 Common ADC Parameters

Parameter	Description
Resolution	The smallest change in input detectable in the digital output; resolutions are commonly expressed in the number of significant bits in the digital output; hence, 8-bit resolution means 1 part in 256; 10 bit, 1 part in 1024, and 12 bit, 1 part in 4096
Linearity	The extent to which the output deviates from a linear relationship with the input; good devices will be linear to ± 1 least-significant bit; i.e., the output value is guaranteed to be within ± 1 of an exactly linear conversion
Range	The maximum (and minimum) input voltages; inputs may be unipolar, e.g., 0–5 V or bipolar ± 5 V; voltages are specified relative to ground unless the inputs are differential, e.g., those designed for bridge sensors
Conversion speed	The time taken to convert an input voltage into a digital output, typically 1 s to 1 μ s; may also be quoted as a sample rate
Linearity	The extent to which the conversion is linear, e.g., a linearity of ± 1 least-significant bit means that the output value is within ± 1 of the ideal linear conversion
Input impedance	The impedance between the input terminal and ground or between differential inputs.

A timer function is often incorporated to allow samples to be taken at regular intervals independently of what the controlling SBC is doing. An interrupt is generated when the conversion is complete, and an interrupt service routine is then activated to read the result of the conversion into memory. The

writing and installation of interrupt service routines is not a trivial task and is best left to those with an intimate knowledge of the operating system running on the SBC. Fortunately, most manufacturers supply software (device drivers) for this purpose. The simpler analog input boards may be driven by writing values directly to registers on them in a similar manner to the example given for digital I/O cards. Manufacturers now commonly provide a software library which may be called from a variety of high-level languages to allow the user to access the card in a more intuitive way. This is discussed further in the section on software.

Analog Output

Analog output cards are available as 8-, 10-, or 12-bit devices. Frequently, a card will support several channels of analog output with provision for delaying the updating of channels so that all can be updated simultaneously. Output voltages may be unipolar or bipolar and current outputs (4 to 20 mA) are also available. Signal conditioning (buffering) is necessary to drive loads drawing currents of more than a few milliamps. Special care should be taken with inductive loads, e.g., motors to avoid damage to the device by transient voltages. Specially designed position control modules incorporating suitably buffered analog and digital I/O are available for this purpose.

External Peripherals

These are usually “intelligent” devices which can operate via their front panel controls without another computer but are additionally capable of being controlled by a computer. Many common laboratory instruments are available with such facilities, including power supplies, signal generators, storage oscilloscopes, voltmeters, spectrophotometers, and position controllers. A computer can coordinate the actions of several such instruments to gather then manipulate and display data in a way which enhances the power of the instrumentation system. An almost trivial example is the use of a computer to control a signal generator and a voltmeter in order to generate the frequency response of an amplifier automatically. Such a system has an obvious role in automatic testing rigs.

Two common methods are used to control such devices: a serial link or the IEEE-488 bus. In both cases the devices are controlled by sending messages consisting of sequences of ASCII characters. Usually the sequences are chosen to have an obvious meaning, as in the example that follows, but this is not always the case — particularly with older devices where user friendliness was often sacrificed as a result of limited memory and processing power! The message sequence

```
“FREQ10kHz”  
“SINE”  
“1.0VOLTRMS”
```

might be used to set a signal generator to produce a 10-kHz sinusoidal signal at 1 V rms. There is little standardization in the form of device messages used although the IEEE standard 488.2 goes some way in this direction. Responses from instruments are sent in the same way, i.e., as ASCII characters so that a voltmeter might respond to a command to make a measurement with the data

```
“AC2.01mV”
```

to indicate that it was on an ac voltage range and measured 2.1 mV. Again, there is little standardization in the format of responses. Large blocks of data may be sent in a binary format where possible (8-bit serial links or IEEE-488 bus) to minimize the amount of data to be transferred.

Serial Devices

Serial control of devices is accomplished using links conforming to one of the serial standards (RS-232, RS-422, or RS-485) described elsewhere in this chapter. This is a relatively simple method of control and has the advantage that much of the preliminary testing and debugging of a system can be done using a terminal or a terminal emulator program such as the public domain KERMIT available from Kermit

Distribution (Columbia University Academic Information Systems, 612 West 115th Street, New York, NY 10025, Phone: 212-854-3703). The writing of custom software that accesses the serial interface of the controlling computer is relatively easy under common operating systems including DOS, Windows, Windows 95, UNIX, and OS-9 using languages such as C, Pascal, or BASIC. It is increasingly common, particularly for DOS and Windows applications, for manufactures to provide software support for their devices.

Disadvantages of serial transfers are the relative slowness when large amounts of data are transferred, the lack of standardization in device messages, and the limited control facilities available. Advantages are the ease of testing, the simplicity of the controlling software, the relative simplicity of the interconnection scheme, and — for remote instrumentation systems — the fact that with the use of modems data can be transferred over large distances using standard telephone lines or even a radio link.

IEEE 488 Devices

The IEEE standard 488 was developed in the 1970s and rapidly became an industry standard for the interconnection and control of test equipment. This standard was modified slightly in 1987 (IEEE standard 488.1) to allow for the considerable enhancements of IEEE standard 488.2 which was introduced at the same time [9,10]. The original IEEE standard 488 specifies the electrical characteristics of the bus, the mechanical characteristics of its connectors, and a set of messages to be passed between interfaces. It does not attempt to provide any syntax or structure for communicating these messages, to specify commonly used commands, or to establish a standard for device-specific messages. These issues are addressed in IEEE standard 488.2.

The bus itself supports synchronous parallel transfers of data using three groups of lines,

- A bidirectional 8-bit data bus,
- Five interface management lines, and
- Three handshake lines,

over distances of up to 20 m and at data transfer rates of up to 1 MB/s.

Devices on the bus are classed as *talkers*, *listeners*, or *controllers*. In general, the computer system is the bus controller which can also talk (send data) or listen (receive data). Most devices are both talkers and listeners: for example, a digital voltmeter will be a listener when receiving instructions to set the voltage range prior to making a measurement but will be a talker when returning the result of the measurement to the controller, which is itself acting as a listener. Each device on the bus must be assigned a unique address which is a number between 0 and 30. This may be done from the front panel of the device or, less conveniently, by setting switches elsewhere on the device.

It is a difficult, time-consuming, and error-prone process to write software to drive an IEEE-488 card. Purchasers of new IEEE-488 interfaces are strongly advised to obtain a device driver from the manufacturer. Such device drivers are now readily available and integrate the card into the filing system of the operating system running on the controlling computer. This allows the interface to be accessed in a natural way from high-level languages running on the controller.

86.6 Software for Instrumentation Systems

The difficulty involved in writing software for instrumentation systems depends largely on the support available from the manufacturers of the subsystems, on the operating system (if any), and on the development tools available. On one extreme, one may be working in a virtual instrument environment, such as that provided by the National Instrument LabVIEW, where software development is entirely graphical and, for small projects at least, is readily undertaken by users with little or no prior experience. On the other extreme, one is faced with the problem of developing software, which is at the very least interrupt driven and probably multitasking, for a target SBC with no resident operating system; this requires considerable expertise in software design and development together with the availability of development tools such as cross compilers and source-level debuggers.

FIGURE 86.7 A layer model for instrumentation systems.

Virtual Instruments

Figure 86.7 shows a layer model of the software for a generalized instrumentation system. The application layer handles the data acquisition, analysis, and presentation. The instrument drivers provide a mechanism for communicating with the instruments in a standard way without requiring the user to know about the often cryptic data strings which need to be sent. For example, all digital multimeters will need the facility to choose a specific input voltage range. The range coding, resolution, etc. that have to be sent to the multimeter to achieve this will vary from instrument to instrument; however, the instrument driver allows the software writer programming in the application layer to call a procedure such as

```
SetVoltageRange(VoltageValue)
```

and this procedure call is the same for all multimeters. Although some manufacturers use the term slightly differently, the instrument driver is in effect the virtual instrument. Writing *instrument drivers* is a time-consuming but not too difficult task. Instrument drivers for proprietary instrumentation software design packages are readily available from instrument manufacturers. Device drivers integrate the controlling interface (e.g., IEEE-488, RS-232, or internal card) into the operating system of the computer. Writing a *device driver* requires a detailed knowledge of the device hardware and of the computer operating system. This is a difficult task and new interfaces should be purchased with a device driver appropriate for the operating system wherever possible.

A number of development environments which are based on the virtual instrument concept are now available. These free the user from the problems of writing conventional software to control instruments and handle the data produced. Instruments appear to the software developer as “front panels” drawn on the computer screen, complete with familiar buttons, knobs, and displays. Data flow is handled by linking instruments in a block diagram using a mouse in an environment that resembles an ordinary drawing package. The software developer is working only in the application layer.

While the graphical environment allows simple systems to be developed rapidly, experienced programmers may find it restrictive. There are software development systems available that give the programmer access libraries containing instrument drivers, data analysis routines, graphics functions and data visualisations facilities in commonly used high-level languages such as C, Pascal, BASIC, and FORTRAN. Table 86.2 lists representative software packages.

Working Directly with Peripherals

It may occasionally be the case that the cost of software support for a virtual instrument development environment is not justified for a small application. Software must then be written to interface directly with the peripheral. The earlier section on digital input and output explained in principal what was necessary to program a simple interface chip. We now continue this example and show using the language C how this might be achieved.

The method of accessing the registers of peripheral cards depends on the microprocessor involved and may not even be a standard feature of the language being used. Where the peripheral forms part of the same address space as the computer memory, such as in the Motorola 680XX series, pointers can be used to read and write values in the registers. The Intel 80 × 86 series of processors often place peripherals in

a separate address space which may not be accessed by pointers. In this case an extension to the language is required. Borland's Turbo C and C++ provide functions to read and write I/O mapped devices:

```
unsigned char inportb(int portid)
void outportb(int portid, unsigned char value)
```

These are used in the code fragment which implements the software for our earlier example. We assume that the 8255 PPI has base address $0 \times 1b0$ and that the program copies the value read from the input port (port A) directly to the output port (port B), until bit 0 of the input becomes zero

```
/* define the addresses of the registers for the PPI */
#define BASE 0x1b0
#define PABASE
#define PBBASE+1
#define CONTROLBASE+3

unsigned char xin; /* declare an 8-bit variable */
outportb(CONTROL, 153) /* set port A as input, port B as output */
do
{
    xin = inportb(PA); /* read the input */
    outportb(PB,xin); /* write the output */
}
while(xin & 1); /* loop if bit 0 is still 1 */
```

This fragment also illustrates that high-level languages generally only support input and output of bytes. Masking techniques must be used to access individual bits.

The Choice of Operating System

The software development support discussed so far is typically available under DOS, Windows 3.1, Windows 95, Windows NT, and UNIX. When a system is multitasking, it has to meet stringent real-time constraints; however, none of these operating systems is particularly appropriate. DOS does not support multitasking, and the others are not optimized for real-time systems which require speedy context switching and rapid interrupt response. The most fundamental requirement of real-time applications is that ability of the system to respond to external events with very short, bounded, and predictable delays. [Table 86.6](#) lists some important real-time operating systems and kernels.

Real-time operating systems tend not to have the mature and powerful software development support available for conventional operating systems. It is not possible simply to develop the software on a familiar operating system and then transfer the working programs to the target system. Much of the debugging, testing, and system integration will have to be done on the target itself to access the hardware. A common solution is a development system in which a conventional workstation is linked to the target system. Software is developed on the workstation using familiar tools, e.g., a Windows-based editor, support for version control, and a powerful filing system. At any time, code can be cross-compiled (i.e., compiled for the processor on the target system) and downloaded to the target. The workstation may then monitor the execution of the software running on the target processor. Features that allow the user to single-step through the source code, seen in a workstation window, while viewing the status of key variables in another are available. It is also possible to set breakpoints and allow the processes to run until one is encountered. Manufacturers of real-time operating systems are often able to provide development support of this type for their product for a variety of workstations.

TABLE 86.6 Some Important Real-Time Operating Systems and Kernels

System	OS/Kernel	Manufacturer
OS-9	OS	Microware Systems Corporation 1900 NW 114th Street, Des Moines, IA 50325

 - Frequency Division Multiplexing • Time Division Multiplexing

87.1 Introduction

Telemetry is the science of gathering information at some remote location and transmitting the data to a convenient location to be examined and recorded. Telemetry can be done by different methods: optical, mechanical, hydraulic, electric, etc. The mechanical methods, either pneumatic or hydraulic have acceptable results for short distances and are used in environments that have a high level of electromagnetic interference and in those situations where, for security reasons, it is not possible to use electrical signals, for example, in explosive environments. More recently, use of optical fiber systems allows the measurement of broad [bandwidth](#) and high immunity to noise and interference. Other proposed telemetry systems are based on ultrasound, capacitive or magnetic coupling, and infrared radiation, although these methods are not routinely used. The discussion in this chapter will be limited to the most-used systems: telemetry based on electric signals. The main advantage of electric over mechanical methods is that electrically based telemetry does not have practical limits regarding the distance between the measurement and the analysis areas, and can be easily adapted and upgraded in already existing infrastructures. Electric telemetry methods are further divided depending on the transmission channel that they use as wire telemetry and wireless (or radio) telemetry. Wire telemetry is technologically the simplest solution. The limitations of wire telemetry are the low bandwidth and low transmission speed that it can support. However, it is used when the transmission wires can use the already existing infrastructure, as, for example, in most electric power lines that are also used as wire telemetry carriers. Wireless telemetry is more complex than wire telemetry, as it requires a final radio frequency (RF) stage. Despite its complexity, it is widely used because it can transmit information over longer distances; thus, it is used in those applications in which the measurement area is not normally accessible. It can also transmit at higher speeds and have enough capacity to transmit several channels of information if necessary.

[Figure 87.1](#) displays a generic telemetry system. It consists of (not all the blocks will be always present) (1) transducers to convert physical variables to be measured into electric signals that can be easily processed; (2) conditioning circuits to amplify the low-level signal from the transducer, limit its bandwidth, and adapt impedance levels; (3) a signal-processing circuit that sometimes can be integrated in the previous circuits; (4) a subcarrier oscillator whose signal will be modulated by the output of the different transducers once processed and adapted; (5) a codifier circuit, which can be a digital encoder, an analog modulator, or a digital modulator, that adapts the signal to the characteristics of the transmission channel, which is a wire or an antenna; (6) a radio transmitter, in wireless telemetry, modulated by

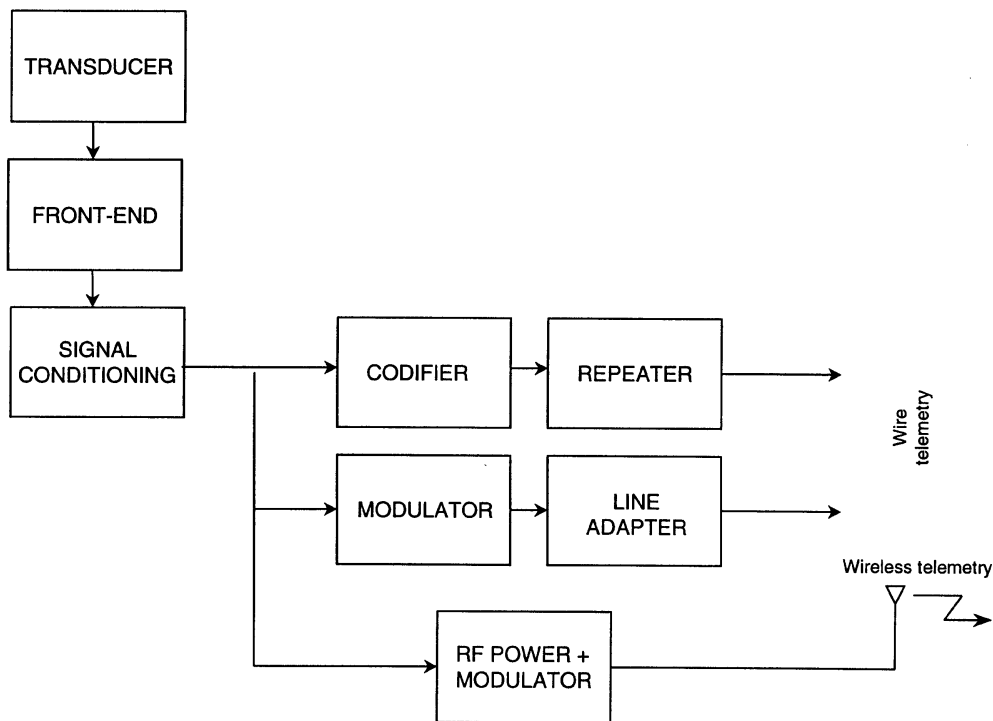

FIGURE 87.1 Block diagram for a telemetry system. Telemetry using wires can be performed in either base-band or by sending a modulated signal, while wireless telemetry uses an RF carrier and an antenna.

the composite signal; (7) an impedance line adapter, in case of wire transmission, to adapt the characteristic impedance of the line to the output impedance of the circuits connected to the adapter; and (8) for wireless communication, a transmitting antenna. The receiver end consists of similar modules. For wireless telemetry, these modules are (1) a receiving antenna designed for maximum efficiency in the RF band used; (2) a radio receiver with a demodulation scheme compatible with the modulation scheme; and (3) demodulation circuits for each of the transmitted channels. For wire telemetry, the antenna and the radio receiver are replaced by a generic front end to amplify the signal and adapt the line impedance to the input impedance of the circuits that follow. The transmission in telemetry systems, in particular wireless ones, is done by sending a signal whose analog variations in amplitude or frequency are a known function of the variations of the signals from the transducers. More recently, digital telemetry systems send data digitally as a finite set of symbols, each one representing one of the possible finite values of the composite signals at the time that it was sampled. The effective communication distance in a wireless system is limited by the power radiated by the transmitting antenna, the sensitivity for the receiver and the bandwidth of the RF signal. As the bandwidth increases, the contribution of noise to the total signal also increases, and consequently more transmitted power is needed to maintain the same signal-to-noise ratio (SNR). This is one of the principal limitations of wireless telemetry systems. In some applications, the transmission to the receiver is done on base band, after the conditioning circuits. The advantage of base-band telemetry systems is their simplicity, although because of the base-band transmission, they are normally limited to only one channel at low speeds.

Not uncommonly, measurement system needs to acquire either different types of signals or the same type of data at different locations in the process that is being monitored. These different information signals can be transmitted using the same common carrier by multiplexing the data signals. Multiplexing allows different signals to share the same channel. Multiplexing techniques are usually considered either [frequency division multiplexing \(FDM\)](#) or [time division multiplexing \(TDM\)](#). In FDM, different subcarrier

FIGURE 87.2 Basic characteristics of (a) FDM and (b) TDM signals. In FDM different channels are allocated at different subcarrier frequencies (f_{c1} , f_{c2} , ...) while in TDM only one channel is transmitted at a given time. The remaining channels are transmitted sequentially.

frequencies are modulated by the different measurement channel signals, which causes the information spectrum to shift from base band to the subcarrier frequency. Then, the **subcarrier** frequencies modulate the RF carrier signal, which allows the transmission of all desired measurement channels simultaneously. In TDM, the whole channel is assigned entirely to each measurement channel, although only during a fraction of the time. TDM techniques use digital modulation to sample the different measurement channels at different times. Then, these samples are applied sequentially to modulate the RF carrier. **Figure 87.2** illustrates these concepts by showing frequency and time graphs for FDM and TDM, respectively.

Almost all instrumentation and measurement situations are candidates for use of a telemetry link. Telemetry is widely used in space applications for either telemeasurement of a distant variable or telecommandment of actuators. In most of these types of applications, for example, in space telemetry, it is very important to design the telemetry systems to minimize the consumption of power [1]. Some land-mobile vehicles, such as trains, also use telemetry systems, either wireless or by using some of the existing power wires to transmit data to the central station and receive its commands [2]. In clinical practice, the telemetry of patients increases their quality of life and their mobility, as patients do not need to be connected to a measurement system to be monitored. Several medical applications are based on implanting a sensor in a patient and transmitting the data to be further analyzed and processed either by radio [3] or by adapted telephone lines [4] from the receiving station. Optical sensors and fiber-optic communications are used in industry to measure in environments where it is not desirable to have electric signals such as explosive atmospheres [5]. The designer of a telemetry system needs also to keep in mind the conditions in which the system will have to operate. In most of the applications, the telemetry systems must operate repeatedly without adjustment and calibration in a wide range of temperatures. Finally, as different telemetry systems are developed, the need to permit tests to be made interchangeable at all ranges increases, which require compatibility of transmitting, receiving, and signal-processing equipment at all ranges. For this reason, the Department of Defense Research and Development Squad created the Guided Missiles Committee, which formed the Working Group on Telemetry. This later became the Inter-Range Instrumentation Group (IRIG) that developed Telemetry Standards. Today, the IRIG Standard 106-96 is the primary Telemetry Standard used worldwide by both government and industry.

FIGURE 87.3 Different configurations for base-band telemetry. In voltage-based-base band telemetry (a) the information is transmitted as variations of a voltage signal. Current-based-base band telemetry (b) is based on sending a current signal instead of a voltage signal to neutralize the signal degradation due to the voltage divider made up by the input impedance of the receiver (Z_{in}) and the impedance of the lines (Z_L). In frequency-based base-band telemetry (c), the information is transmitted as variations of frequency which makes this system immune to noise and interference that affect the amplitude of the transmitted signal.

87.2 Base-Band Telemetry

Base-band telemetry uses a wire line to communicate the signal from the transducer after being processed and conditioned with the receiver. We will briefly describe telemetry systems based either on amplitude or frequency. More in-depth study of these base-band telemetry systems can be found in Reference 6.

Base-Band Telemetry Based on Amplitude

Voltage-Based Base-Band Telemetry

Figure 87.3a shows a simple voltage-based telemetry system. The signal from the transducer is amplified, normally to a voltage level between 1 and 15 V, and sent through a line consisting of two wires to the receiver. By making the low end of the scale 1 V, this system can detect short circuits [6]. The main problem of this configuration is the limitation on the transmission distance, which depends on the resistance of the line and the input resistance for the receiver. Also, the connecting wires form a loop that is very susceptible to interference from parasitic signals.

Current-Based Base-Band Telemetry

The limitation on transmission distance of the voltage-based system due to the impedance of the line are solved by using a current signal instead of a voltage, as is shown in Figure 87.3b. This requires an additional conversion module after the signal-processing circuits from voltage to current. At the receiver end, the signal is detected by measuring the voltage across a resistor. The most-used system in industry is the 4 to 20 mA loop. This means that 0 V is transmitted as 4 mA, while the highest voltage value is transmitted as a 20-mA current. The advantage of transmitting 4 mA for 0 V is the easy detection of an open circuit in the loop (0 mA). Other standard current values are 0 to 5, 0 to 20, 10 to 50, 1 to 5, and 2 to 10 mA. Also, voltage drops due to resistance of the wires do not affect the transmitted signal, which allows the use of thinner wires. Because this is a current mode, the parasitic voltages induced in the line

FIGURE 87.4 In multiple-channel telemetry a common transmission channel is used to transmit the measured signals from different channels using different sharing schemes.

do not affect the signal either. Current-based telemetry allows the use of grounded or floating transmitters with few modifications [6].

Base-Band Telemetry Based on Frequency

Frequency-based transmission is known to have higher immunity to noise than amplitude-based transmission. Frequency-based telemetry, shown in Figure 87.3c, is used in the presence of inductive or capacitive interference due to its immunity to noise. It also offers the possibility of isolating the receiver from the transmitter. The signal at the output of the conditioning circuit modifies the frequency of the telemetry signal, normally using a voltage-to-frequency converter. In the receiver, a frequency-to-voltage converter performs the opposite function. A special case of frequency-based telemetry is pulse telemetry, in which the modulating signal changes some characteristics of a train of pulses. Because of its importance and widespread use, pulse telemetry will be analyzed in-depth in the following sections.

87.3 Multiple-Channel Telemetry

Most of the industrial processes in which telemetry is used require the measurement of different physical variables to control the process, the measurement of only one physical variable at different locations, or normally a combination of both. In these multiple-channel measurements, base-band telemetry is not an option, as it would require building a different system for each channel. Multiple channel telemetry is achieved by sharing a common resource (transmission channel), as is shown in Figure 87.4. The sharing of the transmission channel by all the measurement channels is designated by *multiplexing*. There are two basic multiplexing techniques: FDM and TDM. In FDM, different channels are assigned to different spectral bands and the composite signal is transmitted through the communication channel. In TDM, the information for different channels is transmitted sequentially through the communication channel.

Frequency Division Multiplexing

In FDM, shown in Figure 87.5a, each measurement channel modulates a sinusoidal signal of different frequency. These sinusoidal signals are called *subcarriers*. Each of the modulated signals is then low-pass-filtered to ensure that the bandwidth limits are observed. After the filtering stage, all the modulated signals are fed into a summing block, producing what is known as a base-band signal. A base-band signal indicates here that the final carrier has not yet been modulated. The spectrum of the base-band signal is shown in Figure 87.5b, where it is possible to see how each measurement channel spectrum signal is allocated its own frequency. This composite signal finally modulates a carrier signal whose frequency depends on the transmission medium that is used. The signal is then fed into a transmission wire (similar

FIGURE 87.5 The different channels in an FDM system (a) are allocated at different subcarrier frequencies producing a composite signal shown in (b) that is later modulated by an RF frequency according to the transmission channel used. The guard bands limit the closeness of contiguous channels to avoid intermodulation and cross talk.

TABLE 87.1 Frequency Bands Allocated for Telemetry

Frequency band, MHz	Uses	Notes
72–76	Biotelemetry	Low power devices; restricted by Part 15 of FCC rules
88–108	Educational	Four frequencies in this band; part 90 of FCC rules
154	Industry	Band in TV channels 7–13
174–216	Biotelemetry	Low-power operations restricted to hospitals
216–222	Multiple	BW < 200 kHz
450–470	General	Telemetry as secondary basis; limited to 2 W of RF
467	Industry	Business band; limited to 2 W of RF
458–468	Biotelemetry	Band in TV channels 21–29
512–566	Biotelemetry	Low-power operations restricted to hospitals
1427–1435	Fixed	Uses in land mobile services (telemetry and telecommand)
1435–1535	Aeronautical	
2200–2290	Mobile	

to TV-broadcasting systems by cable) or, more commonly, into an antenna in the case of wireless telemetry systems. In wireless telemetry, the frequency of the carrier cannot be chosen arbitrarily, but is chosen in accordance with international agreements on the use of the electromagnetic spectrum. In the U.S., the Federal Communications Commission (FCC) is the body that regulates the allocation of frequencies for different communication services. Table 87.1 shows the most common telemetry frequency bands and their intended use. Table 87.1 is for informational purposes only, and it is not a comprehensive guide to telemetry frequencies. To find the allowed telemetry frequencies for a specific application, the maximum power allowed, and other limitations, the reader should consult the applicable FCC documents [7,8].

The allocation of bands is a process subject to change. For example, in October 1997 the FCC assigned some of the TV channel bands for patient telemetry inside hospitals, with restricted power. The FCC publishes all changes that affect frequency bands or other technical characteristics for telemetry.

At the receiver end, the carrier demodulator detects and recovers the composite base-band signal. The next step is to separate each of the subcarriers, by feeding the signal into a bank of parallel passband filters. Each channel is further demodulated, recovering the information from the transducer. The main practical problem of FDM systems is the cross talk between channels. Cross talk appears due to the nonlinearities of the electronic devices, which originates when the signal for one channel partially modulates another subcarrier in addition to the one assigned to that channel. Cross talk also originates when the spectra for two adjacent channels overlap. To avoid this effect, the subcarriers have to be chosen so that there is a separation (guard band) between the spectra of two contiguous channels. By increasing the guard band, the possibility of cross talk decreases, but the effective bandwidth also increases. The effective bandwidth equals the sum of the bandwidth of all channels, plus the sum of all the guard bands.

There are three alternative methods for each of the two modulation processes: the modulation of the measurement channel signals and the modulation of the composite signal. These methods are amplitude modulation (AM), frequency modulation (FM), and phase modulation (PM). The usual combinations are FM/FM, FM/PM, or AM/FM [6]. Here, we will analyze only on the subcarrier modulation schemes, while the modulation for the RF signal is analyzed in Chapter 81.

Subcarrier Modulation Schemes for Frequency Division Multiplexing

Subcarrier Modulation of Amplitude.

In an AM subcarrier modulation scheme, the amplitude of a particular subcarrier signal is changed according to the value of the measured channel assigned to that frequency. The resulting AM signal is given by

$$v(t) = A_c [1 + m(t)] \cos(\omega_c t)$$

where A_c is the amplitude of the carrier, $m(t)$ the modulating signal, and ω_c the frequency of the carrier.

The advantage of this type of modulation is the simplicity of the circuits that perform the modulation and the circuits required for the demodulation, in order to recover the modulating signal that carries the desired information. The percentage of modulation denotes the extent to which a carrier has been amplitude modulated. Assuming for simplicity that the modulating signal is sinusoidal of frequency ω_m , such as

$$m(t) = m \times \cos(\omega_m t)$$

the percentage of modulation (P) can be found as

$$P = m \times 100 (\%)$$

In a more general way, the percentage of modulation (P) is expressed as

$$\frac{P}{100\%} = \frac{A_{c(\max)} - A_{c(\min)}}{2A_c}$$

where $A_{c(\max)}$ and $A_{c(\min)}$ are the maximum and minimum values that the carrier signal achieves.

Figure 87.6 shows the spectrum of an amplitude-modulated signal, assuming that the modulating signal is a band-limited, nonperiodic signal of finite energy. Figure 87.6 shows that it consists of two

FIGURE 87.6 Resulting spectrum after amplitude modulation of a signal shown in (a). The resulting spectrum has doubled the required bandwidth, while only 0.25 of the total power is used in transmitting the desired information.

sidebands that are symmetrical in reference to the subcarrier. Figure 87.6 shows the main disadvantages of AM schemes. First, the bandwidth of the modulated channel is two times the bandwidth of the modulating signal, due to the two similar sidebands that appear. This results in an inefficient use of the spectrum. Second, the analysis of power for each of the components in Figure 87.6 shows that at least 50% of the transmitted power is used in transmitting the subcarrier, which is independent of the measured signal, as it does not contain any information. The remaining power is split between the two sidebands, which results in a maximum efficiency that it is theoretically possible to achieve of below 25%. The third main problem of AM is the possibility of overmodulation, which occurs when $m > 1$. Once a signal is overmodulated, it is not possible to recover the modulating signal with the simple circuits that are widely used for AM telemetry transmission.

The limitations of AM subcarrier modulation can be overcome using more efficient modulation techniques, such as double sideband (DSB), single sideband (SSB), and compatible single sideband (CSBB), which are also considered AM techniques. However, the complexity of these modulation systems and the cost associated with systems capable of recovering subcarrier signals modulated this way cause these not to be used in most commercial telemetry systems. Most of the available systems that use AM subcarrier techniques, use the traditional AM that has been described here, because its simplicity overcomes the possible problems of its use.

Subcarrier Modulation of Frequency.

FM (or PM) is by far the most-used subcarrier modulation scheme in FDM telemetry systems. These angle modulations are inherently nonlinear, in contrast to AM. Angle modulation can be expressed as

$$v(t) = A \cos[\omega_c t + \phi(t)]$$

where $\phi(t)$ is the modulating signal, that is, the signal from the transducers after conditioning.

It is then possible to calculate the value of the instantaneous frequency as

$$f = \frac{1}{2\pi} \frac{d}{dt} [\omega_c t + \phi(t)] = \frac{\omega_c}{2\pi} + \frac{d}{dt} \phi(t)$$

This equation shows how the signal $v(t)$ is modulated in frequency. We can analyze two parameters that can be derived from the previous equations: frequency deviation and modulation index. Frequency deviation (f_m) is the maximum departure of the instantaneous frequency from the carrier frequency. The modulation index (β) is the maximum phase deviation. The following equations show how these parameters are related. The value of the instantaneous frequency (f) is [9]

$$f = \frac{\omega_c}{2\pi} + \frac{\beta \omega_m}{2\pi} \cos(\omega_m t) = f_c + \beta f_m \cos(\omega_m t)$$

The maximum frequency deviation is Δf and is given by

$$\Delta f = \beta f_m$$

Therefore, we can write the equation for the frequency modulated signal as

$$v(t) = A \cos \left[\omega_c t + \frac{\Delta f}{f_m} \sin(\omega_m t) \right]$$

The previous equation shows that the instantaneous frequency, f , lies in the range $f_c \pm \Delta f$. However, it does not mean that all the spectral components lie in this range. The spectrum of an angle-modulated waveform cannot be written as a simple equation. In the most simple case, when the modulating signal is a sinusoidal signal, a practical rule states that the bandwidth of an FM signal is twice the sum of the maximum frequency deviation and the modulating frequency. For modulating signals commonly found in measuring systems, the bandwidth is dependent upon the modulation index; that is, as the bandwidth allocated for each channel is limited, the modulation index will also be limited.

Frequency Division Multiplexing Telemetry Standards

IRIG Standard 106-96 is the most used for military and commercial telemetry, data acquisition, and recording systems by government and industry worldwide [10]. It recognizes two types of formats for FM in FDM systems: proportional-bandwidth modulation (PBW) and constant-bandwidth modulation (CBW). It also allows the combination of PBW and CBW channels. In PBW, the bandwidth for a channel is proportional to the subcarrier frequency. The standard recognizes three classes of subcarrier deviations: 7.5, 15, and 30%. There are 25 PBW channels with a deviation frequency of 7.5%, numbered 1 to 25. The lowest channel has a central frequency of 400 Hz, which means that the lower deviation frequency is 370 Hz and the upper deviation frequency is 430 Hz. The highest channel (channel 25) has a center frequency of 560,000 Hz (deviation from 518,000 to 602,000 Hz). The center frequencies have been chosen so that the ratio between the upper deviation limit for a given channel and the lower deviation limit for the next channel is around 1.2. There are 12 PBW channels with a deviation frequency of 15%, identified as A, B, ... L. The center frequency for the lowest channel is 22,000 Hz (deviation from 18,700 Hz to 25,300 Hz), while the center frequency for the highest channel is 560,000 Hz (476,000 to 644,000 Hz), with a ratio for the center frequencies of adjacent channels being about 1.3. There are also 12 PBW channels for a deviation frequency of 30%, labeled from AA, BB, ... to LL. The center frequency for these channels is the same as that for the 15% channels.

TABLE 87.2 Characteristics of Constant Bandwidth (CBW) Channels for FDM

Channel Denomination	Frequency Deviation, kHz	Lowest Channel Center Frequency, kHz	Highest Channel Center Frequency, kHz	No. of Channels	Separation between Channels, kHz
A	±2	8	176	22	8
B	±4	16	352	22	16
C	±8	32	704	22	32
D	±16	64	1408	22	64
E	±32	128	2816	22	128
F	±64	256	3840	15	256
G	±128	512	3584	7	512
H	±256	1024	3072	4	1024

CBW channels keep the bandwidth constant and independent of its carrier frequency. There are eight possible maximum subcarrier frequency deviations labeled A (for 2 kHz deviation) to H (for 256 kHz deviation). The deviation frequency doubles from one group to the next. There are 22 A-channels, whose center frequency range from 8 to 176 kHz. The separation between adjacent channels is a constant of 8 kHz. Table 87.2 shows a summary of the characteristics of CBW channels.

IRIG Standard 106-96 gives in its appendix criteria for the use of the FDM Standards. It focuses on the limits, most of the time dependent on the hardware used, and performance trade-offs such as data accuracy for data bandwidth that may be required in the implementation of the system. The subcarrier deviation ratio determines the SNR for a channel. As a rule of thumb, the SNR varies as the three-halves power of the subcarrier deviation ratio. On the other hand, the number of subcarrier channels that can be used simultaneously to modulate an RF carrier is limited by the channel bandwidth of the RF carrier as well as considerations of SNR. Given a limited RF bandwidth, as more channels are added to the FDM system, it is necessary to reduce the deviation ratio for each channel, which reduces the SNR for each channel. It is then very important to evaluate the acceptable trade-off between the number of subcarrier channels and the acceptable SNR values. A general equation that might be used to estimate the thermal noise performance of an FM/FM channel is the following [11]:

$$\left(\frac{S}{N}\right)_d = \left(\frac{S}{N}\right)_c \left(\frac{3}{4}\right)^{1/2} \left(\frac{B_c}{F_{ud}}\right) \left(\frac{f_{dc}}{f_s}\right) \left(\frac{f_{ds}}{F_{ud}}\right)$$

where $(S/N)_d$ represents the SNR at the discriminator output, $(S/N)_c$ represents the SNR of the receiver, B_c is the intermediate-frequency bandwidth of the receiver, F_{ud} is the subcarrier discriminator output filter (at -3 dB), f_s is the subcarrier center frequency, f_{dc} is the carrier peak deviation for the subcarrier considered, and f_{ds} is the subcarrier peak deviation.

According to the Standard, the FM/FM composite FDM signal that is used to modulate an RF carrier can be of PBW format, CBW format, or a combination of both, with the only limitation that the guard bands between the channels used in the mixed format are equal or greater than the guard bands for the same channels in an unmixed format.

Time Division Multiplexing

TDM is a transmission technique that divides the time into different slots, and assigns one slot to each measurement channel. In TDM, all the transmission bandwidth is assigned entirely to each measurement channel during a fraction of the time. After the signals from the measurement channels have been low-pass filtered, they are sequentially sampled by a digital switch that samples all the measurement channels in a period of time (T) that complies with the Nyquist criteria. Figure 87.7a shows a basic block diagram for an FDM system. The output of the sampler is a train of AM pulses that contains the individual samples for the channels framed periodically, as is shown in Figure 87.7b. Finally, the composite signal modulates an RF carrier. The set of samples from each one of the input channels is called a frame. For

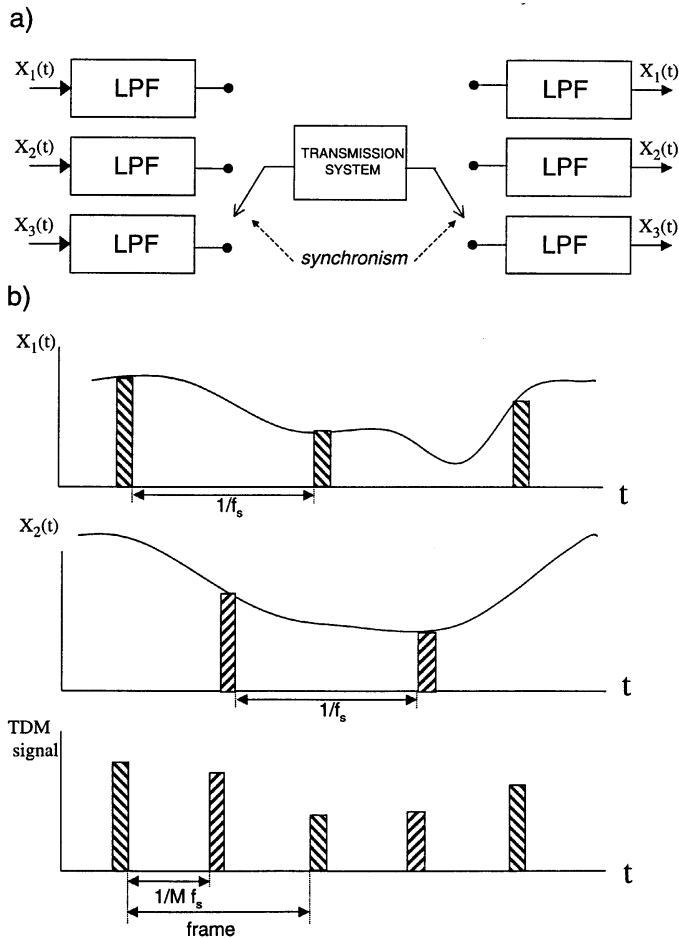

FIGURE 87.7 TDM systems (a) are based on sequentially sampling M different channels at a sampling frequency f_s , and sending the information for each channel sequentially (b). In TDM, the synchronism between transmitter and receiver is critical to recovery of the sampled signal. In this figure, the TDM signal is made of only two channels to increase readability. The blocks labeled LPF represent low-pass filters.

M measurement channels, the period between two consecutive pulses is $T_s/M = 1/Mf_s$, where T_s is the sampling period. The period between samples from the same channel is T_s . At the receiver end, by separating the digital signals into different channels by a synchronized demultiplexer and by low-pass filtering, it is possible to recover the original signal for each measurement channel.

TDM systems have advantages over FDM systems. First, FDM requires subcarrier modulators and demodulators for each channel, whereas in TDM only one multiplexer and demultiplexer are required. Second, TDM signals are resistant to the error sources that originate cross talk in FDM: nonideal filtering and cross modulation due to nonlinearities. In TDM, the separation between channels depends on the sampling system. However, because it is impossible in practice to produce perfectly square pulses, their rise and fall times are different from zero. It is then necessary to provide guard time between pulses, similar to the band guards in FDM systems. Cross talk in TDM can be easily estimated assuming that the pulse decay is exponential with a time constant (τ) approximately equal to

$$\tau = \frac{1}{2\pi B}$$

FIGURE 87.8 Different analog modulation schemes used in TDM. The variations in amplitude of the signal $x(t)$ are transmitted as amplitude variations of pulses (PAM), duration changes of pulses (PDM), or changes in the relative position of the pulses (PPM). In all the cases, the level 0 is transmitted by a pulse whose amplitude (A_0), duration (τ_0), or relative position (τ_0) is different from 0.

where B is the -3 dB channel bandwidth. The cross talk (k) between channels can be approximated as

$$k = -54.5T_g \left(\text{dB} \right)$$

where T_g is the minimum time separation between channels, called guard time.

A common situation in measurement systems occurs when the M signals that need to be measured have very different speeds. The channel sampling rate is determined by the fastest signal, thus needing an M -input multiplexer capable of handling signals at that sampling frequency. A convenient solution is to feed several slow signals into one multiplexer, then combine its output with the fast signal in a second multiplexer [6].

Analog Subcarrier Modulation Schemes for Time Division Multiplexing

In analog modulation for subcarriers the signal that results after the multiplexing and sampling process modulates a train of pulses. The most common methods for analog subcarrier modulation are pulse amplitude modulation (PAM), pulse duration modulation (PDM), and pulse position modulation (PPM). Figure 87.8 illustrates these three modulation schemes, where the pulses are shown square for simplicity. In analog modulation, the parameter that is modulated (amplitude, duration, or relative position) changes proportionally to the amplitude of the sampled signal. However, in PAM and PDM the values have an offset, so that when the value of the sample is zero, the pulse amplitude or the pulse width is different from zero. The reason for these offsets is to maintain the rate of the train of pulses constant, which is very important for synchronization purposes. The common characteristics of the different analog modulation schemes for pulses in TDM are (1) a modulated signal spectrum with a large low-frequency content, especially close to the sampling frequency; (2) the need to avoid overlaying

FIGURE 87.9 Block diagram showing a basic PCM link for telemetry.

between consecutive pulses in order to conserve the modulation parameters; and (3) the possibility of reconstructing the original samples from the modulated signal through low-pass filtering after demultiplexing. The reduction of noise depends on the bandwidth of the modulated signal, with this being the principal design criterion.

Pulse Amplitude Modulation.

PAM waveforms are made of unipolar, nonrectangular pulses whose amplitudes are proportional to the values of the samples. It is possible to define the modulation index using similar criteria as in analog AM. Similarly, in PAM the modulation index is limited to values less than 1.

Pulse Duration Modulation.

PDM is made of unipolar, rectangular pulses whose durations or widths depend on the values of the samples. The period between the center of two consecutive pulses is constant. The analysis of the resulting spectrum shows that it is possible to reconstruct the samples by low-pass filtering [9].

Pulse Position Modulation.

PPM is closely related to PDM, as PPM can be generated through PDM. In PPM the information resides on the time location of the pulses rather than in the pulses by themselves. It is then possible to transmit very narrow pulses to reduce the energy needed; this energy reduction is the most important advantage of PPM.

Pulse Code Modulation for Time Division Multiplexing.

All the previously analyzed subcarrier modulation schemes in telemetry systems are based on an analog signal that modulates either an analog carrier or a train of pulses. Pulse code modulation (PCM) is different: it is a digital modulation in which the measured signal is represented by a group of codified digital pulses. Two variations of PCM that are also often used are delta modulation (DM) and differential pulse code modulation (DPCM). In analog modulation schemes, the modulating signal from the transducer can take any value between the limits. If noise alters the modulating signal, it is impossible to decide its real value. Instead, if not all the values in the modulating signal are allowed, and the separation between the allowed levels is higher than the expected noise values, it is then possible to decide which were the values sent by the transmitter. This immunity against noise makes PCM systems one of the preferred alternatives for telemetry. Figure 87.9 shows the basic elements of a PCM telemetry system. A PCM encoder (or PCM commutator) converts the input data into a serial data format suitable for transmission through lines by wireless techniques. At the receiving end, a PCM decoder (or PCM decommutator) converts the serial data back into individual output data signals. PCM systems transmit data as a serial stream of digital words. The PCM encoder samples the input data and inserts the data words into a PCM frame. Words are assigned specific locations in the PCM frame, so the decoder can recover the data samples corresponding to each input signal. The simplest PCM frame consists of a frame synchronization word followed by a string of data words. The frame repeats continually to provide new data samples as the input data change. Frame synchronization enables the PCM decoder to locate the start of each frame easily.

Pulse Code Modulation Telemetry Standards.

IRIG Standard 106-96 also defines the characteristics of PCM transmission for telemetry purposes, in particular, the pulse train structure and system design characteristics. The PCM formats are divided into two classes for Standards purposes: class I and class II. The simpler types are class I, whereas the more

TABLE 87.3 Summary of the Most Relevant PCM Specifications According to IRIG 106-96

Specification	Class I	Class II
Class format support	Class I (simple formats) supported on all ranges	Class II (complex formats) requires concurrence of range involved
Primary bit representation (PCM codes)	NRZ-L, NRZ-M, NRZ-S, RNRZ-L, BiØ-L, BiØ-M, BiØ-S	Same as class II
Bit rate	10 bps to 5 Mbps	10 bps to > 5 Mbps
Bit rate accuracy and stability	0.1%	Same as class I
Bit jitter	0.1 bit	Same as class I
Bit numbering	MSB = bit number 1	Same as class I
Word length	4 to 16 bits	4 to 64 bits
Fragmented words	Not allowed	Up to 8 segments each; all segments in the same minor frame
Minor frame length	<8192 bits or <1024 words (includes synchro)	<16,384 bits (includes synchro)
Major frame length	<256 minor frames	Same as class I
Minor frame numbering	First minor frame in each major frames in number 1	Same as class I
Format change	Not allowed	Frame structure is specified by frame format identification (FFI) word in every minor frame

complex types are class II. Some of the characteristics of class II systems are bit rates greater than 5 Mbit/s, word lengths in excess of 16 bits, fragmented words, unevenly spaced subcommutation, format changes, tagged data formats, asynchronous data transmission, and merger of multiple format types, among others. [Table 87.3](#) provides a brief summary of relevant PCM specifications. Readers interested in the detailed specifications and descriptions should refer to Chapter 4 of the IRIG 106-96 Standard [10].

The following PCM codes, shown in [Figure 87.10](#), are recognized by the IRG Standards: NRZ-L (nonreturn to zero — level), NRZ-M (nonreturn to zero — mark), NRZ-S (nonreturn to zero — space), BiØ-L (Biphase — level), BiØ-M (Bi-Phase — mark) and BiØ-S (Biphase — space). The Standard also recommends that the transmitted bit stream be continuous and contain sufficient transitions to ensure bit acquisition and continued bit synchronization. Bit rates should be at least 10 bits/s. If the bit rate is above 5 Mbit/s, the PCM system is classified as class II. In reference to the word formats, the Standard defines a fixed format as one that does not change during transmissions with regard to the frame structure, word length or location, commutation sequence, sample interval, or measurement list. Individual words may vary in length from 4 bits to not more than 16 bits in class I and not more than 64 bits in class II. Fragmented words, defined as a word divided into not more than eight segments and placed in various locations within a minor frame, are only allowed in class II. All word segments used to form a data word are constrained to the boundaries of a single minor frame. The Frame Structure allowed by the Standards for PCM telemetry specifies that data are formatted into fixed frame lengths, that contain a fixed number of equal-duration bit intervals. A minor frame is defined as the data structure in time sequence from the beginning of a minor frame synchronization pattern to the beginning of the next minor frame synchronization pattern. The minor frame length is the number of bit intervals from the beginning of the frame synchronization pattern to the beginning of the next synchronization pattern. The maximum length of a minor frame will not exceed 8192 bits nor 1024 words in class I and will not exceed 16,384 bits in class II. Minor frames consist of the synchronization pattern, data words, and subframe synchronization words if they are used. The Standard allows the use of words of different length if they are multiplexed in a single minor frame. [Figure 87.11](#) shows a graphical representation of a PCM frame structure. Major frames contain the number of minor frames required to include one sample of every parameter in the format. Their length is defined as minor frame length multiplied by the number of minor frames contained in the major frame. The maximum number of minor frames per major frame is limited to 256.

FIGURE 87.10 Different PCM codes. All lower levels in NRZ use a value different from zero. In biphase codes the information resides in the transitions rather than in the levels. In NRZ-L, a 1 is represented by the highest level, while a 0 is represented by a lower level. In NRZ-M, a 1 is represented by a change in level, while a 0 is represented by no change in level. In NRZ-S, a 1 is represented by no change of level, while a 0 is represented by a change of level. In Biφ-L, a 1 is represented by a transition to the lower level, while a 0 is represented by a transition to the higher level. In Biφ-M, the 1 is represented by no change of level at the beginning of the bit period, while the 0 is represented by a change of level at the beginning of the bit period. In Biφ-S, a 1 is represented by changing the level at the beginning of the bit period, while the 0 is represented by no change of level at the beginning of the bit period.

FIGURE 87.11 Structure of a PCM Frame. The maximum length of a minor frame is 8192 bits or 512 for class I and 16,284 bits for class II. A major frame contains $N \times Z$ words, where Z is the number of words in the maximum subframe, and N is the number of words in the minor frame. Regardless of its length, the minor frame synchronism is considered as one word. W is the word position in the minor frame, while S is the word position in the subframe.

Appendix C in the 106-96 IRIG Standard gives recommendations for maximal transmission efficiency in PCM telemetry. The intermediate-frequency (IF) bandwidth for PCM telemetry data receivers should be selected so that 90 to 99% of the transmitted power spectrum is within the receiver 3-dB bandwidth. The IF also has effects on the bit error probability (BEP) according to the following equation for NRZ-L PCM/FM [10]:

$$\text{BEP} = 0.5e^{(k\text{SNR})}$$

where $k \approx -0.7$ for IF bandwidth equal to bit rate

$k \approx -0.65$ for IF bandwidth equal to 1.2 times bit rate

$k \approx -0.55$ for IF bandwidth equal to 1.5 times bit rate

Other data codes and modulation techniques have different BEP vs. SNR performance characteristics, but in any case they will have similar trends.

The Standard also specifies the recommended frame synchronization patterns for general use in PCM telemetry. There are different lengths for synchronization patterns, but in all of them the 111 is the first bit sequence transmitted. The patterns for lengths 16 to 30 were selected in order to minimize the probability of false synchronization over the entire pattern overlap portion of the ground station frame synchronization [12]. The spectral density (S) for the NRZ and BiØ codes are

$$\begin{aligned} \text{NRZ Codes} \quad S &= \frac{\sin^2(\pi fT)}{(\pi fT)^2} \\ \text{Biphase Codes} \quad S &= \frac{\sin^4(\pi fT/2)}{(\pi fT/2)^4} \end{aligned}$$

The calculation of spectral densities allows the determination of the BEP for the previous type of codes assuming perfect bit synchronization. These calculations show that for the same SNR, the lowest BEP is achieved for NRZ-L and Bi codes, followed by NRZ and BiØ mark and space codes and finally for random NRZ-L codes (RNRZ-L).

Telemetry data are usually recorded onto magnetic tape for later analysis. When recording PCM data, it is important to ensure that the tape recorder provides sufficient frequency response to capture and reproduce the PCM signal. Useful rules to calculate the maximum bit rate for various PCM codes specify that for NRZ and RNRZ codes the maximum bit rate is 1.4 times the tape recorder frequency response while for all biphase codes, the maximum rate is 0.7 times the tape recorder response. To limit the transmission bandwidth that PCM creates because it is a digital signal with sharp transitions, the PCM signal is usually passed through a premodulation filter before it is fed into the transmitter input. The filter cutoff frequency can be calculated as 0.7 times the PCM bit rate for NRZ and RNRZ codes and 1.4 times the PCM bit rate for all biphase codes.

Defining Terms

Bandwidth: The range of frequencies occupied by a signal.

Carrier: A frequency that is modulated by a signal containing information.

Channel: A subcarrier that carries information.

Constant bandwidth (CBW) channel: A channel whose bandwidth is independent of its carrier frequency.

Deviation ratio: The ratio of the maximum carrier frequency deviation to the maximum data frequency deviation.

Frequency deviation: The difference between the center frequency of a carrier and its upper or lower deviation limit.

Frequency division multiplexing (FDM): A composite signal consisting of a group of subcarriers arranged so that their frequencies do not overlap or interfere with each other.

Frequency response: The highest data frequency that can be carried by the channel.

IRIG: Inter-Range Instrumentation Group of the Range Commanders Council (RCC).

Proportional bandwidth (PBW) channel: A channel whose bandwidth is proportional to its carrier frequency.

Remote switching: Telemetry consisting only of yes/no or on/off orders.

Signaling: Telemetry consisting of binary information.

Subcarrier: A carrier combined with other carriers to create a composite signal.

Subcarrier bandwidth: The difference between the upper and lower frequencies of a modulated carrier.

88.1 Introduction

What Is a Communication Network?

A communication network provides a system by which multiple users may share a single communication path (or medium) to exchange information. The telephone system is an example of a system containing many communication networks, which can be considered to be a single communication network as an abstract example. Communication networks are commonly used in various industries and applications to provide an economical means to allow multiple, geographically separated users to exchange information.

Ordinary Sensors vs. Networked Sensors

A definition of the function of a sensor is to map or convert one measured variable (e.g., spatial, mechanical, electromagnetic, etc.) into another — usually electric — variable or signal. This signal may then be passed to a measurement or processing system for capture and analysis, or as a direct input to some controlled process. In this case, the measured variable is represented as an electric signal. This signal must be handled individually by the measurement system, and it may also be subject to corruption from a variety of sources, such as electromagnetic interference in the case of an electric signal.

FIGURE 88.1 A networked sensor is an ordinary sensor with network communication components added.

In applications where a number of sensing devices are needed, and/or where the sensing devices are distributed geographically (or are distant from the measurement and analysis system), the application designer may wish to use a communication network to transmit sensor data from the measurement point to the measurement and analysis system. Such applications typically involve some sort of digital computing machinery at the measurement and analysis point, or as part of the control system. Figure 88.1 depicts a representative block diagram of a sensor/network system showing the relationship of the various components.

Networked sensors can be distinguished into two components: those performing the measurement function, and those components performing the communication function. In some cases, these two functions may be designed as a single unit, such that the “sensor” intrinsically includes communication capability. In other cases, an ordinary sensor may be connected to a conversion unit, which converts the output signal of the ordinary sensor into a form suitable for the network, and manages the delivery of this information on the network.

Why Use Networked Sensors?

Network communication combined with sensor technology can provide several benefits to an application, as well as to the sensor designer. The most obvious benefit of a network is the simplification of the wiring for the transmission of the signals from one place to another. For a system containing N users, the number of wires or cables T required to individually connect each user with each other user is given by Equation 88.1:

$$T = 2^{(N-1)} - 1 \quad (88.1)$$

assuming each wire or cable can carry information in both directions between the two users connected by that cable. For more than a few users, the number of cables required (T) to provide an individual connection between each pair of users is large. Sensors are often connected to a central measurement and analysis system, and may only need to communicate with the central system. In this case, the number

of individual wires or cables needed is equal to the number of sensors ($N - 1$). Even with this smaller number of cables, the wiring for a large number of sensors in some applications can be quite complex. A network may be able to reduce the total number of cables required to a much smaller number. In fact, in a sensor network, all of the sensors and the central measurement and analysis system can be connected to a single cable.

An indirect benefit of networking may be in its handling of the sensor signal. Because most modern networks are digital in nature, an analog sensor signal typically must be digitized before it can be transmitted on a network. With a networked sensor, the digitization will typically be carried out by circuitry in relatively close proximity to the sensor. As a result, the analog signal will have traveled a short distance before being converted to a digital signal. This can be a benefit in two ways. The first is that the analog signal will not suffer as much attenuation or degradation due to electric losses associated with carrying a signal over a great distance. The second is that once in digital form, the “signal” can be made relatively immune to the effects of distortion or degradation due to electromagnetic interference (EMI). Although digital transmission of signals is still subject to EMI, modern protocols and transmission systems can be designed to be very robust, using signaling that is resistant to EMI as well as using error control techniques. As a result, the effect of attenuation and disturbances can be essentially eliminated by digital transmission of the signal.

Another benefit of networking is the ability to communicate a much wider range of information — in both directions — when compared with a single cable carrying a sensor signal. With many modern networks suitable for networked sensing applications, a microprocessor is used at the sensor to manage the handling of the sensor signal and its transmission on the network. But there is generally no need to limit the microprocessor to this one function alone. The combination of the network and the microprocessor provides a platform upon which many additional functions and features can be incorporated into the networked sensor. For example, the signal of a sensor may need a certain calibration or correction function applied to it before it can be used in calculations. It may be beneficial to load into the networked sensor (through the network) a set of correction parameters or coefficients, and then have the microprocessor correct or calibrate the output of the sensor before transmitting it to the network. Sensors can be easily designed to have multiple sensing functions, such as temperature and pressure, for example. Each signal can be handled separately and transmitted separately on the network, with no need for additional connections. Sensors may be designed to store certain types of information, such as the name of the manufacturer, or certain calibration parameters determined by the manufacturer at the time of manufacture. This information can then be read out over the network and used for a variety of purposes. A sensor can even be designed to have “intelligent” functions, such as the ability to sense its environment and determine when certain parameters have been exceeded (such as operating temperature range), or report a special message containing an “alarm” when the sensor signal level exceeds a certain threshold. The combination of the network and the microprocessor leads to an endless variety of functions and features that can be added to the basic sensor technology.

Potential Problems with Networked Sensors

Networked sensors will generally require more complex circuitry than equivalent, nonnetworked sensors. A drawback of analog-to-digital (A/D) conversion and digital transmission of signals is the time and level quantization effect that A/D conversion can have on the analog signal. These effects can be mitigated with modern, high-speed A/D converters (to minimize the effect of time quantization, or the sampling effect) with the ability to convert in high resolution (i.e., using a large number of digital bits to represent the analog signal level). These drawbacks are not unique to networked sensors but rather to digitized sensor values and digital control whether or not it uses a network. Finally, the capacity of the network to carry information (the bandwidth) must be considered in any communication system. Putting a large number of sensors on a single network may overload the information-carrying capability of the network, resulting in queuing delays in the reception of sensor signals and, in some cases, lost data.

88.2 Communication and Networking Concepts

In order to be able to select an appropriate network technology, it is necessary to understand some basic terminology so that the features and capabilities of various networks and technologies can be categorized and compared.

Station

A station represents a single communicating element on a network system. Each user of the network must access the communication capability of the network via a station. Each station will typically have some implementation of the open systems interconnection (OSI) network reference model as the means of utilizing the network system.

Media Access

Media access is the method by which individual stations determine when they are permitted to transmit, or “use” the media. Media access control (MAC) is a function that is usually performed in the data link layer of the OSI reference model. Some well-known methods of media access control include carrier sense multiple access with collision detection (CSMA/CD) and token passing. CSMA/CD systems (such as Ethernet) allow all stations on a network equal access. Each station must “listen” to the network to determine periods of inactivity before transmitting. Any station wishing to use the network may begin transmitting providing the network is inactive when it checks for activity. If multiple stations attempt to transmit simultaneously, a collision occurs. This is detected by all transmitting stations, which all must immediately stop transmitting and each wait a randomly determined period of time, before attempting to use the network again. Controller area network (CAN), for example, uses a variant of CSMA/CD for media access. Token-passing systems have a logical “token” which is exchanged among stations via network messaging. The station that holds the token has permission to transmit. All other stations are only permitted to receive messages. Stations wishing to transmit but not having the token must wait until the station holding the token passes it on. Another commonly used method of media access control is master–slave. In this method, one station on the network (designated the master) is generally in charge of, and originates, all communications. Slaves only respond to the master, and only respond when the master initiates communications with them via sending a message to the slave. Profibus-FMS (see below) is an example of a protocol which uses both token passing (in some cases) and master–slave (in some cases) to control media access.

Bandwidth

Bandwidth may have several different definitions. For digital communication systems, bandwidth describes the capacity of the system to transport digital data from one place to another. This term may be applied to the raw capability of the physical and data link layers to transport message data (*raw bandwidth*, closely related to the bit rate concept) or it may be applied to the effective rate at which user-meaningful information is transported (*effective bandwidth*). The bandwidth of a given system is generally inversely proportional to the worst-case node-to-node distance. The smaller the network span, the higher its bandwidth can be.

Addressing

Addressing is a concept that assigns generally unique identifiers to each station in a network system. This identifier (the address) can then be used by the network for a variety of purposes, including identifying the origin and/or destination of messages, or arbitrating access to a shared communications medium. Another addressing or identifier concept assigns unique identifiers not to stations, but to unique pieces of data or signals that will be carried by the network. Stations then use an identifier according to what

type of data they will be transmitting. Many, but not all networking methods require establishment of an explicit address for each network station.

Arbitration

Arbitration is a function closely related to MAC. Arbitration is used by some networks to define the procedure followed when multiple stations wish to use the network simultaneously.

Signaling

Signaling refers to the actual physical (e.g., electrical, optical, or other) representation of data as it is carried on the media. For example, in some networks, data elements may be represented by certain voltage levels or waveforms in the media. In other networks, data elements may be represented by the presence of certain wavelengths of light in the media. The association of all the representable data elements (e.g., 0/1 or on/off) with the corresponding signal representations in the media is the signaling scheme or method. An important signaling method where electric wires are used as the medium is differential signaling. Differential signaling represents a particular data element (1 or 0) as two different states on a pair of wires. Determining the data element requires measuring the voltage difference between the two wires, not the absolute level of the voltage on either wire. Different data elements are then represented by the (signed) voltage difference between the two wires. For example, RS-485 represents a digital 1 data element as a 5-V signal level on the first wire and a 0-V signal level on the second wire, and a digital 0 as a 0-V signal level on the first wire and 5-V signal level on the second wire. One of the principal benefits of differential signaling is that it is possible to determine the data being transmitted without knowing the ground reference potential of the transmitter. This allows the transmitter and receiver to operate reliably, even when they have different ground potentials (within limits), which is a common occurrence in communication systems.

Encoding

Encoding refers to the process of translating user-meaningful information into data elements or groups of data elements to be transported by the network system. A code book refers to the set of all relationships between user-meaningful information and data carried by the network. Encoding may occur at several levels within the OSI reference model, as user-meaningful information is transformed successively until it becomes an actual network message, produced by the data link layer. Decoding is the reverse process, whereby a network message is successively translated back into user-meaningful information.

Modulation

Modulation in a classical sense refers to a signaling technique by which data or information is used to control some combination of the frequency, phase, and/or amplitude of a carrier signal. The carrier signal carries the information to a remote receiver where it will be demodulated to retrieve the information. Modulated network systems are outside the scope of this chapter.

Message

A message is the fundamental, indivisible unit of information which is exchanged between stations. User-meaningful information will be grouped into one or more messages by the OSI network reference model.

Multiplexing

Multiplexing refers to the ability to use the media in a network to carry multiple messages or information streams “simultaneously.” Multiplexed systems allow several communication channels to use the same physical wire or media. Each message or information stream may have different sources and destinations.

Multiplexing may be accomplished using a variety of means. Time division multiplexing (TDM) involves breaking access to the media into a series of time quanta. During each time quantum, the media carries a separate message or information stream. The close arrangement of time quanta allows the network media to carry multiple messages “simultaneously.” Code division multiplexing (CDM) involves the separation of the code book (see Encoding) into sections. Each section of the code book provides all of the messages that will be used for a particular information stream. Therefore, a particular information stream within the network media is distinguished by all of the messages that belong to the section of the code book for that stream. Frequency division multiplexing (FDM) divides an available bandwidth of a communication channel into several frequency ranges, and assigns one information stream to each frequency range.

Protocols

A protocol is a defined method of information exchange. Protocols typically are defined at several levels within the OSI network reference model, such as at the application layer and at the data link layer. Protocols are used to define how the services provided by a particular layer are to be exercised, and how the results of these services are to be interpreted.

Service

A service represents a specific function or operation that is supported by a particular layer in the OSI network reference model. For example, an application layer service might be provided for the reading of or writing to a data element contained in another device (or station) on the network. This service might make use of a data link layer service which might be provided for supporting the exchange of a message with another device (or station) on the network.

Topology

Topology refers to the physical or geographic layout or arrangement of a network. Certain types of canonical topologies are commonly discussed in the context of networks, such as trunkline/branchline, star (or hub), ring, and daisy chain.

Bit Rate

Bit rate refers to the speed at which binary pieces of information (bits) are transmitted on a particular network. The raw bit rate of a network generally refers to the actual speed of transmission of bits on the network. The effective bit rate — or throughput — generally refers to the speed at which user information is transmitted. This number is less than or equal to the raw bit rate, depending on what percentage of the bits transmitted is used for carrying user information. The bits not carrying user information are overhead, used to carry protocol, timing, or other network information.

Duplex (Half and Full Duplex)

Half duplex refers to a communication system in which a station can either transmit information or receive information, but not both simultaneously. A full duplex network allows a station to transmit information and receive information simultaneously.

Error Control

Many network systems provide mechanisms to control errors. Error control has four aspects: prevention, detection, correction, and isolation. Error prevention may simply be shielding for the media to minimize electromagnetic disturbances, or it may be more complicated, such as signal sampling control to optimize the probability that a signal will be in the correct state when sampled. Error detection generally depends

on detecting violations of protocol rules at various network levels, or violations of computed data added to a message for error control purposes. Some examples of error detection techniques are parity and cyclic redundancy check (CRC). Both methods involve the computation of additional bits of information based on the data that is contained in a message, and appending these bits to the message. For example, a particular protocol may require that the data link layer compute and append a CRC to a message prior to transmission. The receiver of the message may then also compute the CRC and compare it to the CRC which has been appended to the message. If a mismatch exists, then it is assumed an error has occurred. Error correction may take on a variety of forms. One of the simplest methods of error correction is to require that the data link layer of the transmitter retransmit a message which has been detected to have an error during transmission. This method is based on the assumption that the error was caused by a disturbance which is unlikely to occur again. Another method of error correction involves transmission of additional bits of information along with the user information in a message. These additional bits of information are computed by the transmitter to provide redundant information in the message. When fewer than a certain number of bit-level errors have occurred during the transmission of the message, the receiver is able to reconstruct the original user information accurately using the redundant information (bits) supplied within the message. Error isolation is a capability of some networks to localize the source of errors and isolate the sections of the network or the stations at which the errors have been localized. Error isolation allows the fault-free portions of the network to continue communicating even when other portions of the network have degraded to the point of generating errors.

Internetworking

There are occasions when communications between two or more points are best handled by multiple networks. This may be the case when a single network has limitations that prevent it from tying the points together (e.g., distance limits) or when multiple networks are required for other reasons (e.g., to carry different types of data). When multiple networks are used to provide communications, there may be a need to pass messages or information directly from one network to another.

A repeater may be used when the networks to be joined are logically identical, and the purpose is simply to extend the length of the network or extend its capabilities in some way. A repeater generally has no effect on messages, and simply carries all messages from one cable or port to another (i.e., a change of physical media). A repeater allows for connection of networks at the physical layer level.

A bridge is similar to a repeater, but allows for connection of networks at the data link layer level. Generally, a bridge will pass all messages from one network to another, by passing messages at the data link layer level.

A router usually has the function of partitioning similar networks. Two networks may be based on the same technologies and protocol, but may not be logically identical. In these cases, some, but not all, of the messages on one network may need to be carried or transported to the other network. The router has the function of determining which messages to pass back and forth based on certain rules. Functions to enable efficient, automatic routing of messages may be included in layer 3 (the network layer) of the OSI network reference model, and a router allows for connection of networks at the network layer level.

A gateway may have a function similar to a router, or it may have the function of joining dissimilar networks, i.e., networks based on dissimilar technologies and/or protocols. When functioning like a router, a gateway usually performs its discrimination at a higher protocol level than a router. When a gateway joins dissimilar networks, generally a more complex set of rules must be designed into the gateway so that message translation, mapping, and routing can occur within the gateway as it determines which messages to pass from one network to the other.

ISO/OSI Network Reference Model

The explosion in the use and types of communication networks over the last several decades has led to more precise descriptions and treatment of communication networks in general. The International

FIGURE 88.2 The ISO-OSI Seven Layer Model provides a method for segmenting communication functions

Organization for Standardization (ISO) has recognized one such method of precise description of networks, called the OSI reference model [1]. As shown in [Figure 88.2](#), this model decomposes an arbitrary communication network into a “stack” of seven “layers.” At each layer, certain types of network communication functions are described. The user of the communication system — usually another system that needs to communicate on the network — interacts with layer 7, the highest layer. The actual transmission medium (e.g., copper cable, fiber optic, free space, etc.) is connected to layer 1, the lowest layer. Most communication networks do not implement all of the layers in the reference model. In this case, formal definition, treatment, or inclusion of certain layers of the model in the actual network design are omitted. Layers 1, 2, and 7 are typically present in all networks, but the other layers may only be explicitly included or identifiable when their function is an important part of the network communications. In many sensor communication networks, the functions performed by layers 3,4,5, and 6 are “collapsed” into vestigial additions to the functions of layer 7, the application layer.

Physical Layer

The physical layer is the lowest layer of the model. This layer is responsible for converting between the symbolic or data representation of the network messages and the actual physical representation of data in the network medium. This layer specifies the behavior of the electric circuits referred to as the transmitter and the receiver. It also defines physical structures for connectors.

Data Link Layer

The data link layer, or layer 2, is responsible for several functions. This layer manages access to the network medium (MAC), structures the bits of information into well-defined groups identified as “frames” or messages, handles identification of source and destination stations on the network, and provides for error-free transmission of a message from source to destination stations, all according to the data link layer protocol. A number of standard data link layer protocols exist, which act as the basis for many of the communication networks in wide use. Ethernet, or IEEE 802.3, for example, specifies a MAC sublayer that works with the IEEE 802.2 Logical Link Control layer to form the data link layer protocol used in the majority of office information networks [2].

Network Layer

The network layer encapsulates functions related to routing of messages, both within a single network and among multiple networks. This layer typically uses addressing in a variety of forms as a key part of the functions of directing and routing messages, and the search and usage of the available communication paths.

Transport Layer

The transport layer provides any additional data transfer functions not directly provided by the data link layer for end-to-end reliable messaging. For example, some data transfer functions between stations may require the use of multiple data link layer messages to accomplish a reliable message transfer. The generation of multiple messages and the sequential disassembly, delivery, and assembly of data is accomplished by the transport layer. The transport layer also recovers from lost, duplicated and misordered messages.

Session Layer

The session layer provides for a higher level of control and management of network usage and data flow than that provided at lower layers, including opening or building up a communication channel, maintaining the channel, and closing the channel. This layer is infrequently implemented in contemporary systems.

Presentation Layer

The presentation layer provides functions to transform data from formats that are transportable by the network to the user-accessible formats that are defined in the application layer and understood in the local station.

Application Layer

The application layer, or layer 7, provides communication services directly to the user application. The usage and formatting of these services is summarized in the application layer protocol. The user interacts with the network by invoking functions and services provided by the application layer and passing data to and from the network through these services.

88.3 Network Technologies

There is a wide range of technologies in various stages of development and standardization, which address virtually all levels or layers of the ISO/OSI network reference model. One or more of the available technologies will probably suit almost any networking need. An analysis of the available technologies and their limitations will also be beneficial if it is deemed that a networking method must be designed to meet a particular application. The selection and description of technologies is by no means complete or exhaustive. The technologies presented are selected from several industries which make common use of networking to communicate sensor data. [Figure 88.4](#) provides a comparison of selected parameters for a set of networks.

FIGURE 88.3 A sample RS-485 waveform showing voltages on differential wire pair (V_1 , V_2) and superimposed bit intervals showing 0 and 1 bits. The ground reference is arbitrary within the defined signaling range.

RS-232

RS-232 (ANSI/EIA/TIA-232-E-91) is a widely used method of communication, which has been standardized in a variety of places including the Electronics Industry Association [3]. RS-232 represents elements of layer 1 of the OSI model, for communicating between two (and only two) stations. RS-232 provides a separate wire for transmission of data in each direction between the two stations, and gives the two stations different designations — data terminal equipment (DTE), and data communications equipment (DCE) — so that a method exists to distinguish which station will use which wire to transmit and receive. The signal levels for RS-232 represent a digital 1 bit as a voltage in the range of 5 to 12 V on the wire, and a digital 0 bit as a voltage of negative 5 to 12 V on the wire. RS-232 is typically implemented in a full duplex fashion, since each station can transmit to the other simultaneously using separate wires. RS-232 can be made to operate at a variety of bit rates, but typically is used at bit rates from 300 bit/s up to 115,200 bit/s.

RS-485

EIA RS-485 was made a standard in 1983, derived from the RS-422 standard. RS-485 provides for differential transmission of data on a pair of wires among 32 or more stations. Like RS-232, the standard is a layer 1 specification. RS-485 provides for half duplex communication, since a station cannot simultaneously transmit and receive independent data streams. Each station in an RS-485 system can have either a transmitter or a receiver, or both (commonly called a transceiver). Most implementations provide a transceiver. When one transceiver is transmitting, all others should be receiving (i.e., not transmitting). Which station is allowed to transmit at which time is not specified in the standard, and must be covered by a higher layer protocol (e.g., Interbus-S, Profibus-DP). [Figure 88.3](#) shows a sample RS-485 waveform, indicating the differential nature of the signaling.

Seriplex¹

Seriplex[®] is a digital, serial multiplexing system developed by Automated Process Control, Inc., in Jackson, MS. Square D Corporation purchased Automated Process Control and the rights to Seriplex in 1995, and subsequently launched Seriplex Technology Organization (STO) to manage the protocol. Seriplex is designed to be particularly efficient at handling large numbers of digital or on/off input and output points. Seriplex provides three communication wires, one for a clock signal, one for a data signal, and a ground reference. The system can be operated in two different modes (peer-to-peer and master-slave). In master-slave mode, one station is designated the master. The master synchronizes all data transmission among stations by driving a digital waveform on the clock line which all stations listen to and use for timing of transmit and receive operations. The master generates a repetitive pattern on the clock line

¹Seriplex is a trademark of the Seriplex Technology Organization.

	Length	Stations	Bit Rate	Wires	Media	Topology
RS-232	30 m	2	115 kb/s	2	TP	P-P

FIGURE 88.4 A comparison of selected parameters (maximum values) for various network technologies.** *Notes:* P-P = point to point; D-C = daisy-chain; T-B = trunkline-branchline; TP = twisted pair; STP = shielded twisted pair; UP = unshielded pair. * Maximum 400 m between stations. ** Maximum parameters for networks are not achievable simultaneously, and do not include repeaters, routers, or gateways. Maximum parameters are estimates based on available information.

which causes all stations to transmit and/or receive data on each cycle, or “scan” of the network. Each station is given an address, and uses the address along with the clock signal to determine when to drive the data line (in the case of an input point) or when to monitor the data line for valid output data (in the case of an output point). There are variations possible in implementation which allow for various clock speeds and bit rates (16, 100, and 200 kHz). Other protocol details allow for the handling of analog or multibit input and output points (by combining several bits on sequential scans together), bus fault detection, input redundancy, and communication error control using multiple scans of the network. Implementing the protocol in a sensor or other device typically requires using a Seriplex ASIC (Application Specific Integrated Circuit) which must be licensed from the STO [4].

AS-i

Actuator Sensor Interface, or AS-i, was developed by a consortium of primarily European companies interested in developing a low-cost, flexible method for connecting sensors and actuators at the lowest levels of industrial control systems. The system is managed by an independent worldwide organization [5]. The AS-i system provides a two-wire, nontwisted cable for interconnection of devices. Devices may draw current from the two wires (nominally at 24 V dc) for powering circuitry, and the data communications are modulated on top of the nominal dc level at a bit rate of 167 kHz, under the control of the master. A single parity bit per station is used for error detection. Similar to Seriplex, an AS-i device is typically implemented using a special ASIC which handles the communication.

Interbus-S

Interbus-S was developed by Phoenix Contact [6] and is controlled by the Interbus-S Club. The topology of the network is a ring, with data being sequentially shifted from point to point on the ring under the control of a network master. Each device in the ring acts as a shift register, transmitting and receiving data simultaneously at 500 kHz. The actual serial data transmission between stations conforms to RS-485. Interbus-S transmissions include a CRC for error detection. Interbus-S (Interbus-S Remote Bus) has also been extended to include a subprotocol called Interbus-Sensor Loop (or Interbus-S Local Bus). This subprotocol provides an alternate physical layer, with a single twisted pair carrying power and data on the same lines, and a reduction in the minimum size of the shift register in each station from 16 to 4 bits. Each Interbus sensor loop system can act as a single station on an Interbus-S network, or the sensor loop can be connected directly to a controller or master. Interbus-S devices are usually implemented with a special ASIC.

CAN

Controller Area Network (CAN) is a data link layer (layer 2) network technology developed by Robert Bosch Corporation [7], with an application target of onboard automotive networking. The technology is standardized in ISO 11898 [8], licensed to all major integrated circuit manufacturers, and is widely available — both as separate CAN controllers as well as CAN controllers integrated with microprocessors. As a result, CAN has been used in a variety of industries. As a data link layer technology, it is not a complete network definition. A number of physical layer options are usable with CAN (e.g., twisted pair, fiber optic, radio frequency wireless) and some have been subject to standardization (e.g., ISO 11898). Also, a number of application layer protocols have been developed for use with CAN, such as DeviceNet, Smart Distributed System (SDS), CANOpen [9], and SAE J1939 [10]. Both DeviceNet [11] and Smart Distributed System [12] have developed systems for creating networks of industrial field devices for the factory floor, including sensors and actuators.

4 to 20 mA Current Loop

The 4 to 20 mA current loop is a widely used method for transferring information from one station (the transmitter) to another station (the receiver). Therefore, this system allows for only two stations. A typical current loop system assigns a sensing range (e.g., 0 to 100°C) to the current range between 4 and 20 mA. A loop exists (i.e., two wires) between the transmitter and receiver. The transmitter can impress a certain current in the loop (using a controlled current source) so that the receiver can measure the current in the loop (e.g., by placing a small resistor in series with the loop and measuring the voltage drop across the resistor). After measuring the current, the receiver can then determine the present level of the sensed signal within the defined sensing range. This method uses current signaling, instead of voltage signaling, and therefore is relatively unaffected by potential differences between the transmitter and the receiver. This is similar to the benefit of differential (voltage) signaling, which also requires two wires. Another characteristic of this method is that it is not primarily digital in nature, as many other sensor communication systems are. The measured value can vary continuously in the range of 4 to 20 mA, and therefore can easily represent an analog sensing range, rather than a set of digital signals. Also, the signal is continuously variable and available. Another characteristic of this method is that the integrity of the loop can be verified. As long as the loop is unbroken and the transmitter is in good working order, the current in the loop should never fall below 4 mA. If the current approaches 0 mA, then the receiver can determine that a fault exists — perhaps a broken cable. These systems are widely used in various process control industries (e.g., oil refining) for connecting sensors (transmitters) with control computers. Because one station is always the transmitter and one station is always the receiver, this is a unidirectional, half duplex communication system.

HART²

HART[®] is a protocol which builds upon 4 to 20 mA communication systems. The basic idea is that additional data (beyond the basic sensor signal being carried in the current loop) can be transmitted by modulating a signal on top of the current flowing in the loop. The actual modulation method conforms closely to the Bell 202 standard for analog modem communications on telephone lines at 1200 bit/s. Because a 4 to 20 mA current loop carries a relatively slowly varying signal, it is easy to separate the 4 to 20 mA signal from the digital signal using filters. The Bell 202 standard uses continuous-phase frequency shift keying between two frequencies at up to 1200 shifts/s to modulate digital ones and zeros onto the 4 to 20 mA current loop. This method allows for bidirectional, full duplex communication between the two stations, on top of the 4 to 20 mA signal. It is also possible to configure HART communications on a network that is not carrying a 4 to 20 mA signal, in which case up to 15 devices can be connected together on the network. HART was developed by Fisher-Rosemount Corporation, and has been trans-

²HART is a trademark of the HART Communications Foundation.

ferred to an independent foundation for management [13]. Because HART is compatible with U.S. telephone systems, it can theoretically be run over the telephone line and is therefore capable of running over arbitrarily long distances.

Profibus

Profibus (PROcess FieLd BUS) is one of three networks standardized by a European standard [14]. Profibus is under the control of a global organization, PNO [15]. Profibus is an umbrella network standard which encompasses three subnetworks within the Profibus family. Profibus-DP (Distributed Periphery) is the variant which is designed specifically for communication with field devices (sensors and actuators) at the device I/O level. Profibus-PA (Process Automation) is a variant which has more capabilities designed to support the needs of device-level networking for process industries, such as oil refining. One of the capabilities of Profibus-PA is its ability to be installed in an intrinsically safe way, thus providing a higher degree of safety in environments which may be explosive or otherwise hazardous. Profibus-PA typically uses a special physical layer specification standardized under IEC 1158-2, which is used by several network systems for process automation applications. IEC 1158-2 specifies a two-wire twisted pair implementation carrying both power and data on the same two wires at 31.25 kbit/s. Profibus-FMS (Fieldbus Messaging Specification) represents the highest level implementation, which is used to link together controllers (not field or I/O devices) in a factory.

Profibus-DP systems are typically master–slave systems, where usually a single network master (the host controller) communicates with a number of slave devices (remote I/O blocks and other I/O devices). The protocol provides for cyclic exchange of I/O information as well as on-demand exchange of other types of information. Profibus-DP can be implemented on several different physical layers, including RS-485 and fiber optics, at various bit rates up to 12 Mbit/s. Profibus messages include a CRC for error detection.

Foundation Fieldbus

Foundation Fieldbus (FF) is a networking standard which has grown out of an effort within industry standards organizations, especially ISA-SP50 [16], and IEC SC65C/WG6 [17], to provide a replacement for the 4 to 20 mA analog sensor communication standard. FF provides two basic levels of networking: H1 and H2. H1 is a lower-speed system that can provide intrinsically safe (IS) operation and uses a single twisted pair to deliver both power and data communications to field devices, according to IEC 1158-2. Running at a bit rate of 31.25 kbit/s, H1 is very similar to Profibus-PA, when run on the IEC 1158-2 physical layer standard. The H1 system is designed to be able to connect hierarchically “upward” to an H2 system, which acts as the host. FF H2 can be run at either 1 or 2.5 Mbit/s on twisted pair wires, and also provides an IS option at the 1 Mbit/s rate. The H2 system can act as a network backbone in a factory environment, carrying data among various H1 systems.

WorldFIP

WorldFIP [18] is another technology of the three that were standardized in the European standard EN 50 170, running on the IEC 1158-2 physical layer. Many of the proponents of WorldFIP have embraced FF, and contributed to the development of that standard. WorldFIP is a member of the FF, and FF has incorporated many of the capabilities of WorldFIP as a result. When run on the IEC 1158-2 physical layer, WorldFIP has similar capabilities to FF.

LonWorks³

LonWorks® is a networking technology developed and controlled by the Echelon Corporation [19]. LonWorks is designed to be a general-purpose networking technology suitable for a variety of industries.

³LonWorks, LonTalk, and Neuron are trademarks of the Echelon Corporation.

LonWorks has been applied extensively in the building automation and control industry, as well as a variety of other industries. The core LonWorks technology for devices is contained in special integrated circuits — called Neuron® chips — which combine several microprocessors to manage the network, communications, and provide a general-purpose control environment. These chips are available from Motorola, Inc., and the Toshiba Corporation, which are licensees of the LonWorks technology. Echelon has also announced the possibility to license the LonTalk® protocol to other manufacturers for implementation in other microprocessors. LonWorks networks can be implemented on a variety of physical layers, including twisted pair at several bit rates and wireless options at 4800 bit/s, but the most common is a differential twisted pair system running at 78 kbit/s. Most of the networking details (the LonTalk protocol) are hidden from the user, and are encapsulated as functions within the general-purpose control environment. The user programs (using a language like the C programming language) the Neuron chip for each station to behave in a certain way and communicate various data items to other stations. Then, specialized tools are used to tie all of the stations together (handling addressing and other network details) to yield a functioning network. The system combines flexibility with a certain amount of ease of implementation, and can easily be applied to a variety of applications.

88.4 Applying Network Communications

Shielding

Many communication networks require shielding of the media (the cable). Shielding constitutes an electric conductor which completely encases the communication media (e.g., twisted pair) to provide protection against EMI. Shielding provides an electric conductive barrier to attenuate electromagnetic waves external to the shield, and provides a conduction path by which induced currents can be circulated and returned to the source, typically via a ground reference connection. Shields in communication systems are often grounded at only a single point. This single point of ground prevents the shield from participating in a “ground loop,” which is an alternative path for current to flow between two points of potential difference connected to a common ground. Ground loops can lead to noise problems, and can be destructive if the stray currents are large enough, since a shield ground is usually not constructed to carry heavy currents.

Media

The most common media types for network systems fall into three categories: electric, optical, and electromagnetic. Electric media are based on conductors (e.g., copper wire), whereas optical media are based on optical waveguides, or fiber optics. Electromagnetic media consists of free space, or general electromagnetic wave-permeable materials, and are referred to as wireless systems. Within the category of electric media are a large variety of conductor configurations. The most common are unshielded pair, unshielded twisted pair (UTP), shielded twisted pair (STP), and coaxial (COAX). These conductor configurations have various properties which are significant for the transmission of electric signals, as well as varying degrees of immunity to EMI. As a rule of thumb, the quality of the transmission line characteristics (signal transmission and immunity to EMI) improves in the order listed. Twisted pair systems are generally easier to install, whereas coaxial and fiber-optic systems generally require more specialized tools and termination methods. Of course, wireless systems are easy to install, but attention must still be paid to the media. The characteristics of the free space such as distance and amount of EMI present must be considered for reliable operation of the network.

Bit Rate

Some networks provide only one choice of bit rate, whereas others provide user-selectable options for bit rate. Bit-rate options may be dependent on the type of media that is installed. As a rule of thumb,

Star

Daisy-Chain

Trunkline-Branchline

Ring

FIGURE 88.5 Some examples of the many possible network topologies using four stations.

the bit rate chosen should be the lowest possible bit rate that still supports the application requirements for speed of data transfer and overall bandwidth. This generally results in more reliable operation, and generally gives the network more immunity to minor degradations, specification violations, and EMI.

Topologies

There are a variety of network topologies that are commonly used. Topology refers to the physical arrangement and interconnection of stations by the media. Some networks can be run using several different topologies; some can only be run with a certain topology (e.g., Interbus-S requires a ring topology). The most common topologies are daisychain, trunkline–branchline, ring, and star. Variations on these exist, and networks that incorporate or can be run on highly varied topologies are sometimes called free-form, tree, or free topology networks. [Figure 88.5](#) depicts graphically several different types of topologies. In some cases, networks require certain topologies. Deviating from these can cause degradation in network behavior (e.g., corruption of messages) or network failure.

Configuration

Most networks involve some sort of configuration. Configuration is the process of connecting stations together and assigning certain programmable parameters to each station required for proper operation of the network. The most common configurable parameter in many networks is the station address. Some networks may require other parameters to be preset, such as the communication speed, or bit rate. Some networks have the capability to autoconfigure, which means to assign parameters automatically to stations as part of the network start-up process, without explicit user intervention (e.g., Interbus-S). Many networks define various tools, which may be computer based, to assign parameters to each station in order to configure the network. In other cases, the stations may incorporate switches or other manual means to configure the necessary parameters for network operation.

88.5 Advanced Topics

Wireless Technologies

The need for networking is present even in environments where an electrical or optical cable cannot be easily distributed. This may be due to various limitations, such as difficulty in running a new cable from one building to another, or connecting to sensors in motion or on vehicles. There are two general

categories of wireless communications, based on electromagnetic frequency spectra. Various wireless technologies employ the infrared spectrum. These technologies generally have transmission limited to applications that have a direct line of sight between stations. Also, the distances are generally limited to 100 m or less. Because of these limitations, there are generally no legal restrictions in employing these frequency spectra, and infrared transceivers are now becoming available from a variety of manufacturers.

The other general category of wireless communications is based on radio frequency (RF) communications. In most countries, use of these spectra is tightly controlled by governmental agencies. As a result, employing wireless networking in most of these frequency ranges requires special licensing. However, a number of frequency ranges are reserved for low-power public communications. Within these frequency ranges, devices are allowed to communicate in an unlicensed fashion as long as they transmit according to certain rules about transmitted power output. RF-based wireless systems are generally not limited to line-of-sight applications, and can be designed to cover greater distances than infrared-based systems.

Wireless technologies can be viewed as simply another choice for the physical layer media, i.e., free space. As such, it is possible to consider, in some cases, a wireless media for implementation of a variety of protocols. For example, both CAN and LonWorks systems could be candidates for wireless networking.

Fiber Optics

Another physical layer media choice is fiber-optic media. Fiber-optic media employs pulses of light delivered along a tubular waveguide (glass or plastic fiber) to transmit information from one station to another. Fiber optics enjoy some benefits over traditional copper wiring. First, attenuation of light within fiber optics is generally about an order of magnitude less than attenuation of an electric signal within a copper wire. Second, fiber-optic transmission systems can be modulated (or pulsed) at much higher frequencies, yielding greater potential bandwidths and bit rates than copper media. Finally, fiber-optic systems are generally immune to the traditional sources of EMI that can cause trouble for copper media systems. There are also limitations in present implementations of fiber-optic systems. One of the limitations is that special tools and termination techniques must be used to connect a fiber-optic cable to a sensor or field device. Second, fiber-optic “taps” are not easily created. Therefore, most fiber-optic systems are implemented in a point-to-point fashion. When multiple devices are involved in a network, each device usually acts as an optical repeater, with a fiber-optic input and a fiber-optic output port.

Network Design Considerations

Designing a network communication system from the ground up can be a lengthy undertaking, and should not be considered unless a careful review of available technologies has yielded no solutions to the particular requirements of the application. The designers must take into account a number of fundamental questions to shape the capability of the network. One topic mentioned frequently in the area of networking for control applications is the subject of determinism. This refers to the ability of the network to behave in a predictable fashion under any given set of stimuli, or external conditions. Many networks do not exhibit this characteristic. Another question to be resolved is the subject of priority, and media access. The designers must determine the conditions under which any particular station is allowed to transmit, and if multiple stations are attempting to transmit, how it will be determined which station will be given priority to transmit first. Media access methods often impact the ability of a network to behave in a deterministic fashion.

Integrating Sensors with Communications — IEEE P1451

A recent interesting development in the area of sensor networks is an effort being sponsored by the IEEE [20] out of its TC-9 committee, called IEEE P1451. This activity is working toward the development of a standard to define sensor (or transducer) interfaces to networks generically. The first part of the proposed standard, IEEE P1451.1, includes definitions for the interface between the device and the network (refer to [Figure 88.1](#)). The second part, IEEE P1451.2, includes definitions for the interface

between the transducer (or sensor) and the network interface block within the device. P1451.2 includes a definition for a transducer electronic data sheet, or TEDS, which defines a summary set of information pertinent to the sensor, allowing for standardized exchange of data on the network. The proposed standard has the potential benefits to make it easier to connect a sensor to a variety of networks, and to allow similar sensors from different manufacturers to be handled in a similar fashion on the network.

89.1 Grounding and Shielding

Daryl Gerke and William Kimmel

EMC (electromagnetic compatibility) is crucial to successful operation of industrial systems. Due to the increased electronic content of most industrial controls, electromagnetic interference (**EMI**) problems have increased dramatically in recent years. Two keys to EMC success are grounding and shielding. This section will briefly discuss how to implement these two crucial EMC strategies. It will also provide a general introduction to EMI problems in today's industrial electronic systems. The primary emphasis will be on practical insights and ideas gained in dealing with numerous industrial control problems.

Understanding EMI Problems

Here are three general observations on dealing with EMI problems in industrial electronics.

First, the industrial environment is harsh. The primary EMI threats are power disturbances, **RFI** (radio frequency interference), and **ESD** (electrostatic discharge). In addition, analog sensor circuits are often plagued with 50/60 Hz "ground loop" problems. Industrial electronics need more EMC care than most commercial electronics, and even more than many military systems.

Second, electronics often play a secondary role in electronics systems. Unlike a computer system, where electronics is the core technology, industrial electronics are often used to support another technology, such as chemical, mechanical, or process functions. This leads to EMC challenges when integrating the electronics to nonelectronic technologies.

Third, EMC rules and regulations are finally catching up to industrial electronics. For many years, industrial electronics were exempt from mandatory EMC rules, so unless there was an actual problem, EMC was often ignored. With the EMC directives of the European Union (**EU**) now in force, industrial electronics are no longer exempt.

Three Types of Problems

There are three aspects of the EMC problem: *emissions*, *susceptibility* (also known as immunity), and *self-compatibility*. **Emissions** originate within the equipment, and may upset other nearby equipment. On

the other hand, external energy may upset equipment, leading to **susceptibility** (or a lack of immunity). Finally, energy internal to the system may interfere with other internal circuits, resulting in a self-compatibility problem.

Problems with both emissions and susceptibility have led to EMC regulations. Two of the best known are the **FCC** (Federal Communications Commission) regulations for emissions in the U.S., and the EU regulations for both emissions and immunity in Europe. Industrial controls have always been exempt from the FCC regulations, but they are not exempt from the EU regulations which became mandatory in January 1996.

Four Major EMC Threats

Most industrial EMC problems fall into one of four key areas: *emissions*, *power disturbances*, *radio frequency interference*, and *electrostatic discharge*. In the past, industrial systems were usually only concerned with power disturbances. Today, all four threats must be considered.

Emissions.

Emissions refer to electric energy originating within equipment that can interfere with other equipment. The prime concern of this threat is jamming nearby television receivers, which is the basis for the now mandatory EU emissions regulations. Emissions problems between industrial electronic systems, however, are rare. While it is possible to interfere with any other nearby equipment, most industrial electronics generate only minute amounts of **conducted** and **radiated** interference, well below upset thresholds for digital or analog circuits.

Emissions are best addressed at the equipment design stage. Strategies include printed circuit board design techniques, high-frequency filtering on power and signal interfaces, shielded cables, and enclosure shielding. Fixes in the field are usually limited to shielded cables or enclosures, add-on filters, and ferrite clamps on cables.

Power Disturbances.

Power disturbances can take many forms, from short transients to long sags, surges, or complete power outages. The three most serious power threats to industrial controls are transients, voltage sags, and power outages. Stray 50/60 Hz currents can cause also problems with sensitive analog circuits, particularly due to ground loops (to be discussed later). Other power disturbances, like frequency or waveform variations, often have little effect on electronic systems.

Power disturbances are very common in industrial environments. As a result, most industrial systems are pretty robust against this threat, at least at low frequencies. High-frequency threats, such as fast transients or RF on the power lines, can still cause problems. The EU tests simulate these threats with the **EFT** (electrical fast transient) and injected RF tests.

Most power disturbances are caused by nearby equipment, rather than external sources. (One critical exception is lightning, which can result in some nasty voltage and current surges). Power disturbances solutions include grounding, power filters, transient protectors, and in extreme cases, uninterruptible power systems (UPS).

Radio Frequency Interference.

RFI deals with threats in the RF range. RFI is quite common in industrial environments, and will likely get worse with the proliferation of handheld radios and cellular telephones. It is expected that that wireless LANs (local area networks) will also provide some interesting EMI challenges. There have been cases where handheld radios were banned from use due to repeated EMI problems with industrial electronics.

It turns out that the nearby handheld radio is a much bigger threat than a large commercial broadcast station several kilometers away. A key metric is electric field intensity, measured in “volts/meter.” This is a function of both transmitter power, and distance from the antenna, and can be quickly predicted by the formula:

$$E(\text{V/m}) = 5.5\sqrt{\text{PA}}/d$$

where P = transmitter power in watts, A = antenna gain, and d = distance from the antenna in meters. For example, the electric field from a 1-W radio with a zero gain antenna at 1 m is about 5 V/m, while the electric field from a 10,000 W broadcast station at 1 km is about 0.5 V/m. Since unprotected equipment can fail in the 0.1 to 1 V/m range, problems can and do occur. The EU “heavy industrial” limits of 10 V/m are clearly aimed at protecting against the nearby handheld radio.

Solutions to RFI problems include high-frequency filtering on power and signal cables, shielded cables, and shielded enclosures. Analog circuits are particularly vulnerable to RFI, so they often need extra protection. Do not overlook banning radio transmitters in the immediate vicinity. Often, maintaining a 3 to 10 m distance is enough to solve the problem.

Electrostatic Discharge.

ESD refers to the sudden discharge that can occur after a gradual buildup of electric charge. ESD is most commonly associated with humans (touching controls or keyboards), but ESD can also be caused by internal arcing due to the movement of paper, plastic, etc. Internal ESD problems are increasing in industrial systems.

Although the static buildup can take a long time (seconds or even minutes), the discharge is almost instantaneous (nanoseconds or less). Furthermore, it is the sudden current, not the voltage, that is the culprit. The effect is a bit like having a dam burst — the ESD current is like water running down a mountain, destroying anything in its path. Fortunately, the current surge does not last too long, so the energy levels are not high. They are high enough, however, to damage or upset electronic devices.

The extremely fast discharge results in high frequencies well into the UHF range. At 1 ns, the transient bandwidth is over 300 MHz. As a result, it does not take a “direct ESD hit” to cause a problem. ESD upsets 5 to 10 m away are not uncommon, due to the intense electromagnetic fields associated with an ESD event. These problems are particularly insidious, since the ESD event may be occurring on a different piece of equipment.

Solutions to ESD problems include transient protection, high-frequency filtering, cable shielding, and enclosure shielding. Grounding is a very important factor in ESD protection, but it must be designed for high frequencies. Since many times ESD causes “reset” problems, extra attention to microprocessor reset circuits is beneficial.

Sources, Paths, and Receptors

A common EMI problem is gathering and organizing data. This is particularly important when troubleshooting EMI in the field. The “source–path–receptor” model is popular. Simply stated, three elements are necessary for any EMI problem:

1. There must be a source of energy;
2. There must be a receptor that is upset by that energy;
3. There must be a coupling path between the source and receptor.

All three elements must exist at the same time, and if any one is missing, there is no EMI problem. Sometimes one can identify all three, and, other times, one can only guess. While this may seem simple, it is a useful tool to organize EMI information.

Figure 89.1 illustrates this model, giving typical sources, paths, and receptors. Several possible sources have been discussed: emissions from digital circuits, ESD, RFI from communications transmitters, and power disturbances (including lightning). Several different receptors have also been suggested: communications receivers, analog electronics, and digital electronics. Note the two types of paths: radiated and conducted. In both cases, the object is to block unwanted energy from reaching a receptor, which is done with shielding (for the radiated path) and filtering (for the conducted path).

Grounding

Grounding is probably the most important, yet least understood, aspect of EMI control. Every circuit is connected to some sort of “ground,” so every circuit is affected by EMI grounding issues.

Any interference problem can be broken down into

- the SOURCE of interference
- the RECEPTOR of interference
- the PATH coupling the source to the receptor

Sources	Paths	Receptors

TABLE 89.1 A Ground May Work Over Wide Frequency Ranges

Type	Frequency	Typical Current Levels	Typical Duration
Power	50/60 Hz	10–1 000 A	Seconds or minutes
Lightning	300 kHz	100 000 A	Tens of milliseconds
ESD	300 MHz	10–50 A	Tens of nanoseconds
EMI	dc–Daylight	μA–A	Nanoseconds to years

What Is a Ground?

A major problem with the subject of grounding is the ambiguity of the term. Our favorite definition is one popular in the EMC community, which says that a *ground is simply a return path for current flow*. These currents can be intended, or unintended. The unintended currents are often referred to as “sneak grounds,” and can cause many kinds of EMI problems. Finally, a physical connection is not even necessary at higher frequencies, where parasitic capacitance or inductance may form part of a ground path.

Different Types of Grounds

Grounds are used for many reasons, including power, safety, lightning, EMI, and ESD. Although they may share common functions, they may vary widely when it comes to frequencies and current amplitudes. Recognizing these key differences is key to understanding grounding issues.

Table 89.1 shows some frequency and amplitude requirements of several different types of grounds. Note that power and safety grounds must handle high currents, but only at low frequencies. Grounds for EMI and ESD, on the other hand, must often handle high frequencies at relatively low current levels. Lightning grounds must handle extremely high currents, but at moderate frequencies.

The frequency of transient events is calculated using the formula $f = 1/(\pi t_r)$, where f is the equivalent frequency, and t_r is the transient rise/fall time. This relationship can be derived using Fourier analysis. For example, ESD has an equivalent frequency of about 300 MHz based on a typical 1 ns rise time, and lightning has an equivalent frequency of about 300 kHz based on a 1 μs rise time.

Note that of all these types of grounds, only one actually needs an Earth connection — lightning. Other grounds may be connected to Earth by convention or for other safety reasons. For example, power neutrals are connected to Earth in many parts of the world to help provide lightning protection. On the other hand, in many other parts of the world, the power systems do not have Earth connections. When dealing with power grounding, the local safety codes will determine the proper Earth grounding methods.

TABLE 89.2 Impedance Parameters for 10-cm-Length Wires

Gage	Ω/m	$\mu H/m$	$Z @ 10 \text{ kHz}$	$Z @ 1 \text{ MHz}$	$Z @ 100 \text{ MHz}$

1 MHz	335	369	369
10 MHz	1.16 m Ω	1.16 m Ω	1.16 m Ω
100 MHz	3.69	3.69	3.69
1000 MHz	11.6	11.6	11.6

Ground Impedances

A good ground must have a low enough impedance to minimize voltage drop in the ground system, and must provide the preferred path for current flow. The key to success is maintaining that low impedance over the entire frequency range of interest. We cannot overemphasize this point. Most EMI grounding problems are due to using the wrong approach for a given range.

The impedance of a ground conductor consists of both resistance and inductance ($Z = R + j\omega L$). For frequencies from dc through about 10 kHz, the resistance is the major factor, so heavy-gage wires are often used for low-frequency ground conductors. As the frequency increases, however, the inductance becomes the limiting factor for impedance. As a rule of thumb, the inductance for round wires is in the range of 10 nH/cm.

Table 89.2 gives the resistance, inductance, and inductive reactance for a typical wire sizes used in instrumentation power and signal circuits. Its apparent that at power and audio frequencies (dc to 10 kHz), resistance is the dominant factor in ground impedance. Thus, at low frequencies, look for ways to reduce resistance, typically by using larger wires. At frequencies above the audio range (>10 kHz), inductance becomes the dominant factor in ground impedance. Thus, at higher frequencies, look for ways to reduce the inductance of the ground path. This is accomplished by using ground planes, grids, and straps to lower the inductance.

Table 89.3 gives the impedances for solid ground planes at various frequencies. In this case, the impedances are in “ohms-per-square,” which is a measure of impedance across a diagonal surface. By comparing this with Table 89.2, one can see that at high frequencies (such as 100 MHz) the ground plane impedance may be several orders of magnitude below the impedance of a wire. Furthermore, at high frequencies the thickness is not a factor, since the impedance is limited by the skin effect.

FIGURE 89.2 Typical industrial grounding situation, which also illustrates a ground loop.

Ground Topologies

Now that we have looked at ground impedance vs. frequency, we are ready to look at ground topologies vs. frequency. The impedance limitations yield two different grounding approaches, dependent on frequency. For low-frequency problems (dc to 10 kHz), single-point grounds are preferred, while at high frequencies (above 10 kHz), multipoint grounds with planes or grids become the preferred approach.

This dichotomy often causes confusion with industrial controls, but this can be minimized by determining the frequency of the EMI threat and then selecting the appropriate grounding approach. In many cases, both approaches may be necessary at the same time, leading to “hybrid” grounds, which use capacitors and inductors to alter the ground topology with frequency.

Single-Point Grounds.

At low frequencies, one can usually steer current via wires. Since the inductance is low, the limiting factor is the wire resistance itself. Furthermore, capacitive coupling from the ground wires to adjacent wires or surfaces is small, so virtually all the current follows the wiring path.

Figure 89.2 shows a typical industrial grounding scheme. Note what happens if the system is grounded at both ends. Any common noise current in the common ground path is now coupled into the circuit via the “common ground impedance.” This results in the dreaded “ground loop,” which will be discussed shortly. A single-point ground eliminates the ground loop, since there is no common impedance across which a common-mode voltage can be generated. Thus, single-point grounding is a very practical way to limit “ground noise” problems with the threat of low-frequency ground currents. This is very typical of 50/60 Hz currents getting into sensitive analog instrumentation circuits.

Multipoint Grounds.

Unfortunately, as the frequency increases, the inductive reactance of the wires increases. At the same time, parasitic capacitive reactance to adjacent wires or surfaces decreases, and soon it is no longer possible to maintain a true single-point ground, even if the system is wired that way. The only option left is to lower the ground path impedance, and that is accomplished with planes or grids. Furthermore, a single-point connections to a grid or plane are usually not adequate because of transmission line effects, so multipoint grounds (combined with planes/grids) become the preferred approach above 10 kHz.

Ground grids have been used for years in computer facilities, and are seeing increasing use in industrial facilities. The recommended spacing for grids is no more than $1/20$ of a wavelength at the highest frequency of concern. Computer room grids are often spaced about 0.7 m (about 2 ft), which meets this criteria from dc to about 25 MHz. This is very beneficial in addressing ground noise due to lightning and other power transients, which are usually in the 1 MHz range and below. But a 0.7-m grid does not help with VHF/UHF radio problems or ESD. In those cases, solid surfaces may be necessary.

Ground Loops.

Ground loops are a serious problem for sensitive analog circuits facing low-frequency threats. At high frequencies, ground loops generally do not pose serious threats if proper high-frequency precautions are taken when designing the ground system.

A ground loop exists whenever multiple ground paths exist. Unwanted currents can take unwanted paths, resulting in unwanted noise voltages at unwanted places. The problem is particularly acute with sensitive analog systems, where even a few microvolts can jam intended signals. A classic example is 60 Hz ground currents causing hum in an audio system.

Figure 89.2 shows a typical ground loop problem. Note that there must be the three conditions of any EMI problem: a source, a path, and a victim. In this case, the source can be circulating power currents, the path the common ground impedance, and the victim is often the sensitive analog circuit. With many systems problems, one cannot do anything about either the source or victim, so the solution is with the ground path. As we have already seen, single-point grounding is effective at low frequencies, and ground planes/grids are effective at higher frequencies.

If one cannot change the ground paths, one can still attack the ground loop by “breaking” it in other places. For example, transformers or optical isolators (or even fiber optics) can be used in cable connections, which will block common mode noise currents while passing intended differential mode signals. Balanced input/output (I/O) circuits can be used to “cancel” the noise through common-mode rejection. All of these are most effective at 50/60 Hz, and become less effective at higher frequencies due to parasitic capacitance.

Grounding Guidelines

By now it should be apparent that there is no magic solution for grounding. Rather, different methods and approaches are necessary for different circuits and operating conditions. Two key parameters are the threat frequency (low vs. high), and the circuit operating levels. Here are some guidelines, but keep in mind that even these may need to be modified for a particular situation.

Analog Circuits.

Since most analog circuits operate at low frequencies and are subject to low-frequency threats, single-point grounds are preferred. Typical threats are 50/60 Hz power return currents, stray switching power supply currents, and perhaps digital circuit return currents (if separate analog and digital power and grounds are not provided). Low-level analog circuits are the most vulnerable, since the signal levels are small.

Keep in mind that high-frequency threats (such as a VHF radio) to low-frequency circuits may require high-frequency grounding solutions, such as multipoint grounds. Often, this can be accomplished by using small high-frequency capacitors (1000 pF typical) which appear as a short at 100 MHz, yet still appear as a high impedance at 50/60 Hz.

Digital Circuits.

Most digital circuits today operate at relatively high frequencies, so multipoint grounds and ground planes and grids are preferred. The connections between the circuits and their grounds need to be short, fat, and direct to minimize inductance.

Digital circuits, particularly I/O circuits, are vulnerable to external high-frequency threats like RF and ESD. They are also a key source of high-frequency emissions and internal problems like cross talk. For digital circuits, multilayer boards with internal ground planes are preferred. These ground planes typically are connected to a metallic enclosure through multiple low-inductance connections.

Pay particular attention to where digital and analog circuits meet. A single-point connection is usually preferred to minimize ground loops, but installing a small resistor (1 to 10 Ω typical) or inductor (1 to 100 μ H typical) at that point is often helpful in providing additional isolation. One may need to experiment with this to determine the optimum solutions.

Power Safety Grounding.

Entire books have been written about this subject, and rightly so; this is an extremely important safety issue. The key concern here is human safety and prevention of electric shock. In most parts of the world, exposed metal on line-powered equipment must be bonded to a safety grounding conductor. Furthermore, the electric wiring codes (such as the National Electrical Code in the U.S.) give very specific guidelines on how power grounding must be accomplished.

These guidelines must be followed when wiring any industrial control system, and must never be compromised by “isolated” power grounds or other similar foolishness. *Finally, if there is ever a conflict between EMI and safety grounding, the safety issues must always prevail!*

Shielding

Many systems today require at least some **shielding** for proper operation or to meet radiated emission or immunity requirements. Many engineers consider shielding purely a mechanical issue, but nothing could be farther from the truth. EMI shielding needs both an electrical and a mechanical understanding of key issues to assure success.

Two of these key issues are selecting the right material and maintaining the shielding integrity over the desired frequency range. While most people worry more about the selection, shield integrity is usually much more important. We will soon see that even very thin metallic coatings can be effective shields, yet even very small holes or penetrations can completely destroy a shield. Like grounding, shielding cannot be left to chance, and must be properly designed and implemented.

How Shielding Works

EMI shielding involves two independent mechanisms: *reflection* and *absorption*. In reflection, an electromagnetic wave bounces off the surface, just like light off a mirror. In absorption, the electromagnetic wave penetrates the material and is absorbed as it passes through, much like heat loss through an insulating wall.

Shielding effectiveness is usually expressed as follows:

$$SE \text{ (dB)} = R \text{ (dB)} + A \text{ (dB)}$$

where SE is the total shielding effectiveness in dB, and *R* and *A* are the reflection and absorption losses expressed in dB. Reflection is the primary mechanism for high-frequency shielding (emissions, RFI, ESD), while absorption is the key mechanism for low-frequency magnetic field shielding. The actual formulas for calculating reflection and absorption losses are a bit complex, and beyond the scope of this chapter, but several sources are included in the further information section.

Three Types of Fields

It is customary when dealing with shielding to use three types of “fields” to explain shielding. These three fields account for differences in shielding performance due to differences in frequency and circuit impedance levels. They also explain why the same shield can behave differently for different energy sources. These are plane waves, magnetic fields, and electric fields. [Figure 89.3](#) shows typical shielding curves for copper, with references to each type of field.

Plane Wave Fields.

If one is located greater than about $\frac{1}{6}$ wavelength from a point source, the wave impedance (ratio of electric field intensity to magnetic field intensity) is a constant 377Ω in free space. This field is known as the “far field” or “radiation field,” since real energy predominates here and propagates as a “plane wave.” Since reflection losses are due to a mismatch between the wave impedance (377Ω) and a metallic shield surface impedance (typically milliohms or less), shielding effectiveness is usually very high for plane wave sources.

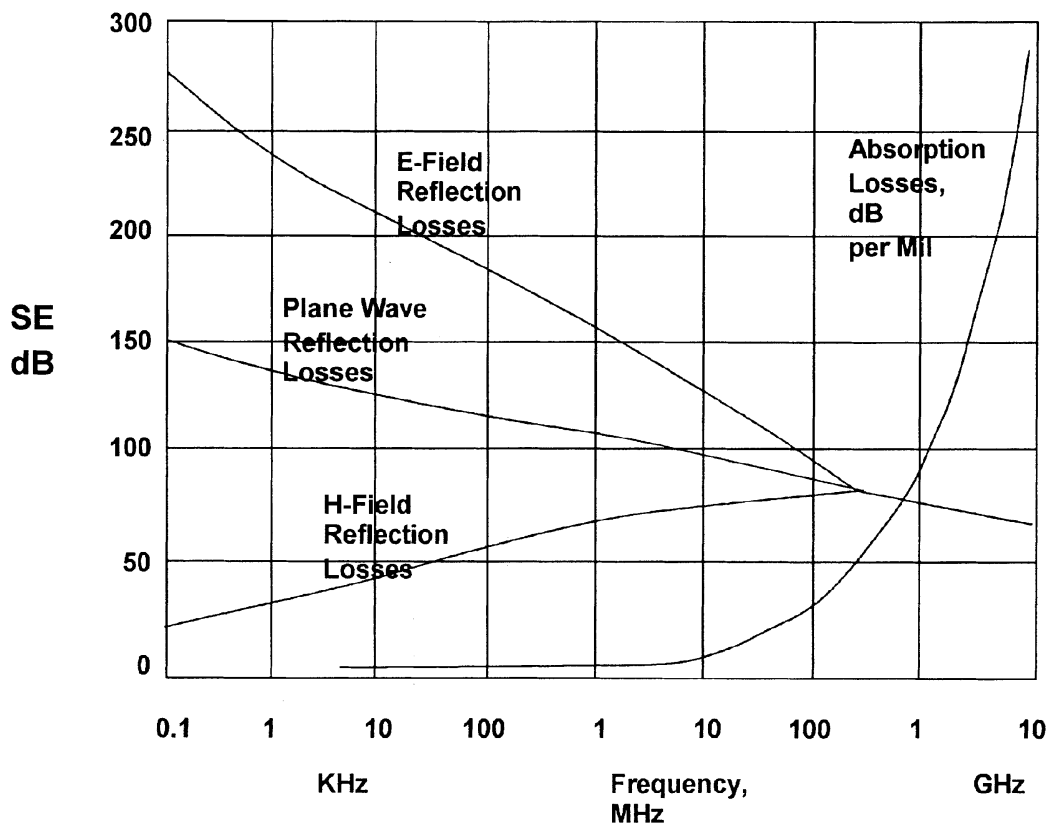

FIGURE 89.3 Typical shielding effectiveness curves for copper. Note two mechanisms (reflection and absorption) and three types of fields (electric, magnetic, and plane wave). Shielding for aluminum is almost the same as for copper.

At frequencies 30 MHz and above, once one is more than about 1 m away, one is in the plane wave region. Thus, even very thin shields work well for emissions, ESD, and RFI problems, with reflection as the prime shielding mechanism.

Electric and Magnetic Fields.

If one is located less than about $\frac{1}{6}$ wavelength from the source, then the wave impedance is dependent on the circuit impedance. This region is known as the “near field,” since reactive energy predominates here. This region is further divided into “electric” and “magnetic” fields, both dependent on source circuit impedance. For high-impedance sources (electric fields), the reflection losses are still high, but for low-impedance sources (magnetic fields), the impedance can be quite low. In the latter case, the reflection losses can become minimal.

For power line frequencies, the near field almost always predominates. As a result, materials like aluminum or copper have no reflection losses and are virtually transparent to power line magnetic fields. (As a rule, remember that aluminum foil is transparent to 60 Hz magnetic fields.) To solve this problem, permeable materials are needed to boost the electric thickness for a given physical thickness. Steel or high-permeability mu-metals are usually used to absorb (not reflect) the magnetic fields. Even so, it can still be very difficult to shield for low-frequency magnetic fields.

Why Shielding Fails

While material selection is important, other factors must also be considered. For low-frequency/low-impedance threats (power supply or power line magnetic fields), steel or other high-permeability materials are needed. For high-frequency threats, however, even very thin materials like conductive paints

FIGURE 89.4 Two shielding failure modes, due to slots/seams and due to penetration of conductors. In both cases, the critical dimension is $1/20$ wavelength for the highest frequency of concern.

provide high levels of shielding. Two problems at high frequencies, however, are shield openings and shield penetrations. Lack of attention to these areas can result in a loss of virtually all shielding effectiveness at high frequencies. Figure 89.4 illustrates these two high-frequency failure modes.

Intuition suggests that any opening in a shield can leak, much like an open window. The surprise is that for electromagnetic leakage it is not the area that is critical, but the longest dimension. For example, a 100×1 mm opening is about ten times more leaky than a 10×10 mm square hole. And that slot may not even be obvious. It could be a painted seam or a poorly fitting panel or door.

Slots act like small antennas. Because they are antennas, the longer they are, the better they radiate. While a half wavelength is very efficient, as a rule of thumb, we like to limit slots to $1/20$ wavelength or less at the highest frequency of concern. For 100 MHz, this is 15 cm (about 6 in.); at 300 MHz (ESD frequencies), this drops to 5 cm (about 2 in.), and at 1000 MHz, it is only 1.5 cm ($2/3$ in.). And even these dimensions may be too large, as they only assure 20 dB (tenfold) of shielding through the slot. Clearly, even small slots and other openings mean big shielding problems at high frequencies.

The other way to destroy a high-frequency shield is to pass unterminated metal through a shield. Hole dimensions do not matter here, and even a pinhole with an insulated wire passing through can carry large amounts across the shielding barrier. The dimension that does matter is how far the penetration extends on either side of the shield. Once again, the critical distance is $1/20$ wavelength or more.

Shielding Guidelines

Now that we have looked at how shielding works (and fails), let us look at how to design good electromagnetic shields. Most of our focus will be on RF shielding in the 30 to 1000 MHz range, necessary for emissions, ESD, and RFI.

Material Selection.

We have already seen that for low-frequency magnetic interference problems, ferrous material like steel or mu-metals are necessary. Most instrumentation problems are either high impedance or high frequency in nature, so most of the time, thin conductive materials will work fine. For high frequencies, however, attention must be given to slots and penetrations.

Many enclosures today are made of plastic. For high-frequency shielding, conductive coatings also work quite well. Popular surface treatments include conductive paints, vacuum deposition, electroless plating, and even metal fabrics. Conductive plastics are also available, but they generally do not perform nearly as well as surface treatments for high frequencies.

Gasketing and Screening.

Large openings, such as ventilation ports or display areas, can be sealed with screening material. Seams or slots can be filled with conductive gaskets. In both cases, the secret is to provide complete and continuous metal-to-metal contact at all junctions. For high-frequency shielding, the connections must be almost watertight. Anything less is asking for problems.

For screening material, the smaller the openings, the higher the shielding. Window screen spacing is almost as effective as solid materials from dc to 1000 MHz, and even 5-mm (about $1/4$ in.) openings are often acceptable at 1000 MHz. In any case, do not exceed $1/20$ wavelength at the highest frequency of concern.

Cable Terminations and Filters.

Poor termination of shielded cables can cause big problems at high frequencies. If a shielded cable is not terminated directly at the shielding barrier, a lot of energy leaks, degrading both the cable and the enclosure shield. Pigtail connections, popular for terminating low-frequency cable shields, are particularly bothersome at high frequencies. In fact, this is a leading cause of EMI failures for RFI, emissions, and ESD. As a rule of thumb, pigtail connections should not be used on cable shields at frequencies above about 1 MHz.

Unshielded cables can also cause problems at high frequencies. In those cases, high-frequency filtering is needed directly at the interface to assure that the shield is not degraded at high frequencies. Common solutions are EMI filters on power and signal lines, or ferrite beads on the lines or cables. These must be installed as close to the shield penetration as possible. The best situation is to mount the filter directly in the shield itself, although this is not always necessary for moderate problems.

Internal Shields.

Finally, do not overlook using internal shield on critical circuits. Radio and television designers have been doing this for years, using selective shields on oscillators, power amplifiers, and the like. A classic example of this approach is the TV tuner, the most sensitive part of a television receiver. It is an inexpensive, yet highly effective shielding strategy.

Defining Terms

Conducted: Energy or interference that is propagated by a conductor, such as power, grounding, or signal interface wiring.

EFT: Electrical fast transient; a high-frequency burst of energy on power wiring.

EMC: Electromagnetic compatibility; the condition wherein electric and electronic equipment operate successfully in close proximity.

EMI: Electromagnetic interference; unwanted electric energy that may impair the function of electronic equipment.

Emissions: Electric energy emanating from an electronic source.

ESD: Electrostatic discharge; the rapid discharge that often follows a buildup of static charge.

EU: European union; formerly called the European Community.

FCC: Federal Communications Commission (U.S. government).

Ground: A return path for current.

Radiated: Energy or interference that is propagated by electromagnetic radiation through space.

RFI: Radio frequency interference; an older term for EMI, now usually used to describe interference caused by a nearby radio transmitter.

Shield: A metallic enclosure used to reduce electric or magnetic field levels.

Susceptibility: Vulnerability of electronic equipment to external sources of interference; often used interchangeably with immunity.

89.2 EMI and EMC Test Methods

Jeffrey P. Mills

Electric and magnetic fields must be measured for a variety of reasons. A radio or TV broadcast station is licensed to provide reliable coverage over a specified geographic area, and any properly operating receiver must pick up the signal and properly respond to it. This can be assured only if the broadcast signal is of a guaranteed minimum strength. Also, the signal must not be so strong that it interferes with a distant station sharing the same frequency. The broadcast field must be measured over its geographic area of coverage to be sure that it satisfies both criteria.

Many electric devices unintentionally radiate electromagnetic fields. Examples include

- Oscillators in superhetrodyne radio or TV receivers
- Digital logic circuits
- Switching contacts, particularly if unsuppressed
- Automotive ignition systems

Stray fields (**emissions**) from these devices can interfere with other devices, or even with the radiating device itself. This process is known as **electromagnetic interference**, commonly abbreviated EMI. Interference between two devices is known as **intersystem EMI**, whereas if a device interferes with itself it is **intrasystem EMI**. Intrasystem EMI is usually easy to spot because the device itself does not operate correctly. Intersystem EMI is usually more difficult to isolate. Its result might be a simple annoyance, such as noise on a radio and TV receiver caused by an electric vacuum cleaner or a power drill. It could, however, be much more serious; a portable radio receiver might affect aircraft navigation or critical communications.

It is also possible for a device to be **susceptible** to fields intentionally generated by a licensed transmitter such as a broadcast or mobile-radio transmitter. Examples include

- Public-address systems
- Music (high-fidelity) systems
- Telephone lines and instruments
- Digital logic circuits

Again, the result may be only an annoyance, or it could be much more serious; aircraft control surfaces have been observed to move uncontrollably due to strong electromagnetic fields. Since the fields themselves cannot be eliminated in these cases, the devices must be made immune to electromagnetic fields.

In the above cases, the interference is usually through electric and/or magnetic fields in space, so the process is known as **radiated coupling**. Another coupling path exists if two devices share the same power source. One device may generate undesired high-frequency voltages on its power leads, which then appear on the power leads of the other. The second device may then malfunction because of this high-frequency voltage. This is known as **conducted coupling**. So we must consider both radiated and conducted noise.

It is not practical to eliminate all interfering fields completely, so a compromise must be reached. A stray field will not cause EMI if it is very weak compared with the desired field, which might be the field of a broadcast signal. The permissible strength of the stray field depends on the strength of the desired field; the stronger the desired field, the more stray field can be tolerated. It also depends on the device that is being interfered with (the *victim*); some receivers can reject undesired signals better than others. Since there are many combinations of interference sources and victims, a worst-case scenario is sought that will protect most real-life situations. This occurs where the weakest legal radio or TV signal (in its licensed area of coverage) is received by the poorest available receiver.

The maximum stray field strength that causes no EMI for this worst-case scenario is incorporated into government regulations. The field actually radiated by every device must then be measured to be sure that it does not exceed this level at the nearest practical distance from it, usually 10 or 30 m. To specify and measure these field strengths accurately, the nature of electric and magnetic fields must be understood.

Unlike most electrical engineering topics, EMI control is not very precise because of the complexity of practical hardware. It is virtually impossible to predict interference more precisely than within a factor of three, and usually the margin of error is even worse. Measurements can vary significantly between two supposedly identical samples, due to slight variations in physical dimensions. If one measures the EMI resulting from two different designs, the design that exhibits less EMI is probably better, but not always. An engineer can often judge if an EMI problem exists, but one must never rely on the accuracy normally expected in other branches of electrical engineering.

Nature of Electric and Magnetic Fields

An electric field is generated by a distribution of electric charge. If the distribution changes with time, then so will the electric field. A magnetic field may be generated by a permanent magnet or by an electric current. If the permanent magnet or the current path moves, or if the current magnitude varies with time, the magnetic field will vary with time. A time-varying electric field creates a magnetic field, and conversely.

Electric fields, designated E , are normally expressed in volts per meter (V/m). Magnetic fields are designated H and expressed in amperes per meter (A/m). More often, magnetic fields are perceived as magnetic flux density, which is designated B and expressed in webers per square meter (W/m^2), also known as *teslas* (T). A non-SI unit, sometimes found in older literature, is the *gauss*, equal to 10^{-4} T. Of course, any unit may be preceded by a scaling prefix such as micro or pico. In free space, B is equal to $\mu_0 H$, where, μ_0 is equal to 0.4π (approximately 1.257) $\mu\text{T}\cdot\text{m/A}$ (equivalent to $\mu\text{H/m}$).

Near a time-varying electric field source such as a charge distribution, the magnetic field is relatively weak, but it becomes stronger when observed from farther away. At a great enough distance, the ratio of E to H approaches $\sqrt{\mu/\epsilon}$, which in free space is equal to 120π (approximately 377) Ω . For a sinusoidal function of time with a frequency f , this occurs at any distance that is large compared with $\lambda/2\pi$ (approximately $\lambda/6$). Here, λ is the wavelength corresponding to f , equal to $3\cdot 10^8/f$ m if f is specified in hertz. Distances much greater than $\lambda/2\pi$ are considered to be in the **far-field region**; nearer distances are in the **near-field region**. For a nonsinusoidal function of time, each Fourier frequency component must be considered separately, and the far-field region begins closer to the source for its higher frequency components.

Near a time-varying magnetic field source such as a current loop, the electric field is weak, becoming stronger when observed from a greater distance. At distances that are large compared with $\lambda/2\pi$ (the far-field region), the ratio of E to H again approaches $120\pi \Omega$.

Since $H = \sqrt{\epsilon/\mu}E$ and $B = \mu H = \sqrt{\mu\epsilon}E$ in the far-field region for either type of source, only E or B must be measured, and the other can easily be calculated from it. In free space, $\sqrt{\mu\epsilon} \approx 10^{-8}/3 \text{ T}\cdot\text{m/V}$ (equivalent to s/m), so, if E is expressed in volts per meter, $B \approx 3.33E$ nT. By choice of a suitable antenna, either field can be measured. Far-field strengths are normally specified in terms of the E field, no matter whether the E or B field is measured.

Alternatively, the far-field strength may be specified in terms of **power density**, expressed in watts per square meter. This denotes the amount of radiated power passing through each square meter of a surface perpendicular to the direction away from the source. The *peak* power density P is equal to EH , and, for a sinusoidal source, the *average* power density is half this value. For a nonsinusoidal source, each frequency component must be considered separately, and the total average power is the sum of the average powers for all frequencies. Since $H = \sqrt{\epsilon/\mu}E$, it follows that $P = E^2/377 \Omega$.

In regions other than the far field, the ratio of E to H varies greatly, approaching infinity for an electric field source or zero for a magnetic field source. A source may generate both electric and magnetic fields; for example, a charge moving between two electrodes causes a current to flow between them. Then the

ratio of E to H may be any value at all. Therefore, at distances less than $\lambda/2\pi$ from a field source, both the E and B fields must be measured separately.

In the far-field region, both the electric and magnetic fields are perpendicular to the direction that an electromagnetic wave is propagating, and they are also perpendicular to each other. This still usually allows the fields to be oriented at many different angles with respect to the surface of the Earth. The direction of the electric field is called the **polarization** of the wave, which may be vertical, horizontal, or somewhere between. Or the wave may be **elliptically polarized**, which results from two waves that are not exactly in phase, one polarized vertically and the other horizontally. If the waves are equal in magnitude and exactly 90° out of phase, the wave is *circularly* polarized. To account for all these cases, all fields must be checked separately for vertically and horizontally polarized waves.

Measurement Antennas

Most electronic components and instruments are designed to respond to voltages or currents, not fields. To measure a field strength it is necessary to convert its effect to a voltage or a current. This is achieved by an antenna. Although many antennas are simple conductor shapes, they must be analyzed carefully if accurate quantitative measurements are desired.

A straight conductor immersed in a time-varying electric field will develop a current in it. If the conductor material is linear (the usual case), the current will be proportional to the applied electric field, so their ratio will be constant. This ratio, however, depends greatly on the geometric dimensions of the conductor and the frequency of the electric field. It must be known to calibrate the antenna.

Similarly, a closed conductive loop immersed in a time-varying magnetic field will develop a current in it. Again, if the conductor is linear, the ratio of the current to the magnetic field strength is constant but depends on the dimensions of the loop and the frequency of the magnetic field.

The easiest way to calibrate an antenna is to immerse it in a known electric or magnetic field and measure the current or voltage at the antenna terminals. The principal problem is generating the known field. To find its strength, one must use a “standard” antenna for which the current-to-field ratio can be calculated.

To calculate the required ratio, Maxwell’s equations must be solved subject to the boundary conditions of the antenna conductor. For most antennas an exact closed-form solution is impossible. However, for a sinusoidally varying field encountering a straight cylindrical conductor called a **dipole antenna**, such a solution is possible, though difficult [1]. Once the solution is obtained, the required ratio becomes a simple expression if the antenna is *resonant* or *tuned*. This occurs for a precise length that is slightly less than one half the wavelength, λ , of the time-varying field. Obviously, the antenna will be resonant at only one frequency, so the ratio will be valid only for a field varying sinusoidally at that frequency. For nonsinusoidal fields, each Fourier frequency component must be measured separately, and the antenna length must be changed as different frequencies are measured. To simplify changing its length, two telescoping rods, mounted end to end, are normally used to make the dipole antenna. The measuring instrument is connected between these two rods via a transmission line.

For a given frequency, at any point on the antenna, there is a certain current I flowing in it, and there is also a certain voltage V on it with respect to ground. The ratio of these phasors, V/I , is known as the **driving-point impedance**. The precise resonant antenna length is that for which V and I are exactly in phase, i.e., for which the driving-point impedance is purely real. As mentioned above, this length is slightly less than half the wavelength, λ , and it also depends on the thickness of the telescoping rods (pp. 547–548 of Reference 1). For a rod thickness of $\lambda/400$, the resonant length is 0.476λ . The driving-point impedance of a dipole antenna of these dimensions is 64Ω . If a voltage-measuring instrument such as a radio receiver or spectrum analyzer is connected to the antenna terminals via a transmission line, and is properly matched to the 64Ω impedance, the measured voltage V_m will be equal to $0.148\lambda E$, where E is the applied field strength and λ is the wavelength at the frequency being measured. The ratio V_m/E , equal to 0.148λ , is known as the **effective length** (l_e) of the antenna, since it relates the field strength in volts per meter to the measured terminal voltage in volts. Obviously, it is not equal to the physical

antenna length but is instead approximately one third of that value. With this ratio known, the electric field strength E that causes a certain terminal voltage V_m can easily be calculated.

To simplify calculations, E is often expressed in decibels with respect to a reference field of $1 \mu\text{V}/\text{m}$ and is designated E_d . Similarly, V_m is expressed in decibels with respect to a reference voltage of $1 \mu\text{V}$ and is designated V_d . The **antenna factor** (AF) is defined as the effective length expressed in negative decibels, or $\text{AF} = -20 \log(l_e)$. Then the multiplication becomes an addition, i.e., $E_d = V_d + \text{AF}$.

The above antenna factor assumes that the antenna is perfectly matched to the receiver, which implies maximum power transfer. A mismatch would change the antenna factor. Therefore, since the antenna driving-point impedance usually is not equal to the receiver input impedance, a matching circuit must be inserted between the antenna and receiver. Another essential consideration is antenna balance. Most receivers and spectrum analyzers have one input terminal grounded. If this grounded terminal is connected to one of the dipole antenna terminals, the impedances connected to the two antenna terminals will be unequal with respect to ground. This also will upset the antenna factor, since one side of the antenna will not be properly matched to the receiver. To prevent this, a balanced-to-unbalanced (**balun**) network must be inserted between the antenna and receiver. Such a circuit provides a high impedance *with respect to ground* for both input terminals, while providing the correct input impedance (such as 64Ω) *between* its input terminals. Normally, a single network provides both the matching and balancing functions.

Unfortunately, unless the dipole antenna is precisely the correct length, its antenna factor is much more complicated. Even if the frequency being measured differs only a few percent from the antenna resonant frequency, the antenna factor becomes unpredictable and the driving-point impedance becomes complex. Thus, the electric field cannot be easily calculated from the measured terminal voltage. To achieve the simple antenna factor described above, the frequencies must be measured one at a time and the dipole antenna length properly adjusted for each frequency. It is impossible to sweep the spectrum rapidly, as when using a spectrum analyzer, unless the antenna length can somehow be varied also. This leads to mechanical difficulties and is usually impractical.

Other types of antennas, however, are less sensitive to frequency. Examples are the biconical antenna and the log-periodic antenna. A biconical antenna can perform acceptably over a range of 20 to 300 MHz, and a log-periodic antenna is useful from 300 to 1000 MHz. Their antenna factors are relatively constant, usually varying by no more than 20 dB, over their useful frequency ranges. The antenna factors are usually too difficult to calculate, but they may easily be measured simply by observing the terminal voltage resulting from a sinusoidally varying field of known strength. The known field is first measured using a tuned dipole antenna, for which the antenna factor can be calculated. The antenna factor is measured in this manner at several frequencies throughout its useful range, and the results are plotted for use with the antenna.

Unlike the tuned dipole, the biconical and log-periodic antennas do not exhibit constant driving-point impedances over their useful frequency range. Since the receiver input impedance cannot be made to follow the variation of driving-point impedance with frequency, an exact match is impossible. This affects the antenna factor just as it would for a mismatched tuned dipole. To compensate for this, the antenna factor must be measured with the antenna terminated into a known impedance, which must then be used for all measurements made with that antenna. Then the mismatch is accounted for in the antenna factor itself. The mismatch does cause the antenna to reradiate the received signal, but this effect may be minimized by performing the measurements in an open-field site, which will be discussed later.

Tuned dipole, biconical, and log-periodic antennas are *linearly polarized* antennas because they respond to only one polarization component of a propagating wave. If the antenna is oriented horizontally, only the horizontally polarized component of the wave will affect it. Similarly, only the vertically polarized component will affect a vertically oriented antenna. Thus, with two measurements, any linearly polarized antenna will detect any type of field polarization. Other types of antennas, such as the spiral antenna, are designed to detect a circularly polarized wave. They will detect vertically and horizontally polarized waves, but they could miss a wave that is circularly polarized in the reverse direction (counterclockwise

instead of clockwise, for example). Consequently, circularly polarized antennas are forbidden for many types of field measurements.

All antennas discussed above respond to the electric field, E . As mentioned earlier, in the far-field region, the magnetic field, B , is simply 3.33 nT times the value of E expressed in volts per meter. In any other region, however, B is not so simply related to E and must be measured separately, using an antenna that responds to magnetic fields. A circular loop or coil of wire is such an antenna. The loop is cut at one point and the radio receiver or spectrum analyzer is connected between its two ends. For quantitative measurements, its antenna factor must be known. The factor can be measured by immersing the antenna in a known magnetic field and measuring its terminal voltage. To find the known magnetic field strength, the electric field is first measured, in the far-field region, using a tuned dipole antenna for which the factor is known. The magnetic field is then 3.33 nT times this value expressed in volts per meter. With the magnetic field thus determined, the antenna factor of the loop may be calculated, as required.

Measurement Environment

A major difficulty with electromagnetic field measurements is repeatability of results. Electromagnetic fields are affected by any materials in their vicinity, even by poor conductors and dielectrics. The measurement environment must therefore be carefully defined, and similar environments must be used for all comparable measurements.

The ideal environment would be one where (1) the only electromagnetic field source is the equipment under test (EUT) and (2) there is no “foreign” material at all that could affect the fields being measured. Unfortunately, the only natural location where this could be achieved is in outer space, since the Earth itself affects electromagnetic fields. Since this is impractical, attempts are made to simulate this environment on Earth.

A large outdoor open area simulates a hemisphere of free space. Such a test site is appropriately called an **open-field site**. If the conductivity, permittivity, and permeability of the Earth were constant, every open-field site would have the same effect on the electromagnetic fields radiating from the EUT. The Earth’s parameters do vary, however. To compensate for this variation, a large conductive floor, or ground plane, is laid under the EUT. This causes all electromagnetic waves to be totally reflected from the ground plane, so that the Earth’s properties have no effect. The ground plane must be large enough so that it appears infinite with respect to the EUT and the associated test equipment. Acceptable dimensions are $1.73d \times 2d$, where d is the distance between the measurement antenna and the EUT, normally 3 or 10 m. Radiated emissions must be measured in all directions from the EUT, and at various angles of inclination. This is most easily achieved by placing the EUT on a turntable, which is then rotated during the test. To allow measurement at various inclination angles, the receiving antenna height must be varied, and this is accomplished by mounting it on a halyard. A typical open-field site appears in [Figure 89.5](#).

An open-field site provides repeatable data only if there are no nearby trees or structures that could cause undesirable reflections. Before it can be reliably used, it must be tested. This is done by generating a known electromagnetic field and measuring it. The field is normally generated by a radio frequency oscillator driving a tuned dipole antenna, for which the radiation can be calculated (pp. 237–238 of Reference 2). This radiation is then measured as though it were generated by a typical device being tested. The ratio of the voltage at the transmitting antenna terminals to that at the receiving antenna terminals is known as the **site attenuation**. If the site attenuation is within 3 dB of its calculated value, the test site is deemed acceptable.

Although an open-field site eliminates reflections, external field sources, such as licensed transmitters, still cause problems. Since electromagnetic radiation can travel thousands of miles, no open-field site will be completely free of electromagnetic fields. To eliminate the effects of these stray sources, testing must be performed inside a shielded enclosure. There, however, severe reflections occur, and measurements become inaccurate and unrepeatable.

An ideal test environment would be a shielded enclosure lined with material that does not reflect electromagnetic waves. Such an enclosure is called an *anechoic chamber*, with the understanding that the

FIGURE 89.5 An open-field test site. Power and antenna cables are run under the ground plane so that they will not affect measured fields. The area outlined by the ellipse must be free of everything except the device under test, the table on which it rests, and the measuring antenna. To facilitate measuring radiation in all directions from the device, it is placed on a turntable. By rotating it during testing, and simultaneously varying the height of the receiving antenna, the direction of maximum radiation is found.

name refers to *electromagnetic* echoes. Until recently, such chambers were not practical except at very high frequencies, but improvements are constantly being made. Such an enclosure is acceptable for testing if it meets the site-attenuation requirements of a true open field. The site attenuation must be measured at several points inside the chamber, to assure that the proximity of the chamber walls has no effect. Unfortunately, such chambers are at present very expensive.

Another type of test chamber is the **transverse electromagnetic (TEM) cell**. This consists of an enlarged section of waveguide, in which the electromagnetic fields can be accurately predicted [3,4]. They are suitable only for testing small devices at relatively low frequencies. The TEM cell can be no larger than a wavelength at the frequency being tested. For example, to test at 200 MHz, the cell could be no larger than 1.5 m, or 5 ft, and the device itself must not exceed $\frac{1}{6}$ of this value, or 10 in. For small devices, however, the TEM cell is very accurate and is unaffected by stray field sources.

If a suitable anechoic chamber is not available, a device may be tested in an ordinary shielded enclosure to learn what frequencies it emits. The field strengths will be inaccurate due to the internal reflections. Then the device is tested in a true open-field site, and the suspected frequencies are measured quantitatively. Any field that exceeds the acceptable limits is then observed while the device is shut off. If it does not disappear, it is obviously not being generated by the EUT. This procedure is acceptable, although not as simple as testing inside an anechoic chamber.

Preliminary measurements may even be performed in an ordinary room. They will not be comparable with similar measurements made anywhere else, because of the effects of nearby conductors and dielectrics. Here, also, the device must be shut off to decide if any emissions are from stray external sources instead of from the EUT. This procedure provides a rough estimate of the emissions from the EUT, and it usually saves time during any later testing at a true open-field site. The various measurement methods appear in [Table 89.4](#).

Permissible emission levels appear in the *Code of Federal Regulations* [5]. These rules assume open-field measurements, which are the most accurate possible. Even there, variations of ± 6 dB are typical. Therefore, a manufacturer should allow a safety factor when performing measurements intended to assure

TABLE 89.4 Comparison of EMI Measurement Methods

Method	Equipment Required	Space Required	Accuracy	Outside Influence	Cost	Comments
Ordinary room	Antenna and receiver	3 or 10 m radius around EUT	Medium, affected by structure, ± 20 dB	May be severe, depending on location	Minimum	Usually acceptable for preliminary tests
Shielded room	Shielded room, antenna, and receiver	4 to 6 m radius around EUT	Poor, ± 30 – 40 dB due to reflections	Usually none	Moderate	Use for preliminary tests in noisy areas
TEM cell	TEM cell and receiver	1 to 3 m ³	Very good, ± 10 dB	Usually none	Moderate	Unusable for large EUT due to high-order modes
Open field	Antenna and receiver	17 × 20 m open field with no nearby structures	Excellent, usually ± 6 dB	May be severe, depending on location	High, due to logistics of site (power, weather, etc.)	Standard test method
Shielded anechoic chamber	Anechoic chamber, antenna, and receiver	6 to 15 m radius around EUT	Very good, ± 10 dB	Usually none	Very high	Use for accurate tests in noisy areas

compliance with government regulations. Otherwise, a device may pass when tested by the manufacturer but fail if later tested by the government using a supposedly identical test procedure. Since the government's measurements then prevail, the manufacturer's integrity could be questioned.

Further details on measurement techniques are available in the References 2 and 6.

Defining Terms

Antenna factor: Its effective length expressed in negative decibels.

Balun: An interface device used to isolate a dipole or other balanced antenna from the effects of a receiver having one grounded terminal.

Conducted coupling: Coupling due to voltages imposed on a shared power source.

Dipole antenna: An antenna consisting of two collinear rods with the feed line connected between them.

Driving-point impedance: The ratio of voltage to current at the driving point (normally the center) of an antenna.

Effective length: The ratio of the voltage observed at the driving-point of an antenna to the strength of its received electric field.

Electromagnetic compatibility (EMC): The capability of two or more electrical devices to operate simultaneously without mutual interference.

Electromagnetic interference (EMI): Any undesired effect of one electrical device upon another due to radiated electromagnetic fields or due to voltages imposed on a shared power source.

Elliptical polarization: Polarization of an electromagnetic wave consisting of two perpendicular electric fields of differing phase.

Emissions: Fields or conducted voltages generated by an electrical device.

Far-field region: Any location that is much farther than $\lambda/2\pi$ from an electric or magnetic field source, where λ is the wavelength at the frequency of concern.

Intersystem EMI: Electromagnetic interference between two or more systems.

Intrasystem EMI: Electromagnetic interference between two or more parts of the same system.

Near-field region: Any location that is much nearer than $\lambda/2\pi$ to an electric or magnetic field source, where λ is the wavelength at the frequency of concern.

Open-field site: A test location free of any conductors which would affect electromagnetic fields and taint the results.

Polarization: The direction of the electric field, E , of an electromagnetic wave.

Power density: Radiated power per unit of cross-sectional area.

Radiated coupling: Coupling due to radiated electric, magnetic, or electromagnetic fields.

Site attenuation: A measure of the degree to which electromagnetic fields at a test site are disturbed by environmental irregularities, obtained by comparing calculations with measured experimental results.

Susceptibility: The degree to which an electrical device is affected by externally generated fields or conducted voltages.

Transverse electromagnetic (TEM) cell: A relatively small test chamber in which fields can be accurately controlled by its geometric properties.

90.1 Introduction

The display system is the final link between the measuring process and the user. If the display is not easy to see and easy to understand, then that process is compromised. The user's sensory capabilities and cognitive characteristics, therefore, must both be addressed in display system selection. Furthermore, display technologies and performance capabilities are easier to evaluate in the context of their intended application. Consideration of the following issues can narrow the search for candidate systems, and can prevent needless frustration during system use:

Environment. Will the display be operated in sunlight or at night?

Application. Will the display present alphanumeric data, video images, graphics, or some combination?

Task scenario. Are portability, handheld operation, or group viewing required?

System characteristics. Weight, volume, power, maintenance, cost, etc.

This chapter begins with basic treatments of light and vision. It then proceeds to discussions of visual capabilities and the display characteristics that must be matched to them.

90.2 Fundamentals of Light Measurement

The foundation metric of light is *luminous flux*, which is the rate at which light energy is emitted from a source, and is expressed in lumens (lm). *Luminous intensity* is luminous flux per unit solid angle, and its unit of measurement is the candela (cd). This is distinguished from *illuminance*, or illumination, which is simply luminous flux per unit area, expressed as lux (lx). *Luminance*, is a measure of the brightness, i.e., the amount of light, per unit area, either emitted by or reflected from a surface. Units of luminance measurement are candelas per square meter (cd/m²) or nits. Finally, *reflectance* is a unitless ratio of the amount of light striking a surface to the amount of light leaving it:

$$R = \pi \times \frac{\text{luminance}}{\text{illuminance}} \quad (90.1)$$

High reflectance can create glare, dramatically reducing visual performance.

90.3 Fundamentals of Vision

The eye functions very much like a conventional camera. Light enters the eye through a transparent *cornea* and is modulated by the *pupil*, a variable aperture opening controlled by muscles of the *iris*. The pupil grows larger in dark surroundings and smaller in bright surroundings to control the range of light intensity to the eye. Light rays are then refracted by an adjustable *lens* and brought into focus on the *retina*, where neural imaging begins. The retina contains both *cones* and *rods*, two distinctly different types of photoreceptors. Cones are concentrated near the *fovea*, or the central 2° of the visual field, and decrease rapidly with distance from this region. In contrast, rods are essentially absent in the fovea and increase in density with distance.

The eye is sensitive to three characteristics of electromagnetic radiation: (1) *brightness* (the intensity of ambient or incident light, measured in lux), (2) *hue* (the wavelength of light, measured in nm), and (3) *saturation* (relative concentration of specific hues in light, measured as a dimensionless ratio from 0 to 1). Cones are differentially sensitive to wavelength, i.e., hue, and have greater resolving power than rods because of their one-to-one mapping onto visual nerves. Cones can be further divided into three types, each maximally sensitive to a different portion of the visible light spectrum: (1) red (670 nm peak), (2) green (470 nm peak), and (3) blue (400 nm peak). Rods are more sensitive to light than cones and have many-to-one connections with the nerves that exit the eye, a feature that permits neural summation of low light signals. Human ability to discriminate differences in levels of brightness, saturation, or hue is governed by a psychophysical function known as *Weber's law*:

$$K = \frac{\Delta I}{I} \quad (90.2)$$

where ΔI is the difference, or change, in intensity, I is the initial intensity, and K is the Weber fraction. Values of K have been experimentally determined for brightness (0.079), saturation (0.019 for red), and hue (≈ 0.02 to 0.04, depending on the region of the visible spectrum).

Photopic vision occurs at light levels where both rods and cones are sensitive. The minimum light intensity required for photopic vision is approximately 2 lx; colors are seen in this region. As brightness decreases, a transition from photopic to scotopic vision takes place and color perception drops out gradually, a phenomenon that can impact the interpretation of color-coded information in poor light. Perception of blues and reds is lost first, then cyan and yellow-orange, and finally green, i.e., the wavelengths where the eye is most sensitive. The eye becomes most sensitive to wavelengths of about 550 nm (green) near the limit of photopic vision. *Scotopic vision* occurs at low light levels (2×10^{-7} lx to 2 lx) and primarily involves the rods; only achromatic shades of gray are seen. The transition from photopic

to scotopic vision occurs slowly, requiring approximately 30 min for complete adjustment from photopic to scotopic visual sensitivity.

90.4 Visual Performance

Visual acuity is the ability to discriminate detail. The action of the lens, to change focus for objects at different distances, is called *accommodation*. *Minimum separable acuity*, the most common measure of discrimination, is determined by the smallest feature that the eye can detect, and is measured in terms of the reciprocal of the visual angle subtended at the eye by that feature. *Visual angle*, in minutes of arc, is calculated as

$$VA = \frac{3438H}{D} \quad (90.3)$$

where H is the height of the object and D (in the same units) is the distance from the observer. The ability to distinguish an object from its surroundings is known as *visibility*. The term is related to visual acuity, but implicitly combines factors of object size, contrast (i.e., including differences in hue and saturation), and brightness that all interact to determine true visual detection performance. On a more functional level, *readability* or *legibility* describe the ability to distinguish meaningful groups of objects (e.g., words extracted from groups of letters on a display).

Other parameters affecting visual performance include viewing angle and viewing distance. *Viewing angle* at the eye is measured from a line through the visual axis to the point being viewed, and determines where an object will register on the retina. The best image resolution occurs at the fovea, directly on the line of gaze, and visual acuity degrades with increasing angle away from this axis. *Viewing angle* at the display is the angle, in degrees, between a line normal to the display surface and the user's visual axis. The best viewing angle is, of course, on the visual axis and normal to the display surface, as luminance falls off for most displays as the angle from normal increases. Luminance reduction with viewing angle can be calculated as

$$E = E_m \cos^4 \theta \quad (90.4)$$

where E_m is the illuminance at the center of the display and θ is the viewing angle. Note that two viewing angles — at the eye and at the display — have been defined. *Viewing distance* is determined primarily by the minimum size requirements (i.e., visual angle) for objects that the user must see. A conventional reading distance is about 71 cm, although VDTs are frequently read at 46 cm. Most design criteria assume a viewing distance of between 50 and 70 cm.

Visual fatigue is an imprecise term, but one in common use, referring to the annoyance, irritation, or discomfort associated with visual tasks performed under poor conditions or for extended periods of time. A common cause of visual fatigue is *glare*, which can be due to a combination of high brightness, high reflectance, and specular (mirrorlike) reflections causing source light to reflect directly into the eye. Minimizing or eliminating glare is essential for effective display performance, and usually involves a thoughtful placement of the display, proper positioning of room lights, control of ambient light (e.g., window shades), or the use of display hoods.

90.5 Display Performance Considerations

Resolution is a measure of the smallest resolvable object on a display, and is expressed as display lines per millimeter or centimeter. Although *sharpness*, and its converse *blur*, are normally defined by the subjective reaction of the display user, sharpness has been formally measured as the ratio of the blurred border

zone of letters to their stroke width [3]. Legibility is related to character quality, or readability, and depends on the sharpness of characters.

Contrast, or contrast ratio, is the measure of the luminance difference between an object and its background. While different definitions exist in the literature, luminance contrast as adopted by the International Lighting Commission (CIE) is given as

$$C_R = \frac{\text{luminance of brighter object} - \text{luminance of darker object}}{\text{luminance of brighter object}} \quad (90.5)$$

Lower luminance displays require greater contrast to achieve the same visibility of objects. The *contrast*, or *luminance ratio* between two surfaces in the central field of vision (e.g., a display and the desk on which it rests) should be around 3:1, while the ratio between the central field and surfaces farther away (e.g., around a room) can be as high as 10:1. Ratios greater than this can induce glare. The simplest methods for contrast enhancement are the use of hooded shades or displays that can be tilted away from the offending light. Contrast-enhancing *filters*, however, can be more effective. All filters involve reducing the amount of ambient light reflected back to the user, while leaving the emitted light from the display content as unchanged as possible. Several strategies for filtering exist, including *etching* or *frosting* the display surface to break up and scatter specular reflections. *Neutral density filters* increase contrast by reducing the amount of light passing through them; ambient light must pass through twice before reaching the user's eye, while display content must only pass through once. Micromesh filters placed on the display surface limit light penetration so only rays falling perpendicular to the mesh can penetrate; this stops both specular and diffuse reflections and increases contrast. *Circular polarizers* are neutral density filters that polarize incident light, which is then prevented from returning through the filter. *Quarter-wave thin film coatings* interfere with both specular and diffuse reflections.

Gray scale refers to the number of luminance levels, or shades of gray, available in a display. The common definition is a luminance ratio of 1.4 between levels, although the eye can discriminate changes as small as 1.03 (a Weber's *K* value of 0.03). The number of gray shades is useful for evaluating the capability of a display to render pictorial information or the range of luminance levels that can be used for coding. The highest luminance level is determined by display capabilities, but the lowest level is determined by the luminance of the display surface when no signal is present. Bright light incident on the display can elevate this minimum level and reduce the number of usable gray shades.

Flicker is the term for detectable changes in display luminance, and occurs when the frequency of those changes is below the integrating capability of the eye. The minimum frequency at which this occurs is the *critical flicker fusion* frequency, or CFF, which depends on the luminance level of the image; i.e., displays which do no flicker at high luminance levels may still flicker at low levels. The CFF is calculated as

$$CFF = a \log L_a + b \quad (90.6)$$

where $a = 12.5$ for high (photopic) ambient light levels and 1.5 for low (scotopic) levels, L_a is the average luminance of the image in cd/m^2 , or nits, and $b = 37$. This is an empirical formula, and the values for a and b are only approximate. Because the eye cannot adapt to flicker fast enough to control the light on the retina, visual irritation usually occurs where flicker is present.

Many display parameters are stated in terms of the *pixel*, or picture element. The pixel is the smallest addressable element in an electronic display, or the smallest resolvable information element seen by the user. *Refresh rate* is the frequency with which display pixels are reilluminated. Refresh rates below 50 to 80 Hz may induce perceptible flicker. The *update rate* is the frequency with which the information content of display is changed.

Linearity is the deviation of a straight line from its exact form, expressed as a percentage of total line length. *Pattern distortion* is the deviation of any element of a pattern (e.g., a grid) from its exact location, expressed in dimensions of the total pattern. While no specific limits are associated with these parameters,

FIGURE 90.1 Examples of alphanumeric displays.

interpretation of measurement data can obviously be affected if nonlinearities are observable on the display.

Several mathematical models have been developed to quantify display *image quality* as single “figures of merit.” These models, while useful, are too involved for treatment here and the reader is referred to an excellent summaries in the literature [1] for further information.

90.6 Display Content Considerations

Configurable software packages for scientific measurement (e.g., LabView™) allow great flexibility in the design of display formats. Human factors principles for display content, therefore, are as important to effective measurement as the electronic characteristics of the display itself. The following principles are an introduction to the kinds of issues that must be considered when designing display content. The interested reader is referred to Helander (1987) and Grandjean [3]) for information on human factors and design guidelines beyond those presented here.

Alphanumeric Displays

The size of a letter is its *pitch*. A general recommendation is that characters should subtend a minimum of about 12 min of arc at common reading distances. Alphanumeric displays are usually constructed of pixel arrays or segmented bars (Figure 90.1). A 5×7 pixel array is considered the minimum necessary to represent the ASCII character set. More pixels can increase legibility, but at higher cost for the control electronics. The seven-segment bar matrix is also common design and has good performance, but up to 16-segment arrays are available for better appearance.

Stroke width is the ratio of the thickness of the stroke to the height of the letter. Recommendations for legibility are 1:6 to 8 or 1:8 to 10 [2]. As illumination is reduced, thick letters are easier to read than thin ones. With low illumination and low contrast, letters should be boldface type with low stroke width–height ratios (e.g., 1:5).

Quantitative and Status Displays

While numeric readout displays are easy to implement in software, analog pointer displays show an advantage when it is important to observe the direction or rate of change of the values presented [4]. If the measurement application involves “more or less” or “up or down” interpretations, a straight-line or

thermometer scale is preferred because it shows the measurement in relation to zero. *Moving pointers* are better able to convey minor changes in readings than fixed pointers or numeric readouts. *Scale markings* should reflect the length of the smallest unit to be read. It is desirable to have a marker for each unit, so that no interpolation is required.

Check reading indicators are used to determine whether a condition is “normal.” The normal criterion point, therefore, should be clearly coded. If several indicators are grouped together, they should be arranged so that the deviant reading stands out (e.g., by indicating a different column height or dial angle, etc.).

Color is an excellent method for organizing information on a display and for locating objects rapidly. Although display users can distinguish between many different colors, they usually cannot remember more than seven to ten of them, so the number should be limited if color is going to be used as a coding dimension.

Summary

The next sections address different display technologies in light of the principles discussed here. While display guidelines are available for essentially any parameter, it is important to remember that visual perception is an integrative process. No single guideline functions alone, and display quality is usually a product of interacting needs and trade-offs.

90.7 Cathode Ray Tube Displays

The cathode ray tube (CRT, see Chapter 91) is by far the most common display technology in use today, and its widespread use in televisions and computer monitors should guarantee its continued presence throughout the foreseeable future. Advantages of CRT-based displays include (1) versatility (the same CRT can be used for alphanumeric, pictures, or graphics), (2) high-resolution capability and high luminous efficiency, extremely fast dynamic response (which can be important for rapidly changing signals), (3) extensive commercial availability (e.g., 2.5 to 64 cm, diagonally), (4) high reliability, (5) long life, and (6) relatively low cost. CRT displays can function well in high ambient illumination if filtering is used. Potential disadvantages of CRT displays are bulk (the depth of conventional CRT tubes can match or exceed their diagonal dimension, although flat CRTs are available), and vulnerability to ambient reflections and high illumination. Light falling on the smooth display surface can produce a veiling illuminance that **washes out** screen contrast and reduces the number of colors that can be perceived.

CRT Performance

Many characteristics of CRT displays depend on the type of phosphor selected for the design. Phosphor materials vary widely in their luminous efficiency, their color, and their decay time. **Decay time** interacts with display refresh rate; a phosphor with a short decay time will require a higher refresh rate to avoid observable flicker effects. Selecting a CRT with a high phosphor decay time will also result in selecting a tube with a high average luminance. Resolution depends on the **spot size** of the energized phosphor (which is effectively the thickness of the raster line). Spot size will also depend on the acceleration voltage and beam current of the cathode gun, so manufacturer’s data must be noted for the voltage and current where the measurements were recorded, and compared with expected operating conditions. CRT resolution is measured in two ways. *Television lines* are the number of the most closely spaced, discernible lines that can be distinguished on an EIA (Electronic Industries Association) test chart. *Shrinking raster lines* involve a process of reducing the spacing between lines of a test pattern until no lines can be seen. This point is then expressed as the number of lines per centimeter, and is a better metric for measurement display applications. Increasing numbers of scan lines improve symbol legibility and image quality. Most conventional CRT monitors have 525 scan lines, but up to 5000-line systems are available [5]. The primary method for achieving *color CRT* displays is the use of single or multiple electron beams to energize

phosphors for three primary colors — red, blue, and green. A complete range of colors is obtained by selectively energizing appropriate combinations of these three basic phosphors. Beam efficiency is reduced in this process, which means that color CRT displays are not as bright as monochrome CRT systems.

Contrast ratio is diminished by high ambient light levels, and it is often necessary to compromise between light requirements for work tasks and light levels for optimum CRT visibility. In low ambient lighting conditions, a CRT contrast ratio of 10:1 is usually attainable. A ratio of 25:1 can be achieved with contrast-enhancing filters, but at the expense of brightness.

Types of CRT Displays

In addition to the conventional, raster-scanned CRTs used for computer monitors and workstations, two variants of CRT technology should be mentioned, the direct-view storage CRT and the flat CRT. *Direct-view storage CRTs* have been designed to get around the need to refresh phosphors constantly. Direct-view systems usually add an additional, electrically charged layer — the storage element — somewhere behind the phosphor layer and an additional electron gun to maintain this charge. Displayed information is retained until it is actively erased. *Flat CRTs* have been developed to answer the need for CRT performance in a smaller physical package. The basic design technique places the electron gun at right angles to the screen and, through additional focusing circuitry or a slightly angled phosphor screen, writes the raster pattern at a high angle. Additional detail on these and other CRT designs can be found in Sherr [1].

90.8 Liquid Crystal Displays

Liquid crystal displays (LCDs, see Chapter 92) belong to the class of nonemissive technologies, i.e., displays that do not generate light of their own but control the transmission or reflection of an external light source. LCDs alter the optical path of light when an electric field is placed across the liquid crystal (LC) material.

The principal advantages of LCDs include (1) very low power consumption (important for battery-operated and portable systems such as calculators), (2) a flat display package, (3) low cost of the basic materials, and (4) excellent contrast in high ambient illumination. Some LCDs, however, have slow dynamic response (i.e., for switching display elements on and off); 100 to 500 ms rise times, for example, are visually noticeable and such systems may be unacceptable for measurement applications. Low luminance is another drawback, and can make the display difficult to read in low-light conditions without an external light source. In addition, viewing angle is limited by inherent LC characteristics, and is usually less than 45° without special designs. Many LCD features, such as switching thresholds and response times, are temperature dependent.

LCD Performance

A full range of resolution capabilities is available, from simple alphanumeric displays to systems with 63 million pixels and resolutions of 47 lines/cm [6]. LCDs are primarily used in small display applications (e.g., calculators, watches, etc.), although 53 cm diagonal, full-color video-capable displays have been developed [7].

Contrast in polarized systems is determined by the *extinction ratio* of the polarizer, i.e., the ratio of light transmitted in the parallel polarizing orientation to light transmitted in the cross-polarizing orientation. Polarizers with good extinction ratios, however, also suffer high loss of light in the transmitting orientation, so maximum brightness is traded for contrast. Contrast ratios of up to 50:1 [6] have been achieved, although 20:1 is more common.

Color displays can be achieved by placing a color mosaic over the LCD and switching the cells behind the proper combinations of mosaic holes into their transmission states. This method reduces resolution and brightness, however, as the available pixels must be assigned to each of the three primary colors. The

use of thin-film transistors (TFT) as a switching technology for LCDs is the latest approach to generating large, high-resolution displays and is the subject of extensive engineering research [8].

90.9 Plasma Displays

The simplicity and durability of plasma displays (see Chapter 93) makes this technology an attractive candidate for diverse measurement needs, especially where harsh environments are expected. In addition, the switching characteristics of plasma gases have not yet been fully exploited, and this technology offers excellent potential for future engineering improvements. Plasma methods are used extensively for alphanumeric displays in portable, laptop, and handheld computers, and for the display of video imagery. Advantages of plasma displays include enhanced memory capability, brightness, and luminous efficiency. It is also possible to retain pixels in the on state without continuous refresh signals, which means that increased brightness can be obtained for the same power and driving circuitry. This advantage also allows for excellent contrast ratios in high ambient illumination.

Plasma displays also exhibit long display life and ruggedness. It is not unusual for the display to outlast the life of the product in which it is installed, and the relatively simple panel construction can tolerate high shock and vibration environments, or extremes of temperature. Some disadvantages of plasma displays include high cost (relative to CRTs) and high power requirements (relative to LCDs). Other technologies can compete effectively with plasma devices for small alphanumeric displays in benign conditions.

Plasma Display Performance

Commercial plasma displays are available with resolutions of 40 lines/cm, and systems with almost 50 lines/cm are under development. Systems of 2 million pixels have been constructed [9]. Gray scale is achieved with dc displays by adjusting the discharge current in each cell. Displays using ac voltage can trade resolution for gray scale with spatial modulation methods, i.e., by controlling the number and location of activated pixels, rather than the level of pixel illumination. While plasma displays have good gray scale, their brightness is not yet equivalent to that of CRTs. Plasma displays show the color of the ionized gas, usually orange (i.e., where neon is used), although different gas mixtures or phosphors have been successfully used to expand the range of colors. The *hybrid ac-dc display* was designed to combine the memory capability of ac systems with the efficient matrix circuitry of dc devices [10]. The display uses both types of current to generate gas discharge; the dc component controls the pixel addressing, while the ac component controls the memory states of the cells. The *hybrid plasma-CRT display* attempts to use the gas discharge effect of the plasma panel as a matrix-addressable source of electrons for the CRT. The result is a full-color system with high brightness and good luminous efficiency.

90.10 Electroluminescent Displays

With the exception of light-emitting diodes (LEDs, see Chapter 95), electroluminescent (EL, see Chapter 94) technologies are not as prominent in the commercial arena as other types of display systems. EL materials are complex (i.e., driven and controlled by processes related to solid-state semiconductor physics) and are more difficult to work with than other display materials. Nevertheless, they offer great potential for high brightness and low cost that deserves consideration, especially as new designs become available. Matrix addressing is used for control of information display applications. EL materials are applied in two forms — powders (PEL) and thin films (TFEL) — and are controlled by both ac and dc voltages, generating four basic design approaches. Some advantages of EL displays are (1) high luminous efficiency (except ac powder designs), (2) readability in sunlight, (3) color capability, (4) compact, flat panel designs, and (5) significant potential for low-cost manufacture. A disadvantage of EL displays is that ac powder (ACPEL) systems have low luminance and contrast ratio. In addition, phosphors in powder designs scatter and reflect ambient light, reducing their contrast.

EL Display Performance

Contrast ratios of 50 to 150:1 have been demonstrated with monochrome thin-film (ACTFEL) systems, while 15 to 20:1 have been achieved with dc designs. ACTFEL designs also show excellent brightness, with demonstrated luminance levels of over 157 cd/m² (monochrome) and 26 cd/m² (color). DCPEL designs, representing newer technologies, have achieved over 100 cd/m² with monochrome designs, but may soon meet or exceed ac-based values. Resolution of EL displays is limited by the duty factor of matrix addressing; a finite amount of time is needed to energize each row, and a minimum luminance level is needed for adequate display performance, so the remaining variable becomes the number of addressable lines. A demonstrated ACTFEL display with 640 × 400 elements, with six colors and a resolution of 27 lines/cm, is typical of this technology.

90.11 Light-Emitting Diode Displays

Light-emitting diode (LED) displays (see Chapter 95) involve single-crystal phosphor materials, which distinguishes them from the polycrystal EL materials discussed in the previous section. The basic physics behind their operation is, however, quite similar. LED displays are highly versatile and well suited to a variety of measurement applications. Advantages of LED displays include high reliability and graceful degrades; individual LED elements can fail without affecting overall display performance. LEDs are rugged, for operation in harsh environments, and they are more tolerant of temperature extremes than other technologies. LEDs demonstrate better viewing angles than LCDs, and excellent brightness for visibility in sunlight. Unfortunately, LED displays also have high power consumption when packaged in large, flat panel displays, and the cost is high for the complex assembly. Optical cross talk between array elements can occur if transparent substrates are used. LEDs are the most-restricted display in terms of color range (e.g., no blue device is commercially available).

LED Display Performance

LED devices have excellent brightness, but because display brightness is also a function of the filters or magnification lenses used over the LED elements, device luminance is not, by itself, a reliable measure of overall system performance. LED displays also show very good luminance contrast. *Chrominance contrast*, however — the color difference between the LED and its background — is a factor in evaluating LED performance that is not found in other technologies. Chrominance contrast is significant because of the high saturation of most LED phosphors. It is affected by display filters, and can have significantly more influence on display performance than luminance contrast.

LED displays with resolutions of 20 to 25 lines/cm have been constructed. Flat panel displays of 38,400 discrete elements have also been demonstrated with luminance levels of around 137 cd/m² (increasing to 240 cd/m² with reduced resolution), and at least one aircraft display with 49,000 elements has been built. CRT-equivalent displays with 600 × 400 elements have also been realized with engineering development models.

Defining Terms

Decay time: The time required for the peak brightness of a phosphor to drop to a defined fraction of peak luminance; a measure of how long the phosphor remains illuminated after being energized by the electron beam.

Duty cycle: The time spent addressing each pixel during a refresh cycle; inversely proportional to the number of pixels.

Font: Refers to the form in which alphanumeric and symbols are produced.

Spot size: The size of the illuminated spot from the electron beam; limits the size of the raster line.

Transillumination: Illumination from the side of a display surface, to highlight information on the surface itself, e.g., lighting for automobile or aircraft instruments.

Wash out: The loss of contrast (i.e., reduction in dynamic range) in an LED as the ambient light reflected off the background of the display surface approaches the light level of the active area.

91.1 Introduction

The cathode ray tube (CRT) is unequalled in its ability to produce dynamic, quality, high-information-content imagery at high resolution. Even more impressive is that it achieves this for a lower cost per pixel than any other comparable electronic display technology. For the instrument designer requiring a high-information-content display, it offers numerous advantages. As a raw image tube, it is commonly available as an off-the-shelf item with a broad infrastructure of vendors, integrators, support, and part suppliers. Interface standards are well established and as a complete system, ready to take a standard signal input, it is available worldwide in a variety of performance ranges. To meet different application requirements, it is available in diagonal sizes from 12 mm to over 1 m with resolution from thousands of pixels to over 5 million pixels per frame. Tube characteristics improve on a yearly basis, and prices continue to decrease. Stanford Resources has been tracking the CRT market for almost 20 years, and is an excellent source of information. In its latest report, it indicates that despite competition from other display technology, the CRT will remain the single largest market in the display industry. The worldwide market for CRT tubes in 1997 was 261 million units worth \$26 billion U.S. This is expected to grow to 341 million units worth more than \$34 billion by 2003 [1, 2]. Although there are many competing information display technologies, the CRT will be with us well into the 21st century.

91.2 History

The CRT has a rich and distinguished history. The roots of today's CRT technology extend back more than 100 years to the latter half of the 19th century. Eugene Goldstein first introduced the term *cathode rays*; John W. Hittorf, Heinrich Geissler, Julius Plücker, and others made important contributions specific to CRT technology [3]. Throughout the 19th century, researchers were interested in the nature of a luminous gas discharge and shadowy rays that occurred when a high voltage potential was applied between two electrodes in a vacuum. Sir William Crookes was an active experimentalist in this field, and early cathode ray devices came to be known as Crookes tubes. Crookes noted that a glow was generated by the surface that the rays struck; the rays themselves were not the source of light. By producing tubes with a vacuum of 1.3×10^{-4} Pa (10^{-6} torr), he eliminated the luminous gas discharge and worked directly with the cathode rays [4]. Crookes demonstrated the following: luminance depended directly upon the material properties of the surface the rays struck; a magnetic field would deflect the path of the rays; the deflection was proportional to the strength of the magnetic field; and a magnetic field could be used to focus the rays into a beam. He also suggested the rays emitted by the cathode were a stream of charged tiny particles, which were soon to be identified by Joseph John Thomson as electrons. Continuing CRT experimentation led to the discovery of x rays by Wilhelm Konrad Röntgen in 1895.

Ferdinand Braun was the first person to envision the CRT as a tool for the display of information and is generally credited with the invention of the first device to be a direct forerunner to the modern CRT [5]. Braun in 1896 designed a CRT “indicator tube” for monitoring high frequencies in power-generating equipment. His design contained all of the same elements as today's CRTs. It utilized a cathode as an electron source, two control coils for vertical and horizontal deflection, an anode for electron acceleration and beam control, and a focusing slit. He also incorporated a phosphor screen normal to the beam for tracing its path. Although crude by later standards, this was the direct prototype for CRT oscilloscopes. In 1903 to 1905 Arthur Wehnelt added several very significant advances to Braun's design. Wehnelt developed and implemented a hot oxide-coated cathode and a beam control grid [5]. This lowered the voltage necessary to generate the electron stream and provided for much finer control of the beam current. These developments were the forerunner of the modern electron gun.

The CRT remained mostly a laboratory device until three important applications ushered it onto the center stage of information display: oscilloscopes, television, and military radar. By the early 1900s oscilloscopes were being widely used for the study of time-varying electric circuits in communication. Television was developed in the 1920s and in July of 1930 the National Broadcasting Company began the experimental broadcast of television in New York City. During World War II the CRT underwent a second wave of maturation with the advent of radar technology. By the end of the 1940s the TV-CRT was available as a consumer product. In the 1950s RCA perfected shadow mask technology and before long color became a new standard, gaining wide consumer acceptance in the 1960s. While the principal components of a CRT system have not fundamentally changed in many decades, the CRT has continued to improve.

91.3 Image Formation with a CRT

Although there are many different CRT designs, some of which are quite intricate, the process of forming an image using a CRT is straightforward. The procedure can be divided into four basic stages: beam formation, beam focusing, beam deflection, and energy conversion. These stages occur in four different regions of the CRT and follow in order from the rear of the tube (the neck) to the faceplate. As shown in Fig. 91.1, the elements at the rear of the tube are collectively called the electron gun.

Beam Generation with the Electron Gun

The cathode generates the stream of electrons used to form the image-writing beam. The traditional cathode is a metal conductor such as nickel coated with a thin layer of oxide, typically a barium strontium compound. To reduce the voltage required to generate electron emission, the cathode is heated to 700

FIGURE 91.1 Example of a typical CRT with electromagnetic focus, and electromagnetic deflection. This type of tube design is usually used for demanding applications such as bright, high resolution image projection. Tubes like this are available from a number of manufacturers such as Sony, Matsushita, and Thomson.

to 1200°C. Applications that require high brightness often use more advanced and expensive dispenser cathode designs to increase the beam current while maintaining reasonable cathode life. These designs incorporate complex cathode structures and materials such as barium ceramics, molybdenum, rhenium, and tungsten. Readers interested in advanced cathode designs and additional information on CRT materials technology should consult References 6 through 10. The flow of electrons from the cathode is controlled by varying the potential between the cathode and a series of control grids commonly known as G1 (the control grid) and G2 (the acceleration grid). A voltage potential of 100 to 1000 V between G2 and the cathode creates the potential necessary to pull a stream of electrons off the cathode, forming the beam. The beam amplitude can be controlled and even completely shut off by varying the potential on G1. Thus, the voltage at G1 controls brightness because the brightness is proportional to beam current. The design of the cathode with respect to impedance and loading influences the maximum rate at which the beam can be modulated. The cathode and its associated control grids can be designed to produce a crossover flow of electrons or a laminar flow. In crossover gun designs, the emitted electrons converge to a point in front of the cathode. By using electron optics, this beam spot is imaged onto the phosphor screen. Due to inherent advantages, the crossover design is widely used. A crossover beam is narrow, making it easier to deflect than a thicker beam, and the spot can be very small, improving resolution at the screen. In theory, a laminar flow design provides for the possibility of higher beam current from a similar-sized cathode. In practice, the improvement is not usually advantageous enough to offset the added difficulty of controlling a wider beam.

Electron Beam Focusing

Beam focusing and beam current are critical in determining the final spot size and thus the resolution of the CRT. Focusing a beam of electrons is directly analogous to focusing a beam of light; the discipline is called electron optics. Concerns familiar to optical imaging such as magnification, spherical aberration, and astigmatism also confront electron optics. As CRTs become larger, and operate at higher deflection angles, spot control becomes critical. Beam focusing is achieved using either electrostatic focusing grids or electromagnetic focusing coils. Electrostatic focus is the most extensively used technique. It can be found in use in applications from television to desktop computer monitors. Electrostatic focus is achieved by applying a succession of potentials across a complex sequence of focusing grids built into the electron gun. As designers seek to improve performance further, grid designs have become intricate [11, 12]. Magnetic focus is the system of choice for all high-performance systems where resolution and brightness

are design objectives. Magnetic lenses are better at producing a small spot with few aberrations. External coils in a yoke around the neck of the tube control the beam. Since it provides superior performance, electromagnetic focus is common on high-resolution commercial systems. Magnetic focus can also be achieved using permanent magnets and specialized hybrid electrostatic/magnetic focus components. Due to the tremendous impact focus has on resolution, tube suppliers continue to improve focus control [13, 14]. For an excellent and comprehensive treatment of electron physics in CRTs, beam control, detailed design discussions, and other aspects of CRT devices, consult Sol Sherr's textbook [15].

Electron Beam Deflection

The beam deflection system is responsible for controlling the position of the spot on the front face of the CRT. As with focusing, beam deflection techniques can be electromagnetic or electrostatic. A magnetic deflection system consists of two electromagnetic yokes on opposite sides of the CRT neck; a horizontal deflection coil and a vertical deflection coil. The position of the beam is easily controlled; the amount of beam deflection is directly proportional to the current in the coil. Deflection coil design also influences spot size and shape. Coil designs can incorporate correction for coma, convergence errors, and pincushion distortion [16]. Because of its low cost and efficiency, CRTs for both moderate- and high-resolution applications normally use magnetic deflection. Electrostatic deflection provides faster beam displacement but less spot size control. It is typically used in oscilloscope systems, where resolution requirements are moderate and deflection speed is paramount.

91.4 CRT Addressing: Raster Scanning vs. Stroke

Raster scanning is the most common CRT addressing technique. In raster scanning the electron beam writes each frame one line at a time. This means the horizontal deflection system requires a higher bandwidth than the vertical deflection system. High-performance raster CRTs have a horizontal bandwidth of 15 to 150 kHz, and a vertical deflection bandwidth of 30 to 180 Hz. The information is written onto the front face of the CRT from left to right and top to bottom, one line at a time. Raster scanning can be interlaced or progressive (noninterlaced). In interlace scanning, each frame of information is decomposed into two fields. The first field consists of all of the odd-numbered lines in the original frame, and the second field contains all of the even-numbered lines. Each field is scanned onto the CRT at twice the frame rate. Commercial television is interlaced. In the U.S., the frame rate is 30 Hz and the field rate is 60 Hz; this scheme is known as the NTSC standard. PAL and SECAM are two other well-known commercial formats in use today. There are numerous other standards, both analog and digital, in use worldwide, each with slightly different scan rates, resolution/addressing formats, luminance and color encoding, and timing protocols [17, 18]. Interlace scanning is an engineering compromise that conserves transmission bandwidth, electronics bandwidth, and CRT bandwidth, while maintaining acceptable performance with respect to moving imagery, resolution, and flicker. Computer monitors employ a progressive raster scan. Each frame has one field. The display is generated line by line, in order from the first pixel to the last pixel. Frame rates for the typical desktop monitor vary from 60 to 85 Hz to over 180 Hz for specialized systems.

Stroke is an alternative addressing technique that was once quite common. The name for the technique comes from the phrase "the stroke of a pen." Stroke is a point-to-point addressing system. The beam is directed to the starting point of a line, turned on, and then moved directly to the end of the line. Because there are no raster lines, stroke CRT resolution is independent of direction and is limited primarily by spot size. Stroke addressing is excellent for low-information-content screens with detailed graphic characters or simple vector graphics. It provides extremely high quality drawing, clean lines, precise detail, and high speed while conserving power and bandwidth. Stroke systems address the CRT only where there is information, not the entire screen as in raster scanning. This technique is uncommon today because it is too slow and computationally intensive for systems that have high information content, gray scale, or imagery.

FIGURE 91.2 Phosphors can have a wide range of spectral characteristics. This graph illustrates the spectral profiles of two representative cases. The blue source is an example of a phosphor with a wide and smooth profile. The maximum output for this phosphor is in the blue at a wavelength of 452 nm. The red phosphor shows a sharper profile with several narrow peaks. The largest peak for this phosphor is at 612 nm.

91.5 The Phosphor Screen

The phosphor functions as the CRT transducer. It converts the energy of the electron beam into light. This conversion process is called cathodoluminescence. CRT phosphors are inorganic crystalline materials doped with one or more impurities called activators and coactivators. Phosphors emit light in two ways, fluorescence and phosphorescence. Fluorescence is the emission of light by the phosphor material while it is under bombardment by the electron beam. The continued emission of light after the bombardment has ceased is called phosphorescence. The length of time phosphorescence lasts is known as persistence. Persistence can vary from tens of nanoseconds to many minutes, or even hours. CRTs take advantage of both forms of cathodoluminescence. Briefly, cathodoluminescence occurs when the electron beam excites the electrons of the phosphor into higher, unstable energy states available due to the presence of the activators. When the electrons transition back to their stable states, light is emitted. The choice of phosphor depends on the requirements of the application with respect to wavelength characteristics (narrow emission spectra or broadband emission), color, brightness, resolution, and persistence. Commercial television CRTs typically make use of the following phosphor powders: ZnS:Ag:Cl (blue), Zn(Cd)S:Cu:Al or ZnS:Cu:Au:Al (green), and Y₂O₂S:Eu [19]. Television CRTs use moderately short-persistence phosphors. This ensures a new frame does not exhibit blurring due to the previous frame. Traditionally, phosphors for radar displays, where the screen is refreshed infrequently, had a mix of short and long persistence. However, with the advent of today's digital systems, the use of long-persistence phosphors has declined. The Electronics Industries Association maintains an information database of commercial phosphors for CRTs. The interested reader should consult its publication TEP116-C [20]. [Figure 91.2](#) illustrates the spectral characteristics of several typical phosphors.

91.6 Color CRTs Using Shadow Masks

Color has been a part of the CRT world since the early 1950s. A sound understanding of human color perception is important for a detailed understanding of color in CRTs. Readers interested in an excellent comprehensive treatment of color science should consult Wyszecki and Stiles [21] or Robertson and Fisher [22] for a brief overview. The most common method of introducing color to the CRT is the three-gun shadow mask technique. The shadow mask is a metal grid of many tiny apertures held in place

immediately before the phosphor screen. The phosphor screen is an array of three different phosphor subpixels. Three electron guns are placed closely together in the neck of the tube, one gun for each one of the primary colors (red, green, and blue). The guns make a small angle with respect to each other. The shadow mask and beams are aligned so that each beam falls on the appropriate phosphor dot. The dots are placed closely together so the eye spatially integrates the subpixels into a continuous blend of color. There are two common configurations, delta and in-line. Delta, the traditional method, arranges the electron guns and the phosphor dots in a triad. This requires a shadow mask consisting of a grid of circular apertures. More recently, Sony introduced the Trinitron™ design. In the Trinitron tube the guns are placed in line, the shadow mask consists of vertical slots, and the phosphors are in vertical stripes. The design offers improved vertical resolution and is easier to converge, but the mask is slightly more difficult to support and is subject to thermal stress problems.

Trinitron continues to be an important and popular design [23]. The shadow mask technique of producing a color image has three main drawbacks. First, the shadow mask typically absorbs more than 75% of the electron beam energy, limiting brightness and causing undesirable thermal effects. Second, both require precise beam control to converge the three different images from the electron guns. Third, the resolution of the display is limited by the requirements of spatial color; three subpixels are needed to make each full-color pixel.

91.7 Alternative Techniques for Realizing Color Using CRTs

There are alternative approaches to producing color with CRTs. In its own way, each seeks to improve upon one or more of the enormously successful shadow mask designs. The three most noteworthy challengers are beam index tubes, penetration phosphor tubes, and field sequential color systems. All three have been around for decades, but only field sequential color systems are commercially available.

Beam Index and Penetration Phosphor Tube Designs

A beam index tube uses a slotted mask and vertical phosphor stripes. One electron beam is focused to less than the width of a phosphor stripe. A reflected ultraviolet signal from the mask provides a feedback signal. This signal is used to index the position of the beam very accurately. Color selection is achieved by precise beam positioning and rapid beam modulation. Although beam indexing offers perfect convergence, few guns, energy savings, and high resolution, practical problems in control and manufacturing have left this approach unrealized. Penetration tubes are potentially even more advantageous since color is produced with one electron gun and no mask is required. The phosphor screen consists of a layering of several different phosphors. There are many approaches to the layering structure, but the basic principle is that each layer produces a different color. To select among the different colors, the beam energy is varied, altering its layer penetration. In theory, multiple layers of phosphors could be used to produce a full-color display. Unfortunately, this design requires high switching voltages, and the color purity is poor because of the dilution caused by leakage from the unselected phosphor layers. In the past, a few two-color systems have been produced on a limited basis with stroke writer systems (p. 147 of Reference 4).

Field Sequential Color

Field sequential color (FSC) is a different approach to realizing color using a monochrome CRT and color filters [24]. The shadow mask relies on the ability of the eye to perform a *spatial integration on a group of color elements*. Field sequential color exploits the ability of the eye to perform a *temporal integration of color fields*. Field sequential color is not a new concept; it was an early design suggestion for commercial color television. To implement field sequential color, each full-color frame is decomposed into primary color fields (red, green, and blue). Each of these color fields is displayed sequentially on a monochrome CRT while simultaneously a color filter is placed over the front of the CRT. The filters must

be rapidly changed to stay in sequence with the individual fields which are displayed at three times the desired frame rate. This sequence is so quick that the eye fuses the individual color fields into a steady blend of continuous color. Field sequential color systems have all of the advantages of a monochrome CRT, namely, superior resolution and simplicity. The major historical drawbacks to field sequential color have been the difficulty in controlling a bulky, spinning, mechanical filter wheel, and two thirds of the light energy of the phosphor is thrown away in each field. In the past, some viewers have reported the ability to perceive the individual color fields intermittently; this artifact is known as “color break up.” Field sequential color systems have seen a commercial rebirth due to several factors. The luminous efficiency of several phosphors has improved to the point where the light loss penalty is no longer a severe price to pay. Awkward, mechanical filter wheels have been replaced by several different types of compact, low-power, liquid crystal shutters. The use of faster frame rates and digital sampling techniques has reduced color artifacts. And finally, monochrome CRTs using field sequential color meet the growing market need for small high-resolution displays.

91.8 Image Quality and Performance

For any display technology, the ultimate test of performance and quality is how the image looks to the viewer in a real-world environment. This is highly subjective, but critical none the less. [Table 91.1](#) highlights some important parameters associated with performance and image quality. Resolution is the most critical characteristic of any CRT. A note of caution, resolution should not be confused with addressing. A system can have a precise addressing format, but if the spot is too large the CRT resolution capability will be poor despite the addressing format. Alternatively, if the spot is precise and the addressing format is coarse, the *image* will be low resolution, but the CRT resolution will be high. Resolution is affected by almost every system parameter: spot size, focus, deflection, raster format, the mask, and beam current. For a perfectly designed system, line width and spot size will ultimately determine the resolution. Spot diameter is limited by the quality of the electron optics, the particle size and thickness of the phosphor layer, and beam current. The cross section energy distribution of the electron beam is approximately Gaussian. The higher the current, the larger the beam cross section. Scattering by individual phosphor particles also increases the spot size. Thus, high resolution is much more difficult to achieve for high-brightness applications. The champions of small spot sizes are the small 12 to 25 mm monochrome CRTs. Several commercial systems achieve $\leq 25 \mu\text{m}$ spot sizes, and sizes $\leq 15 \mu\text{m}$ have been reported [25]. Monochrome CRTs in the 53 cm class (21-in.) have spot diameters $\leq 150 \mu\text{m}$. Color CRTs with shadow mask pitches $\leq 250 \mu\text{m}$ are available in sizes up to 21 in. at commodity prices, and this will continue to improve. Spot size does not tell the whole resolution story. In most systems something other than spot size limits performance. The scan format may be well below the performance of the CRT, the bandwidth of the support electronics is frequently less than the tube bandwidth, and, for color, the shadow mask will limit resolution more than spot size. Engineers can still design a CRT that maintains its performance even with state-of-the-art electronics. MTF (modulation transfer function) is the standard metric for resolution. MTF compares the modulation of the displayed output with the modulation of a known input signal. As the spatial frequency of the input increases, the performance of the output will show a steady roll-off in modulation depth and quality. Readers interested in an introduction to this complex topic should consult Infante’s review [26]. Contrast and its related companion, gray scale, are also important to CRT image quality. Since contrast can be measured and stated in so many different terms, gray scale is probably a more practical indicator of performance from a user’s standpoint. As it attempts to replace traditional film, the medical imaging community demands the most of the monochrome CRT. Medical CRTs can produce up to 256 shades of gray with 8-bit controllers. Systems are available that will do 10-bit monochrome and color. Although frequently quoted, *shades of gray* is not a true indication of CRT performance and should not be confused with true *gray scale* capability. Shades of gray is a characteristic of the image source and the capability of the electronics; gray scale reflects the capability of the CRT. Gray scale is typically defined as a series of steps in brightness in increments of

TABLE 91.1 Parameters That Influence CRT Performance and Image Quality

Resolution	Spot size and shape Focus accuracy Line width Addressing/scan format Shadow mask design
Luminance	Dynamic range Maximum brightness Gray scale in high and low ambient light Gray scale vs. display brightness Phosphor luminous efficiency
Contrast	Contrast under high ambient illumination Contrast under low ambient illumination Large area contrast Pixel-to-pixel contrast (small area)
Image fidelity	Frame rate Flicker/refresh Uniformity and linearity Aberrations (linearity, pincushion, barrel distortion, keystone, and focus)
Color	Phosphor selection Convergence accuracy Color gamut and saturation Color uniformity Color accuracy
Bandwidth	Video bandwidth (cathode design) Horizontal deflection design Vertical deflection design Bandwidth of the CRT supporting electronics Bandwidth of the signal delivery electronics

$2^{1/2}$ from black to maximum CRT output. Thus, gray scale is a realistic indicator that combines CRT dynamic range, contrast ratio, halation, and ambient reflections. More than 12 steps of gray scale is considered good performance.

The subject of display image quality and evaluation is an important topic. In addition to resolution and gray scale, users and designers need to consider many other metrics, such as luminance, dimmability, contrast, readability, color, persistence, and convergence. Users may also be aware of visual distortions such as pincushion, barrel, and keystone. A discussion of these topics and the other issues raised by Table 91.1 is beyond the scope of a single chapter; indeed, it has been the subject of books. There are good sources of information in this area [15, 27]; in particular, Keller's [28] text is superb. It is essential to remember that no matter which metrics are used, the most single most important metric is the subjective determination of the end users. Although many factors will affect final display performance, the bottom line remains *how good does the display look* in the real-world application environment it was designed to meet.

91.9 CRT and Phosphor Lifetime

The lifetime of a CRT depends on how it is driven. The higher the beam current, the more rapidly its performance will degrade. In general, degradation is due to a failure of three parts of the CRT — the cathode, the phosphor, and the glass. Brighter displays require higher beam current, and this, in turn, requires a higher level of cathode loading. Oxide cathodes can comfortably operate with a loading range of 0.1 to 10 A/cm². This will provide a typical lifetime in the range of 10,000 h. Dispenser cathode designs can improve cathode life 2 to 3 times, but again individual cathode life depends on how much brightness the user regularly demands from the tube. Phosphor degradation is the second mechanism affecting CRT lifetime and performance. All phosphors degrade under constant electron bombardment, an effect called phosphor burning. The rate of degradation is related to beam current, anode voltage, and material

TABLE 91.2. The Strengths and Weakness of CRT Technology

Advantage	Weakness
Highest resolution technology	High power consumption
Versatile addressing formats	Weight of glass
Excellent image fidelity	Size of footprint
High speed	Emits EM radiation
Bandwidth (≥ 350 MHz)	Must be refreshed
Excellent contrast/gray scale	
Good selection of phosphors	
High luminous efficiency	
Bright display (up to 20,000 fL)	
Excellent color gamut	
Simplicity of interface	
Universal interface standards	
Good design flexibility	
Broad application base	
Long life and reliability	
Mature and broad knowledge base	
Worldwide sources of tubes and parts	
Inexpensive — low cost per resolution element	

parameters specific to each phosphor. Today, there is a broad range of good phosphor materials with greatly improved aging characteristics. The third mechanism is glass browning. This effect is a complicated interaction between the high energy of the electron beam and the molecular structure of the glass [10]. In recent years, glass suppliers have made great strides in providing CRT manufacturers with improved glass materials. However, phosphor aging and glass browning are still important concerns, especially in extremely bright (high beam current) applications, such as CRT projection.

91.10 CRT Strengths and Weaknesses

With a century of development behind it, the CRT has abundant advantages that make it an attractive display option for the system designer dealing with high information content or dynamic imagery. [Table 91.2](#) lists some attributes, positive and negative, which the system designer should consider in evaluating whether or not to use CRT technology. The most notable traits of the CRT are flexibility and cost. CRTs can operate over a wide range of resolution formats from commercial television to the strict requirements of medical imaging and digital-to-film recording. One unit can easily be designed to accept a myriad of scan formats and resolutions from static text to dynamic imagery with megapixels at frame rates of hundreds of frames per second. This flexibility means the system can be upgraded later without having to redesign the display subsystem. Interfacing with the CRT is also straightforward; there are well-established standards and hardware for many scan formats from the television NTSC to the RGB standards of the personal computer industry. Finally, cost is important to emphasize; CRTs are inexpensive. The desktop CRT delivers its performance for $\leq \$0.00005$ per color resolution element! Currently, no other high-information-content display technology can match this cost.

91.11 CRT Selection

The design requirements for (1) resolution, (2) brightness, and (3) screen size will quickly steer the system designer to a particular class of CRTs. If the design requirements are close to either television or desktop computer monitors, the choice is easy. There are literally hundreds of vendors offering integrated CRTs and electronic drivers as off-the-shelf items. Color shadow mask systems with more than 40 elements/cm are commonly available. If higher resolution is required, then medical imaging and film recorder CRTs may meet the requirements. Physically large display requirements can be supplied by

projection CRTs or by tiled CRTs using video wall processors. Small to miniature CRTs provide resolutions up to 500 to 600 elements/cm and portability. If the application falls out of the mainstream, the designer will need to speak directly with CRT vendors. Table 91.3 is a partial list of CRT suppliers. Since CRTs have been designed to satisfy a broad range of specialty applications, the chances are excellent that an acceptable design will already exist. If not, the CRT is so mature that vendors working from a proven experience base can design a tube directly to customer specifications with little in the way of design problems or surprises.

91.12 Future Trends in CRT Technology

CRT technology is mature, and the industry does not foresee major surprises on the horizon. The CRT will continue to evolve, resolution will improve, screens will be flatter, deflections angles will be larger, and footprints will be reduced. The computer world continues to demand more resolution. In 1987, the 36-cm (14-in.) VGA class monitor (640×480) with its 300,000 pixels and 16 colors was the new standard. In 1998, the 43-cm (17-in.) desktop monitor is now capable of 1600×1200 performance (1.9 megapixels) with 24-bit color. The 53-cm (21-in.) monitor class, once an expensive custom device, is also widely available. The trend of increasing resolution and performance for decreasing cost shows every sign of continuing. The medical community is quickly moving to monochrome systems with 12-bit gray scale at a resolution of 2560×2048 (5 megapixels). All of this means the instrument designer has better resolution and fidelity for less money.

There is a quiet revolution taking place in the information display industry, which may have a significant effect on CRTs and all information display technology. There is a design trend to decouple the resolution and fidelity of the display device from its physical size. There are a number of applications motivating this change: communications, military, portable computing, simulation, and virtual reality. This is why miniature CRT technology has been more active in recent years. This is also the engine driving some of the major competitors to the miniature CRT, such as on-chip field emission displays (FED), deformable mirror devices (DMD), ferroelectric liquid crystal integrated circuit displays, and on-chip active matrix liquid crystal display (LCD) technology. If realized, these promise to be low-cost solutions because they are built on the technology foundation of the silicon chip industry. These challengers have the very real potential of eliminating the miniature CRT, and in some application areas, the LCD panel as well. However, the CRT backed by its formidable 100 years of design evolution and maturity is not standing still; its assets and market remain impressive. Although it is one of the few

92.1 Introduction

Liquid crystals (LC) are an important class of materials with applications ranging from display devices, optoelectronic devices, sensors, and biological and structural materials. The focus of this chapter will be on LCs for display applications. In general, most substances have a single melting point where a solid possessing a positional and orientational order changes upon melting to an isotropic liquid that has neither positional nor orientational order. However, some materials when melted from the solid state change into a cloudy liquid with orientational order at one temperature, and upon further heating change into an isotropic liquid that has no order, as shown in Fig. 92.1. Thus, an LC is a mesophase existing between the melting temperature T_m , of a crystalline phase, and clearing point T_c , of the liquid phase; i.e., below T_m , the material has a crystalline phase, above T_c , it has a liquid (isotropic) phase, and between T_m and T_c it has a liquid crystal phase. This type of LC in which the mesophase is defined by the temperature (between T_m and T_c) is called a *thermotropic* LC. When the mesophase is defined by a solvent concentration, it is called a *lyotropic* LC. Thermotropic LCs are used for display applications. The orientational order in LC materials results in important physical properties, such as birefringence, that make these materials useful for display devices. Because LCs have the attributes of low drive voltage, low power consumption, thin form factor (flat panel displays), light weight, full-color, gray scale with a wide dynamic range, full motion video, superior image quality, and high reliability, LC displays (LCDs) are the preferred approach for battery-powered (portable) applications ranging from wristwatch displays and handheld TVs to laptop computer displays. They are also replacing cathode ray tubes (CRTs) in select applications such as avionic displays because of their high brightness and readability in sunlight.

FIGURE 92.1 Illustration of a solid, an LC, and a liquid. A solid has an orientational as well as a positional order for the molecules. An LC has an orientational order only. A liquid phase is isotropic with neither positional nor orientational order.

LCs are also being used in projection display devices for head-mounted display (HMD) and for large-screen display applications. The following will discuss the various types of LC materials, their properties, LCD materials and fabrication processes, various LCD modes, and display addressing methods. There are many good general references, for example, References 1 through 7, on LCs and LCDs. At the time of this writing, LCD technology is advancing very rapidly with respect to technology development for LCD products with improved viewing angles, improved image quality, lower power consumption, and larger display sizes. The purpose of this chapter, however, is to present the basic LCD principles and technologies, as opposed to reviewing the current state of the art.

92.2 Types of Liquid Crystal Materials

Most of the LC materials are organic compounds which consist of rod-shaped or disk-shaped molecules. For display applications, LC materials with rod-shaped molecules are the most commonly used. The LC materials are broadly classified into three types (phases) — smectic, nematic, and cholesteric — according to their molecular order, as shown in Fig. 92.2. In a smectic liquid crystal, the rod-shaped molecules are arranged in layers with molecules parallel to each other. There are many different smectic phases, but smectic A and smectic C are the most common. In the smectic A LC, the molecular axis (director) is perpendicular to the layers as shown in Fig. 92.2a, and in smectic C it is tilted at an angle from the layer normal as shown in Fig. 92.2b. Also, in the nematic LC, the rod-shaped molecules are parallel to each other, but the individual molecules move relatively easily in the direction along their axis without a layer structure, as shown in Fig. 92.2c. In the cholesteric LC, the molecules are arranged in a layered fashion as in smectic LC, but the molecular axis is in the plane of each layer as shown in Fig. 92.2d. In addition, the cholesteric LC shows a helical structure in which the director \mathbf{n} changes from layer to layer. The same LC material may have different LC phases at different temperatures. For example, the LC material may have a smectic C phase at a lower temperature, and as the temperature increases it may change to a smectic A phase and then to a nematic phase, before changing to an isotropic liquid phase at T_c .

The nematic LC is the basis for most widely used active matrix-addressed twisted nematic (TN) LCDs, and passive matrix-addressed supertwisted nematic (STN) LCDs. An example of a smectic C LC display is a passive matrix-addressed ferroelectric LCD [8]. An example of a cholesteric display is a passive matrix-addressed stabilized cholesteric texture (SCT) display with bistability [9]. A classic example of a nematic LC material is *p*-azoxyanisole (PAA) with a nematic phase in the range of 117 to 136°C.

FIGURE 92.2 Molecular orientation in (a) smectic A, (b) smectic C, (c) nematic, and (d) cholesteric LC phases.

In PAA, the two benzene rings are nearly coplanar and the rigid rod is about 20 Å long and 5 Å wide. Another historical example of a nematic LC is *N*-(*p*-methoxybenzylidene-*p*-butylaniline) (MBBA) with a nematic phase in the range of 22 to 47°C.

MBBA has a central group that connects the two ringlike cores firmly and serves to maintain the linearity of the entire LC molecule. The terminal groups and conjugated bonds in the core are largely responsible for the dielectric, optical, and other anisotropic properties of the material. Azoxy and Schiff's base compounds were among the materials used earliest in LCDs. Because of environmental stability problems, they were replaced by biphenyl materials. More recently, phenylcyclohexane, bicyclohexane, and estercyclohexane compounds are developed to satisfy the requirements of broad temperature operation and enhanced electro-optical characteristics. The LC materials used in current LCDs are highly developed mixtures of various compounds tailored to meet the requirements of environmental stability, wide operating temperature range, proper response to the applied electric field, high electrical resistivity for matrix addressing, and fast response time.

The degree of order in the LC is an important parameter, and is defined by the *order parameter*, S , given by

$$S = \frac{1}{2} \langle 3 \cos^2 \theta - 1 \rangle \quad (92.1)$$

where θ is the angle between the molecular axis and the predominant molecular orientation \mathbf{n} . The symbol $\langle \rangle$ represents averaging over the whole space. The predominant molecular orientation, which is known as the LC *director* \mathbf{n} is defined as the average alignment direction of the long molecular axis. For a perfect orientational order, i.e., when all the molecules align parallel to the director, as in a perfect crystal, $\theta = 0$ and thus $S = 1$. For no orientational order, i.e., for a completely random molecular orientation, as in an isotropic liquid, $S = 0$. In a typical nematic LC, S is in the range of 0.3 to 0.7, and in a typical smectic LC it is in the range of 0.7 to 0.8, with higher values at lower temperatures. Figure 92.3 shows the temperature dependence of S for the LC material PAA [10] as an example. The order parameter decreases rapidly to a value of around 0.3, close to the clearing point T_c , and becomes zero in the isotropic state. The exact dependence of S on temperature T depends on the type of molecules considered. However, the following analytical expression derived from theory has been shown to be useful [11]:

$$S = \left(1 - \gamma \cdot T / T_c \right)^{\beta} \quad (92.2)$$

FIGURE 92.3 Temperature dependence of the order parameter S of the nematic LC $P =$ azoxy anisole (PPA) [10]. S decreases with increasing temperature T , and rapidly approaches 0 near the clearing temperature, T_c .

where T_c corresponds to nematic–isotropic transition, γ is of the order of 0.98, and β is an exponent in the range of 0.13 to 0.18 depending on the material in question.

92.3 Physical Properties of Liquid Crystals

Because of ordered structure with the molecules aligned with their long axis parallel to each other, LC molecules exhibit anisotropic properties. That is, various physical properties, such as dielectric constant ϵ , refractive index n , magnetic susceptibility χ , conductivity σ , and viscosity η , have different values in the direction parallel (\parallel) and perpendicular (\perp) to the molecular axis. The anisotropic physical properties, in conjunction with the ease of controlling the initial orientation (boundary condition) by surface alignment and the ease of reorienting the molecular axis by applying a voltage, is the basis for application of LCs for displays. The following will discuss the anisotropy of the dielectric constant and refractive index, elastic constants, and electro-optical characteristics which are important in the use of LCs for displays.

Dielectric Anisotropy

LC molecules exhibit dielectric anisotropy because of their permanent and induced dipoles. The dielectric anisotropy, $\Delta\epsilon$, is expressed as

$$\Delta\epsilon = \epsilon_{\parallel} - \epsilon_{\perp} \quad (92.3)$$

where ϵ_{\parallel} and ϵ_{\perp} are the dielectric constants measured parallel and perpendicular to the LC director. Materials that exhibit positive dielectric anisotropy ($\Delta\epsilon > 0$) are referred to as p -type materials and the materials that exhibit negative dielectric anisotropy ($\Delta\epsilon < 0$) are referred to as n -type materials. The p -type LC materials tend to align themselves with their molecular axis parallel to the applied electric field, whereas n -type materials align themselves with their molecular axis perpendicular to the applied field. Generally, the dielectric constant ϵ_{\parallel} decreases with increasing frequency [12] due to the relaxation phenomenon. However, ϵ_{\perp} is independent of frequency over a large range of frequencies. At the crossover frequency, f_c , where $\epsilon_{\parallel} = \epsilon_{\perp}$, the LC material becomes isotropic. Depending on the material, this frequency, f_c , falls in the range of 100 kHz to >1 MHz. The dielectric constants ϵ_{\parallel} and ϵ_{\perp} also change as a function of temperature [13], as shown in Fig. 92.4 for the nematic LC cyanobiphenyl. The two dielectric constants rapidly converge as the temperature approaches T_c , where $\epsilon_{\parallel} = \epsilon_{\perp} = \epsilon_{\text{isotropic}}$.

FIGURE 92.4 Temperature dependence of dielectric constant of the nematic LC cyanobiphenyl at a frequency of 100 KHz [13] exhibiting positive dielectric anisotropy ($\epsilon_{\parallel} > \epsilon_{\perp}$). ϵ_{\parallel} decreases with temperature, whereas ϵ_{\perp} increases with temperature until both are equal at the clearing temperature corresponding to the isotropic liquid.

Refractive Index Anisotropy

An LC is birefringent with anisotropic refractive indices. It has two principal refractive indices, n_o and n_e , as shown in Fig. 92.5. For the ordinary refractive index n_o , the electric field vector of the light beam oscillates perpendicular to the optic axis, and for the extraordinary refractive index n_e , the electric field vector oscillates parallel to the optic axis. In the nematic and smectic LCs, the direction of the LC director \mathbf{n} is the optic axis of the uniaxial crystal and therefore the refractive indices for light rays with oscillations in the directions parallel and perpendicular to the director are n_{\parallel} and n_{\perp} , respectively, i.e., $n_o = n_{\perp}$, $n_e = n_{\parallel}$, and the optical anisotropy or birefringence, Δn , is given by

$$\Delta n = n_{\parallel} - n_{\perp} = n_e - n_o \tag{92.4}$$

FIGURE 92.5 Refractive index anisotropy of uniaxial LC.

FIGURE 92.6 (a) Temperature dependence of the refractive indices $n_{||}$ and n_{\perp} for a nematic LC MBBA at $\lambda = 546$ nm; (b) wavelength dependence of refractive indices of the nematic LC 4-butoxyphenyl ester of 4'-hexyloxybenzoic acid at 80 $^{\circ}\text{C}$.

Fig. 92.6a and b show the temperature dependence [2] and wavelength dependence [2] of the refractive indices of typical LC materials. The dependence of refractive index on wavelength λ is generally expressed by the so-called Cauchy equation:

$$n_{o,e} = n_{\infty} + \alpha_{o,e} / \lambda^2 \quad (92.5)$$

where n_{∞} is the refractive index extrapolated to infinite wavelength and α is a material-specific coefficient.

Elastic Constants

In uniaxial LCs, the preferred or equilibrium orientation of the LC molecule is given by the director \mathbf{n} , which may be imposed by the surface treatments at the boundary conditions or by an external field. When the LC is perturbed from an equilibrium condition by application or removal of an external field, the elastic and electrical forces determine the static deformation pattern of the LC. The transition of the director from one direction to the other induces curvature strain in the medium. Frank [14] showed that an arbitrary deformation state can be envisaged as the combination of three basic operations; *Splay*, *Twist*, and *Bend*, denoted by the elastic constants K_{11} , K_{22} , and K_{33} following the notation of the Oseen–Frank theory. Figure 92.7 illustrates the *Splay*, *Twist*, and *Bend* deformations. The elastic part of the internal free energy, F , of a perturbed liquid crystal is given by the equation:

$$F = \frac{1}{2} \left[K_{11} (\nabla \cdot \mathbf{n})^2 + K_{22} (\mathbf{n} \cdot \nabla \times \mathbf{n})^2 + K_{33} (\mathbf{n} \times \nabla \times \mathbf{n})^2 \right] \quad (92.6)$$

The free energy density is thus a quadratic function of the curvature strains with the elastic constants appearing as constants of proportionality. The elastic constants K_{11} , K_{22} , and K_{33} are temperature dependent, and decrease with increase in temperature. The magnitudes of the elastic constants, K_{ij} , can be approximated [15] by

$$K_{ij} \propto S^2 \quad (92.7)$$

Electro-Optical Characteristics

When an electric field is applied to an LC with an initial molecular (director) orientation, it will change to a new molecular orientation due to the dielectric anisotropy ($\Delta\epsilon = \epsilon_{||} - \epsilon_{\perp}$) of the LC. This change in

FIGURE 92.7 Deformation of nematic LC molecules from equilibrium configuration is shown in (a). Three types of deformations — (b) splay, (c) twist, and (d) bend can describe all possible types of deformations.

molecular orientation is accompanied by a change in the optical transmission/reflection characteristics of the LC which forms the basis for LCDs. This phenomenon of an electrically driven optical modulation is known as the electro-optic effect of the LC. When an electric field E is applied to an LC, it produces an electric energy, f_e , given by

$$f_e = -\frac{1}{2}\epsilon_{\perp} E^2 - \frac{1}{2}\Delta\epsilon(n \cdot E)^2 \quad (92.8)$$

The initial molecular orientation (boundary condition achieved by surface alignment) of the LC molecules (director \mathbf{n}) is either parallel (for $\Delta\epsilon > 0$) or perpendicular (for $\Delta\epsilon < 0$) to the plane of the two parallel electrodes of the display. When a field is applied across the parallel electrodes with the LC material in between, the director \mathbf{n} orients parallel to the electric field E in $+ve \Delta\epsilon$ materials, and it orients perpendicular to the field in $-ve \Delta\epsilon$ materials. The total free energy, F , of the LC when the initial undeformed molecular orientation undergoes deformation due to the applied field is given by the sum of the electric energy f_e and the elastic energy. This transition from an undeformed state, known as *Freedericksz transition*, occurs as the field is increased to a critical field E_c . The Freedericksz transition is simply a transition from a uniform director configuration to a deformed director configuration; i.e., at any point in the LC, the order of the molecules relative to one another remains the same. The threshold electric field, E_c , is calculated by a free energy minimization technique [3], and it is given by

$$E_c = (\pi/d)(K_{ii}/|\Delta\epsilon|)^{1/2} \quad (92.9)$$

Thus the threshold voltage V_{th} of the LC electro-optic effect is given by

$$V_{th} = E_c \cdot d = \pi(K_{ii}/|\Delta\epsilon|)^{1/2} \quad (92.10)$$

In Equations 92.9 and 92.10, d is the thickness of the LC and k_{ii} is the appropriate elastic constant. When the field is perpendicular to the initially homogeneous orientation of the director, $K_{ii} = K_{11}$ or K_{22} . When the field is parallel to the initially homogeneous orientation, $K_{ii} = K_{33}$. In the case of a twisted orientation, $K_{ii} = K_{11} + (K_{33} - 2K_{22})/4$.

92.4 LCD Materials and Fabrication Processes

There are several types of LCDs utilizing different LC materials and LCD modes which are discussed in the next section. However, the general display assembly processes and materials are very similar for all

FIGURE 92.8 Plan (a) and cross-sectional view (b) of a passive matrix-addressed LCD.

these LCD modes. [Figure 92.8a and b](#) show the plan and cross-sectional view of a passive matrix-addressed LCD. The display fabrication can be broadly divided into three parts: (1) lower and upper glass fabrication processes, (2) cell assembly processes, and (3) polarizer and driver attachment and module assembly processes as illustrated in [Fig. 92.9](#). The following will describe the various display materials and the assembly processes.

Glass Substrate

The quality of the glass substrate is important with regard to its chemical compatibility with the LC materials, surface flatness, defects, and dimensional stability under processing temperatures associated with various display fabrication steps. With a typical LCD cell gap in the range of 5 to 10 μm , the importance of the glass flatness and surface quality is clear. Glass substrate defects such as voids, scratches, streaks, and attached particles can cause electrode defects and hinder uniform LC cell spacing. Therefore, depending on the type of display, glass substrates are sometimes polished to achieve the required surface quality. Typical display glass materials include borosilicate (e.g., Corning 7059) and aluminosilicate glasses (e.g., Corning 1737), with a thickness of 0.7 or 1.1 mm.

Color Filters

In full-color LCDs, color most often is generated by use of red, green, and blue (R, G, B) color filters fabricated at each pixel, as shown in [Fig. 92.8b](#), using a white backlight system. The color filter require-

FIGURE 92.9 LCD assembly flowchart.

ments include proper spectral transmission characteristics and chemical, thermal, and dimensional stability. The display color gamut is a function of the spectral characteristics of the backlight used and the color filter transmission characteristics. By a suitable choice of these parameters, an LCD can achieve a color gamut comparable to a that of a high-quality CRT. However, trade-offs are sometimes made between color purity and transmission (brightness) characteristics of the LCD. Typical color filter thickness is about 2 μm . Color filter materials include dye and pigment dispersed polyimides and photoresists. The color filter materials are applied on the display glass by various processes, such as spin coating, printing, electrodeposition, and photolithography. First, color filter material of the first color is applied and photolithographically patterned. Then, the color filter material for the second color is processed, and then the third. A black matrix material is also applied and patterned between the color filters to block the light transmission from the interpixel regions. In some cases, a passivation layer such as low-temperature SiO_2 dielectric is deposited on the color filters to act as a barrier for impurities and to achieve a smooth surface for the subsequent transparent electrode deposition.

Transparent Electrodes

Most often, indium tin oxide (ITO) with a typical concentration of 90% In_2O_3 and 10% SnO_2 is used as the transparent conducting electrode material. The typical transmission of ITO is about 90%. It is

generally deposited by e-beam evaporation or sputtering in an oxygen-containing atmosphere. The film thickness is typically 50 to 300 nm depending on the required sheet resistance and transmission. Typical resistivity is in the range of $2 \times 10^{-4} \Omega\text{-cm}$. Light transmission through ITO is not linearly proportional to the film thickness because of light interference.

Alignment Materials and Techniques

After the transparent electrodes are patterned, an LC alignment coating is applied. Depending on the display mode of interest, either a homogeneous (parallel), tilted, or a homeotropic (vertical) alignment is achieved using an appropriate alignment material and process. The most commonly used TN LCD requires a tilted alignment to eliminate reverse tilt disclinations. Inorganic films such as an obliquely evaporated SiO₂, as well as organic materials such as polyimide, can be used as alignment materials. Polyimide is most commonly used as an alignment layer. It is spin-coated or printed to achieve a layer thickness of about 50 nm, and cured around 150 to 200°C. It is then buffed (rubbed) using a roller covered with cotton or a synthetic fabric. For TN LCD, the alignment process is selected to achieve a pretilt angle of around 2 to 5°.

Cell Spacing and Sealing

The cell assembly process starts after the alignment layer treatment of the two substrates by rubbing. To control the LC cell spacing (thickness) accurately, spacing materials are applied in the active area of the display as well as in the peripheral seal area, where the two glass substrates are sealed. Typical spacing materials include glass or plastic fibers (cylinders) or spheres (balls), with a tightly controlled size (diameter) distribution. A sealing adhesive material such as an epoxy is then applied at the seal area with an opening (fill hole) left for LC material injection after the sealing process. The seal is typically 1 to 3 mm wide and is a few millimeters from the active display area. The requirement for the seal material is that it must not chemically react with (contaminate) the LC material and must be a barrier against moisture and contamination from outside. After the spacers and seal materials are applied on the first (active) substrate, it is precisely aligned to the second (color filter) substrate, and the seal is cured either by heating it to a higher temperature, typically 100 to 150°C, or by ultraviolet exposure depending on the type of epoxy seal material used.

LC Material Filling

After the empty cell is fabricated, it is filled with the LC material. Because the cell thickness (spacing) is small (~ 5 to 10 μm), it is filled using special techniques. The most popular filling method is by evacuating the cell in a vacuum chamber, dipping the fill hole into a vessel containing the LC material, and increasing the pressure in the chamber. As the chamber pressure is raised, the cell gets filled by capillary action. After the cell is completely filled, the fill hole is capped by using an epoxy adhesive that is chemically compatible with the LC material.

External Components

The external components of an LCD include polarizers, reflectors, display drivers, and a backlight assembly. A reflective LCD uses a reflector at the back of the display, works by modulating the ambient light, and does not require backlighting. In the most commonly used transmissive mode TN LCDs, a polarizer is attached on the front as well as back surfaces of the LCD after the cell assembly is complete. Also, in the most commonly used normally white mode TN LCD, the polarizers are attached with their polarization axis crossed and along the rubbing directions of the alignment layers. The polarizer is a three-layer composite film with a stretched iodine doped polyvinyl alcohol (PVA) polarizing film in the center, and two outer films of triacetyl cellulose (TAC) for protecting the PVA film from the ambient

(moisture, temperature, and harsh environment) conditions. A typical transmission range of a polarizer is 41 to 45%, with a polarization efficiency in the range of 99.9 to 99.99%.

The display row and column IC drivers are attached to the row and column bond pads of the display either by TAB (tape-automated bonding) using an ACA (anisotropic conductive adhesive), or chip on glass (COG) approaches. For backlighting transmissive LCDs, a fluorescent lamp is generally used. The R, G, B emission spectrum of the backlight and transmission spectrum of the R, G, B color filters are tuned together to achieve the desired color coordinates for the primary colors. Also, a diffuser is used to achieve uniform backlighting of the display. The backlight system may also use brightness enhancement films to tailor the light intensity distribution in the viewing cone. In addition to the above components, LCDs for specialized applications requiring enhanced performance may use a cover glass with EMI and antireflection coatings at the front, and a heater glass at the back side (between the backlight and the LCD) which facilitates low-temperature operation.

92.5 Liquid Crystal Display Modes

LC displays based on many different modes of operation have been developed. Historically, the phase change (PC) effect was discovered first in 1968 by Wysoki et al. [16]. The same year, dynamic scattering (DS) mode [17] and guest–host (GH) mode [18] were announced by Heilmeyer et al. Then in 1971, the TN mode [19] was reported by Schadt and Helfrich and electrically controlled birefringence (ECB) was reported by Schiekell and Fahrenschon [20] and Hareng et al. [21]. The physical effects and the various display modes based on these effects include

- | | |
|-------------------------|-----------------------|
| Current effects: | • DS effect |
| Electric field effects: | • TN effect |
| | • STN effect |
| | • ECB |
| | • GH effect |
| | • Phase change effect |
| Thermal effects: | • Smectic effect |

The DS effect is based on the anisotropy of the conductivity. Because of higher voltage operation and higher power consumption, the DS mode is not currently used. The TN and STN effects are most widely used among all the LCDs. The following will discuss various display modes.

Twisted Nematic Effect

Fig. 92.10 shows a schematic of a display based on the TN effect. It consists of nematic LC material with a positive dielectric anisotropy ($\Delta\epsilon > 0$) with a layer thickness of about 5 μm , sandwiched between two transparent substrates with transparent electrodes. The surfaces of the transparent electrodes are coated with a polyimide alignment layer and rubbed to orient LC molecules at the substrate surfaces along the rubbing direction with a small ($\sim 3^\circ$) pretilt angle. The molecules on the two substrates are oriented 90° from each other as shown in Fig. 92.10a; i.e., the LC molecular axis rotates (twists) continuously through 90° from the first substrate to the second substrate. The TN display can be fabricated to operate in a normally black (NB) or normally white (NW) mode based on how the polarizers are attached to the outer surface of the two glass substrates. Figure 92.10a and b shows the on- and off-state of a NW mode TN LCD with crossed (orthogonal) polarizers attached with their polarization direction parallel to the LC director orientation on that substrate. Since the pitch of the twist is sufficiently large compared with the wavelength of the visible light, the direction of polarization of linearly polarized light incident normally on one surface of the display rotates through 90° by the twist of the LC molecules as it propagates through the cell and exits through the second polarizer. When a voltage is applied to the TN cell, the molecules align parallel to the direction of the field as shown in Fig. 92.10b, and the 90° optical rotatory

FIGURE 92.10 Illustration of TN effect: (a) in the off-state, the incident polarized light is transmitted through the entrance polarizer, the 90° TN LC, and the crossed exit polarizer; (b) in the on-state; (c) the solid line shows the voltage-transmission behavior for the NW configuration, shown in (a) and (b), with crossed polarizers. The dashed line is for an NB configuration with parallel polarizers.

power is eliminated. Thus, the incident polarized light from the first polarizer is not rotated as it goes through the LC cell and gets blocked by the crossed exit polarizer.

Fig. 92.10c shows the voltage-transmission characteristics of a TN cell for NB and NW modes of operation. For an NW mode, when a sufficiently high voltage is applied, LC molecules are aligned homeotropically (parallel to the field) and there is no rotation of the electrical field vector of the polarized light. This results in complete suppression of transmission regardless of the wavelength of light. The transmission in the on-state is, however, wavelength dependent, but this does not have a significant effect on the contrast ratio, although it can influence the color balance. In the NB mode of operation, the transmission is suppressed to zero [22] for the off-state only for a monochromatic light of wavelength, $\lambda = 2d\Delta n/\sqrt{3}$. Therefore, in a practical display using a broadband backlight, there is a small amount of light leakage which lowers the display contrast ratio. In a color display, the cell gaps for the R, G, B pixels can be optimized to eliminate the light leakage and improve contrast [22].

The threshold voltage of a TN mode LCD is given by

$$V_{th} = \pi \cdot \sqrt{\left\{ \left[K_{11} + (K_{33} - 2K_{22})/4 \right] / \epsilon_0 \cdot \Delta\epsilon \right\}} \quad (92.11)$$

V_{th} depends on the dielectric anisotropy and elastic constants, and is generally in the range of 2 to 3 V, with the maximum operating voltage being in the range of 5 to 8 V. This low voltage driving, coupled with low current due to high resistivity of LC materials, contributes to the very low power consumption ($\sim 1 \mu W/cm^2$) of LCDs. The response times measured by the rise and decay times of the display τ_r , τ_d , are given by [23]:

$$\tau_d = \gamma \cdot d^2 / \Delta\epsilon (V^2 - V_{th}^2) \quad (92.12)$$

$$\tau_r = \gamma \cdot d^2 / (\Delta\epsilon \cdot V_{th}^2) \quad (92.13)$$

where γ is the rotational viscosity coefficient. The above equations show that rise time can be improved by using a thinner cell gap d , a higher $\Delta\epsilon$, and a higher drive voltage V . Similarly, the decay time can be improved by reducing the cell gap. The turn-on time τ_r is usually shorter than the turn-off time τ_d . At

room temperature, these times are of the order of 10 ms, which is adequate for many common applications such as computer and TV displays. In a TN LCD, gray scale is generated by varying the voltage using the electro-optic curve shown in Fig. 92.10c. The shallow slope of the electro-optic curve works well for the gray scale generation in active matrix-addressed displays (see next section). However, in the case of passive matrix addressing, the shallow slope greatly limits the multiplexability (number of addressable rows) of the display, which led to the development of the STN effect.

STN Effect

In a passive matrix-addressed display, the addressability or the maximum number of addressable rows N is given by the Alt and Pleshko [24] limit:

$$V_{\text{on}}/V_{\text{off}} = \sqrt{(N^{1/2} + 1)/(N^{1/2} - 1)} \quad (92.14)$$

where V_{on} and V_{off} are the rms voltages at the select and nonselect pixels. Equation 92.14 shows that as N increases V_{off} approaches V_{on} and the contrast ratio becomes 1, which makes the display not viewable. For $N = 100$, $V_{\text{on}} = 1.11 V_{\text{off}}$, i.e., select voltage is only 11% higher than the nonselect voltage. This will result in a very low contrast ratio when using a TN mode with a shallow turn-on curve (Fig. 92.10c). STN displays have been developed [25, 26] to achieve a steep electro-optic curve, so that large numbers of rows can be multiplexed. The STN effect uses a twist angle of 180° to about 270° with a relatively high pretilt angle alignment. Figure 92.11 [25] illustrates the STN effect. The figure shows the voltage dependence of the midplane director tilt of a chiral nematic layer with a pretilt of 28° at both substrates. Bistability is achieved when a twist angle, ϕ , greater than 245° is used. In highly multiplexed displays twist angles in the range of 240° to 275° and tilt angles in the range of 5° to 30° are generally used. High pretilts ensure that competing distortional structure which has 180° less twist is eliminated. For a 270° left-handed twist, optimum results are achieved when the front polarizer is oriented with its polarization axis at 30° with the LC director and the rear polarizer is oriented at an angle of 60° with the projection of the director at the rear substrate. Due to interference of the optical normal modes propagating in the LC layer, the display has a yellow birefringence color in the nonselect state (yellow mode). Rotation of one of the polarizers by 90° results in a complementary image with a bright colorless state, and a blue nonselect state (blue mode). White-mode STN displays are made using retardation films. The response time of a typical STN display is on the order of 150 ms. These displays typically have a lower contrast ratio and a narrow viewing angle.

Electrically Controlled Birefringence (ECB)

This display technique is based on controlling the birefringence of the LC cell by application of an electric field. There are a number of types of this display depending on the molecular orientation of the LC cell used; examples include DAP type, homogeneous type, HAN (hybrid aligned nematic) type, and IPS (in-plane switching) type. A DAP type (homeotropic orientation) is made using an LC with a negative $\Delta\epsilon$, sandwiched between transparent electrode substrates and placed between crossed polarizers, as shown in Fig. 92.12. In the off-state (with no electric field), the incident polarized light does not see birefringence when passing through the cell, and thus gets blocked by the crossed exit polarizer. In the on-state (when a voltage is applied), the molecular axis of the LC is inclined at an angle θ (as shown in Fig. 92.12), so the linearly polarized light becomes elliptically polarized as it passes through the cell due to birefringence. Hence a portion of the light passes through the crossed exit polarizer; the intensity I of the transmitted light through the cell is given by [20]

$$I = I_0 \sin^2 2\theta \cdot \sin^2(\pi \cdot d \cdot \Delta n(V)/\lambda) \quad (92.15)$$

FIGURE 92.11 Calculated curves of tilt angle of local directors in the midplane of an STN cell as a function of reduced voltage V/V_{th} , where V_{th} is the Freedericksz threshold voltage of a nontwisted layer with a zero pretilt angle. The steepness of the curves increase as the twist angle, Φ , is increased, and bistability is achieved when $\Phi > 240^\circ$.

FIGURE 92.12 Illustration of an ECB display: (a) with homeotropic alignment and crossed polarizers, the off-state is black; (b) in the on-state, the output light through the LC is elliptically polarized due to the LC birefringence and the light is transmitted through the crossed polarizer.

where I_0 is the intensity of the incident light, θ is the angle between the direction of polarization of the incident light and the direction of oscillation of the ordinary light within the cell, d is the cell spacing, $\Delta n(V)$ is the birefringence of the cell, $d\Delta n$ is the optical phase difference, and λ is the wavelength of the incident light. The equation shows that I depends on the applied voltage and λ .

In case of the homogeneous technique, the LC cell uses positive material with a homogeneous orientation. With this method, the threshold voltage is obtained by replacing the bend elastic coefficient K_{33} , with splay elastic coefficient K_{11} . The HAN cell is characterized by a hybrid orientation cell in which the molecules are aligned perpendicular to one substrate, but parallel to the second substrate. In this mode, both positive and negative $\Delta\epsilon$ materials can be used, and since there is no clear threshold voltage, it has

the advantage of a very low drive voltage. Recently, an ECB mode based on an IPS type display has been developed to produce LCDs with extremely wide viewing angles. In the IPS mode displays, LC is homogeneously aligned and switched between on- and off-states using interdigitated electrodes fabricated on one of the display substrates [27]. The IPS mode displays use an NB mode with either positive or negative $\Delta\epsilon$ LC materials.

Guest–Host Type

Some organic dyes show anisotropy of light absorption; i.e., they absorb more light in a specific wavelength band when the E vector of the light is parallel to the optic axis of the dye molecules, than they do when it is perpendicular. LCDs based on this principle are called guest–host (GH) displays. In these displays a small amount of a dichroic dye (guest) is mixed in the LC material (host). These dye molecules get aligned to the LC molecules; hence, their orientation can be changed (by changing the orientation of the LC molecules) by application of an electric field. When an LC material with a positive $\Delta\epsilon$ is used, in the off-state, the E vector of the polarized light coincides with the light absorption axis of the dichroic dye; hence, light is absorbed and transmitted light is colored. When a voltage is applied for the on-state, the E vector of the polarized light is orthogonal to the absorption axis of the dye; hence, no absorption takes place, and transmitted light is not colored (white). GH LCD requires only one polarizer. Further, because the optical effect is based on absorption, the display provides a better viewing angle than a TN mode LCD.

Phase-Change Type

The phase change type of display is based on a change in molecular orientation from a helical cholesteric phase to a homeotropic nematic phase, and vice versa. For this technique, a cholesteric LC with a long helical pitch with a positive or negative $\Delta\epsilon$ is used. No polarizers are used in this display. In the off-state of this display, the incident light passing through the cholesteric cell with a focal conic orientation is optically dispersed (scattered), and the cell looks cloudy. However, when a voltage is applied, helical structure of the cholesteric phase changes to a nematic phase with a homeotropic orientation, and the cell becomes transparent.

Thermal Effects

Thermal effect is based on a change in the electro-optical behavior due to a change in the molecular orientation of the LC when it is heated or cooled. This effect is utilized with smectic LCs with a homeotropic alignment. When this cell is heated until the isotropic phase is reached and cooled, then if the cooling is sudden, the cell becomes cloudy, whereas, if the cooling is gradual, the cell becomes transparent. These cloudy and transparent states correspond, respectively, to the focal conic and homeotropic orientations of the smectic A LC. This effect is used for large-size memory type displays, in which a laser beam is used to write the image thermally. The heating can also be accomplished by one of the transparent electrodes, while the other transparent electrode is used as a signal electrode.

92.6 Display Addressing

Display addressing (driving) techniques have a major influence on the LCD image quality. The addressing techniques can be classified in three essential types, namely, direct (static) addressing, passive matrix addressing, and active matrix addressing. In the case of low-information-content displays such as numeric displays, bar graph displays, and other fixed pattern displays, using segmented electrodes, direct addressing is used. A common example of direct-addressed displays is a numeric display using seven segmented electrodes for each digit. Each of these segmented electrodes on the front substrate and the common electrode on the back substrate are directly connected to drive signals. A voltage is selectively applied to each of the segments so that any of the digits between 0 and 9 can be displayed. For high-information-

content displays, this approach becomes impractical because of the huge number of interconnects, and, hence, either passive matrix or active matrix addressing is used.

Passive Matrix Addressing

A passive matrix (PM) display comprising an LC between a matrix of transparent conducting row and column electrodes (Fig. 92.8) is the simplest and least expensive matrix-addressed LCD to manufacture. An example of a PM LCD is a color (R,G,B) VGA (video graphics array) display using the STN effect, with a pixel format of $640 \times 3 = 1920$ H \times 480 V, with 1920 columns and 480 rows, for a total of 2400 interconnects used for addressing a display containing 921,600 pixels. In PM addressing, the row voltages are scanned in succession with a voltage, V_r , while all the columns in a given row are driven in parallel, during the row time, with a voltage of $\pm V_c$ depending on whether the pixel is selected to be ON or OFF. As discussed above under the STN effect, the contrast ratio of PMLCDs is influenced by the Alt and Pleshko [24] addressability limitation. To enhance the operating margin for improved contrast ratio, DSTN (dual-scan STN) configuration is used in higher-information-content displays. In a DSTN, the display is separated into two halves, and the rows in each half are scanned simultaneously and synchronously, to essentially double the duty ratio of the ON pixels to increase the contrast ratio. One of the major shortcomings of the passive matrix-addressed STN display is the slow response time of the LC, which is of the order of 150 ms. This slow response time is not adequate for video applications and is barely fast enough for the graphical interface of a computer. The response time of the STN LCDs can be improved by active addressing or multiline addressing techniques [28, 29]. These techniques involve simultaneous addressing of several rows of a display to suppress the frame response problems of conventional STN LCDs.

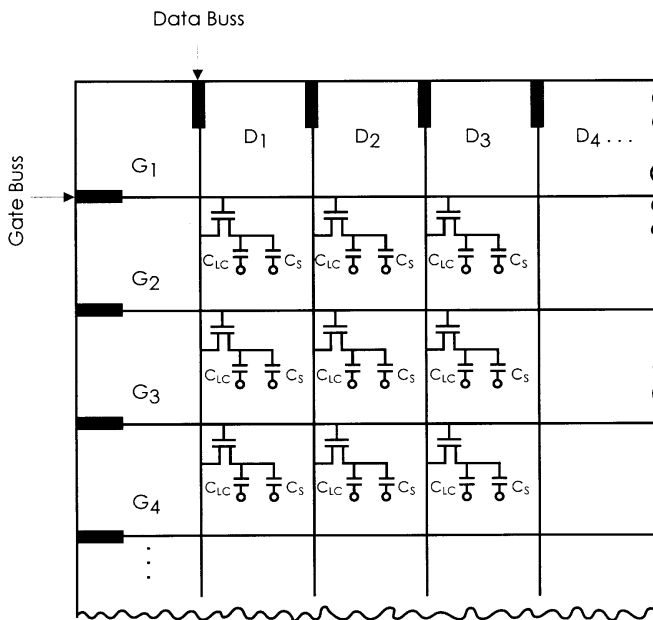

Active Matrix Addressing

Active matrix (AM) addressing removes the multiplexing limitations [24] of the PM LCDs by incorporating a nonlinear control element in series with each pixel, and provides 100% duty ratio for the pixel using the charge stored at the pixel during the row addressing time. Figure 92.13a illustrates an active matrix array with row and column drivers and the associated display module electronics. Figure 92.13b shows a magnified view of the active matrix array in the AM LCD panel. In the figure, C_{LC} and C_s represent the pixel capacitance and the pixel storage capacitance. Typically a storage capacitor, C_s , is incorporated at each pixel to reduce the pixel voltage offset (see Equation 92.16 below) and for a broad temperature operation. Figure 92.14 shows the cross section through an AM LCD illustrating various elements of the display. Figure 92.15 shows a typical AM LCD pixel, showing the gate and data busses, thin-film transistor (TFT), ITO pixel electrode, and the storage capacitor. Fabrication of the active matrix substrate is one of the major aspects of AM LCD manufacturing. Both two-terminal devices such as back-to-back diodes, and metal-insulator-metal (MIM) diodes as well as three terminal TFTs are developed for active matrix addressing. While two-terminal devices are simple to fabricate and cost less, their limitations include lack of uniform device performance (breakdown voltage/threshold voltage) over a large display area, and lack of total isolation of the pixel when neighboring pixels are addressed. For a superior image quality AM LCDs use TFT for the active matrix device, which provides a complete isolation of the pixel from the neighboring pixels. Large-area AM LCDs use amorphous silicon (a-Si) TFTs [6], while polysilicon TFTs with integrated row and column drivers are used in small high-resolution LCDs [30].

Figure 92.16 shows the electric equivalent of a TFT-LCD pixel, display drive waveforms, and the resulting pixel voltage. As in most matrix-addressed displays with line-at-a-time addressing, the rows (gates) are scanned with a select gate pulse $V_{g,sel}$, during the frame time t_f , while all the pixels in a row are addressed simultaneously with the data voltage $\pm V_d$ during the row time $t_r (= t_f/N)$. During the row time the select gate voltage, $V_{g,sel}$, “turns on” the TFT and charges the pixel and the storage capacitor to the data voltage V_d . After the row time, the TFT is “switched off” by application of the nonselect gate voltage, $V_{g,non-sel}$; hence, the voltage (charge) at this pixel is isolated from the rest of the matrix structure

(a)

(b)

FIGURE 92.13 (a) AM LCD module electronics block diagram; (b) magnified view of the region shown in (a) illustrating active matrix TFT array.

until it is time to charge the pixel during the next frame time. Note that the LC pixel must be driven in an ac fashion with $+V_d$ and $-V_d$, during alternate frame periods, with no net dc across the pixel. A net dc voltage across the pixel results in flicker and image sticking effects [33], resulting from LC conductivity. Large and sustained dc voltages also degrade the LC material due to electrolysis. The shift in pixel voltage, ΔV_p shown in Fig. 92.16, at the end of the row time is due to the parasitic gate-to-drain capacitance, C_{gd} .

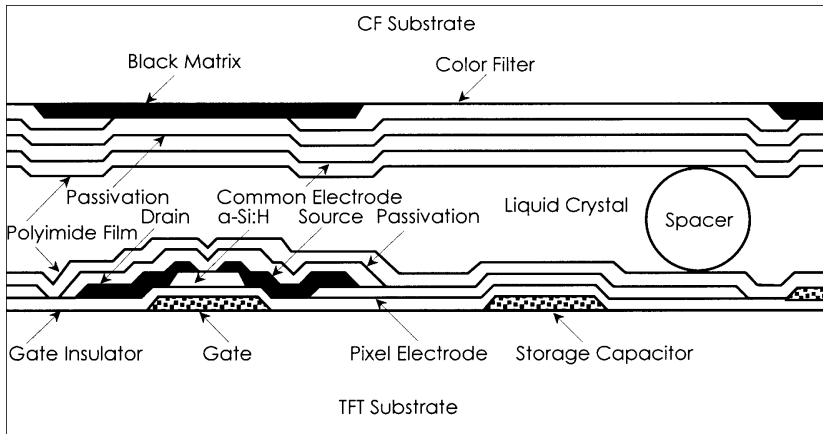

FIGURE 92.14 Cross-sectional view through an AM LCD showing TFT, pixel electrode, storage capacitor, polyimide alignment layers, color filter, and black matrix.

FIGURE 92.15 Layout of a pixel in a TFT-LCD showing the TFT, pixel electrode, and storage capacitor.

of the TFT. When the gate voltage is switched, the distribution of the charge from the TFT gate dielectric causes the pixel voltage shift ΔV_p , given by

$$\Delta V_p = (\Delta V_g) \cdot C_{gd} / (C_{gd} + C_{lc} + C_s) \quad (92.16)$$

For the *n*-channel enhancement mode a-Si TFT, this voltage shift ΔV_p is negative for both the positive and negative frames; thus, it helps pixel charging in the negative frame and hinders it in the positive frame. Further, due to increased gate bias during the negative frame, the pixel attains the data voltage much more rapidly during the addressing period. Hence, the TFT is designed for the worst-case positive frame conditions. ΔV_p is reduced by minimizing C_{gd} by decreasing the source drain overlap area of the TFT and by using a storage capacitor. Further, ΔV_p is compensated by adjusting the common electrode voltage V_{com} as shown in Fig. 92.16. Note that C_{lc} is a function of the V_p (V_{lc}) due to the dielectric

FIGURE 92.16 (a) Electric equivalent of a TFT-LCD pixel; (b) gate drive voltage waveform; (c) data voltage waveform and pixel charging behavior in the positive and negative frames.

anisotropy of the LC; and hence, adjustment to V_{com} alone does not eliminate dc for all gray levels, and modification of the gray scale voltages is required to compensate for the dielectric anisotropy of the LC.

Display Module Electronics

Figure 92.13 shows a block diagram for an AM LCD module electronics. The control block and power supply generation means are separately mounted on a PC board and connected to the row and column drivers of the LCD on one side and to the host controller on the other. The control block may include level shifters, timing generators, and analog functions in some cases; the control block takes in digital data from the host system, which is typically a graphics controller chip, and converts it into timing and signal levels required by the row and column drivers. The architecture and design of the module electronics encompassing row and column drivers have a significant impact on not only the display system cost and power consumption, but also the image quality. The LC material typically requires about 5 V to achieve optical saturation (see Fig. 92.10c). Considering the need for an ac drive, the required voltage swing across the LC material is about 10 V. To achieve this 10 V swing across the LC material, the column drivers typically use 12 V power supplies. Column driver voltage can be reduced by using a V_{com} modulation drive method. In this method, the V_{com} node (which is connected to all pixels in the display) is driven above and below a 5 V range of the column drivers. Each and every row time, the V_{com} node is alternated between a voltage above and a voltage below the 5 V output range of the column drivers. This achieves 10 V across the LC material using 5 V column drivers. This method requires additional components and consumes additional power due to the oscillation of the V_{com} node. In addition, to avoid capacitive injection problems, the row drivers usually have their negative supply modulated with the same frequency as the V_{com} node. Note, however, that compared to 10 V column drivers, 5 V column

drivers consume less power, and are simpler to design and fabricate using small-geometry CMOS. The V_{com} modulation drive method can be used with a row (polarity) inversion scheme only (for elimination of pixel flicker) which results in some horizontal cross talk. However, column inversion and pixel inversion schemes provide better image quality with much-reduced cross talk, but they cannot be used with the V_{com} modulation drive.

93.1 An Introduction to Plasma-Driven Flat Panel Displays

Development History and Present Status

Plasma-driven flat panel display pixels were invented by Bitzer and Slottow at the University of Illinois in 1966 [1-3]. [Figure 93.1](#) shows one of the inventors' early designs and demonstrates its simplicity. Parallel sets of thin conducting wires are deposited on two glass substrates which are then mounted with the conductor sets perpendicular to one another as shown in the [Fig. 93.1](#). A spacer, in this case a perforated glass dielectric, is used to maintain a gap separation of about 100 μm between the glass plates. The gap region then is filled with an inert gas, typically at a pressure of half an atmosphere. Individual pixels formed by the intersection of two conductor wires are aligned with the perforations. Pixels are illuminated by applying a voltage between two intersecting wires sufficient to initiate gas breakdown. Over the years, this basic pixel design has undergone a multitude of refinements and improvements, but the fundamental concept is still widely used.

Throughout the 1980s, plasma display products on the market were monochrome and operated with neon-based gases, directly producing within the discharge volume the red-orange (585 to 640 nm) visible photons that are characteristic of the quantum energy level structure of the neon atom. Dot matrix displays of the type shown in [Fig. 93.2](#) were widely used [3,4]. Early work by Owens-Illinois led to improvements in glass sealing and spacer supports [5,6], and work by IBM led to improved understanding

and control of the discharge [7-15]. These advances ultimately paved the way for manufacture of large-area, high-resolution monochrome displays. The largest area plasma display panels ever manufactured were produced by Photonics Imaging. These monochrome displays had a 1-m diagonal dimension and contained over 2 million pixels with a pixel pitch of 20 pixels/cm (50 lines/in.) [4].

Advances in lithography, patterning, and phosphors have enabled continued improvement of plasma display performance and resolution. Today, many of companies offer full-color plasma flat panel displays. [Table 93.1](#) presents a summary list compiled by the National Research Institute of display panel specifications for some of the major companies investing in plasma flat panel manufacturing [16]. According to Stanford Research, Inc., sales for plasma display panels in 1995 totaled \$230 million, but projected sales for 2002 are \$4.1 billion [17]. NEC projects a more aggressive market growth reaching \$2.0 billion by the year 2000 and \$7.0 billion by 2002 [17]. The production capacities listed in [Table 93.1](#) represent investments committed to manufacturing as of January 1997. As these production facilities come online, color plasma flat panel display production will grow to nearly 40,000 units per month by the end of 1998, and to over 100,000 units per month by early in 2000. In 1993 Fujitsu was the first to market a high-information-content full-color plasma flat panel display, a 21-in. diagonal, ac-driven system with a 640×480 pixel array [17,18]. Two examples of more recent market entries are shown in [Figs. 93.3](#)

TABLE 93.1 Plasma Flat Panel Display Specifications and Manufacturer's Business Plans

Company	Product Specification			Efficiency Specification				Plan			
	Inch	Aspect	Pixels	Luminescence (cd/m ²)	Contrast	lm/w	Power (W)	Factory	Capital Cost (\$M)	Product Ability unit/month	Target Region
Fujitsu	42	16:9	852 × 480	300	70:1	0.7	350(set) 300(panel)	Miyazaki	20	10,000	Europe (Philips), Japan

and 93.4. The first example is the NHK full color, 102-cm (40-in.) diagonal, high definition television (HDTV) [19-22]. The system comprises 1,075,000 full-color pixels (1344×800) with a pixel pitch of 0.65 mm in both horizontal and vertical directions (15.4 pixels/cm). This pulsed, dc-driven display has a peak luminance of 93 cd/m^2 , a contrast ratio of 80 to 1, and produces 256 gray levels. The display has an overall thickness of only 8 cm and weighs only 8 kg. The dimensions of the display panel itself are $87.5 \times 52.0 \text{ cm}$ with a width of only 6 mm. Shown in Fig. 93.4 is the 76-cm (30-in.) diagonal, full-color AC Plasma Display manufactured by Photonics Imaging [23-24]. The display contains an array of 1024×768 full-color pixels. At 16.8 pixels/cm (pixel pitch = 0.59 mm) this is the highest resolution full-color, plasma display manufactured to date. This unit has 64 gray levels per color channel and an average area (white) luminance greater than 103 cd/m^2 (30 fL).

dc and ac Plasma Pixels

As indicated above, plasma display pixels can be designed for either ac or dc operation. Figure 93.5 shows schematic diagrams for the simplest dc and ac pixel designs. In either case, sets of parallel conductor wires are deposited on glass substrates. In most cases display costs are kept low by utilizing ordinary soda-lime float glass. The two glass plates are then mounted with a separation of about $100 \mu\text{m}$ and with the conductor wire sets perpendicular to one another. The gap region between the glass plates is filled with an inert gas, which discharges and illuminates the pixels when sufficient voltage is applied across two intersecting wires.

For dc pixels, shown in Fig. 93.5a, the working gas is in direct contact with the electrodes. Electrons produced within the discharge volume flow rapidly to the anode, while ions produced flow more slowly toward the cathode. At 53.3 kPa (400 torr), a gas gap of $100 \mu\text{m}$ and an applied voltage of 200 V, the electron and ion transit times across the gap are roughly 0.2 and 20 ns, respectively. Once breakdown is initiated, the electrical resistance of the discharge is negligible. Consequently, dc operation requires that external resistors in series with each pixel be included in the circuit in order to limit the current amplitude. Often, dc pixels are operated in pulsed discharge mode with frequency modulation used to define the pixel brightness. For either ac or dc pixels, a base firing frequency of 50 kHz is typical. This frequency is too fast for the human eye to detect any *on-off* flicker, but allows sufficient flexibility for intensity and refresh control. In reviewing the literature on plasma displays, it is easy to confuse dc and ac pixels since dc pixels are often operated in pulsed mode and with electrode polarity reversal which distributes sputter damage over both electrode surfaces. The dc pixels are readily identified by conducting electrodes in direct contact with the discharge gas and the inclusion of a current-limiting resistor in the circuit for

FIGURE 93.4 The 40-in. diagonal ac driven plasma display from Photonics Imaging. (From Friedman, P.S., *Inf. Display*, 11(10), October 1995. With permission.)

each pixel. While polarity reversal is optional for dc pixel operation, it is inherently required for ac pixel operation as discussed below. Drive electronics, current limiting, gray scale, and other aspects of both dc and ac pixel operation are discussed in greater detail in subsequent sections.

Figure 93.5b shows a schematic representation of an ac plasma pixel configuration. One can see that the differences between ac and dc pixel geometry are slight; however, the resulting operational differences are significant. In the ac pixel, the conductor wires are covered with a dielectric film. Typically, lead oxide (PbO), which has a dielectric constant of about 15, is deposited at a film thickness of about 25 μm . Most ac pixels are made with a thin film (50 to 200 nm) magnesium oxide (MgO) dielectric coating covering the PbO and in contact with the working gas. This dual material dielectric film serves two principal functions, charge storage and secondary electron emission.

The exact voltage required for gas breakdown depends upon the gap width, the gas pressure, the gas composition, and MgO surface conditioning. For the pixel parameters shown in Fig. 93.5b, an externally applied voltage of about 120 to 180 V is required to initiate a discharge. In the ac pixel, once the discharge is initiated, electrons and ions flow toward the anode and cathode, respectively, as in the dc pixel. However, in the ac case, charge carriers are unable to reach the conductor wires and instead collect as a surface charge on the dielectric coating. The electric field within the gas gap is always the sum of that produced by the externally applied voltage and that produced by the surface charge. During pixel firing, if the externally applied voltage is held constant for only a few microseconds, the net electric field within the gas gap very quickly decreases (~ 100 to 200 ns). The gap potential

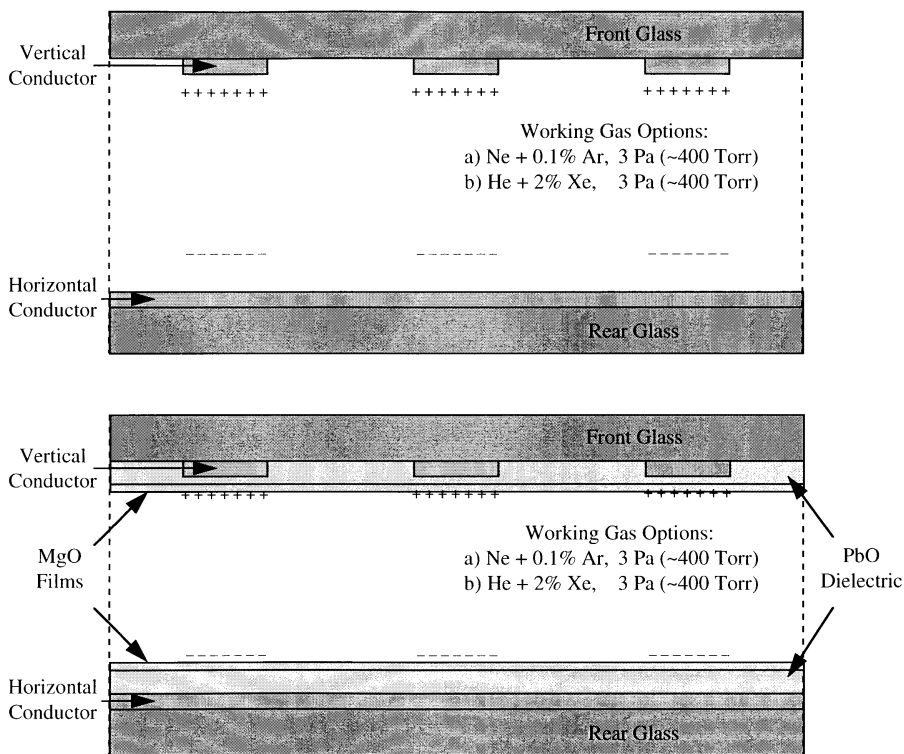

FIGURE 93.5 Schematic diagrams of (a) dc and (b) ac opposed electrode plasma pixels.

drop produced by the surface charge shields out that produced by the externally applied voltage. Eventually, the gap electric field is insufficient to sustain the discharge and the pixel turns *off*. Thus, each ac pixel is inherently self-current-limiting and, unlike the dc pixel, requires no external resistance in series with it. At the start of the next ac half cycle, the externally applied voltage is reversed. When this occurs, the voltage across the gas gap is the sum of the external voltage and the voltage produced by the surface charge established during the previous discharge. If a sufficient surface charge is present, a new discharge pulse can be initiated by application of an external voltage, which by itself would be insufficient to break down the gas. Within the new discharge, charge carriers flow quickly to reverse the polarity of the surface charge concentrations. Once again, the field within the gap is diminished and the discharge turns *off*. Storage of surface charge make ac pixels easily controllable and provides them with their inherent memory properties. The presence or absence of surface charge determines whether or not a given pixel will discharge at the onset of the next ac half cycle of the externally applied voltage. The details of how these discharge dynamics are used to write, erase, and sustain each pixel are discussed in subsequent sections, along with drive mechanisms for gray scale and for pixel array refresh.

General Attributes of Plasma Displays

Plasma-driven flat panel displays offer a number of advantages over competing display technologies. The highly nonlinear electrical behavior of each pixel, with inherent memory properties, can be used to advantage in design of the drive electronics required to refresh and to update the pixel array of the display. The simplicity of the pixel design makes large-area manufacturing problems, such as alignment and film thickness uniformity, somewhat more manageable. Relative to color active matrix liquid crystal displays

FIGURE 93.6 Structure of the ac color plasma display manufactured by Fujitsu. (From Mikoshiba, S., *Inf. Display*, 10(10), 21, 1994. With permission.)

(AMLCDs) which use a thin-film transistor (TFT) to control each pixel, less-complicated manufacturing and less-complicated drive electronics give plasma flat panel displays advantage for large-area applications. On the other hand, plasma displays require more robust drive electronics with voltages of 100 to 275 V. Plasma displays are also not well suited for portable applications since power consumption is high relative to other display technologies, but not restrictive for office or domestic use. The 76-cm (30-in.) diagonal color display manufactured by Photonics Imaging shown in Fig. 93.4 has a peak power consumption of only 300 W [23]. At high power levels, plasma-driven flat panel displays are bright enough to be readable in sunlight. The displays are also easily adjusted to a low-ambient-light condition by discharge amplitude or frequency modulation.

Plasma flat panel displays are well suited for large-area (0.5 to 5 m) applications such as videoconferencing, large meeting room displays, outdoor displays, and simulators requiring large viewing areas. Thin, high-resolution, large-area, color plasma displays are also very attractive for desktop workstation or personal computer applications requiring high-resolution graphics. Note, too, that plasma flat panel displays have very large viewing angles, greater than 160° in many designs [22–24]. For displays using metal electrodes, one often finds that the best viewing angle is slightly off normal since the front electrode wire blocks out a portion of the pixel emission. This occurs both for monochrome pixels producing visible emissions within the discharge and for color plasma displays where the viewer sees visible red, green, and blue (RGB) emissions from vacuum ultraviolet (VUV) photon-stimulated phosphors. Some manufactures have investigated use of transparent electrodes, such as indium-tin oxide (ITO), but there is a trade-off with power consumption since the conductivity of ITO is less than that of metal electrodes [18]. In contemporary designs, the metal conductor width is thin ($\sim 20 \mu\text{m}$) and its opacity does not present a major problem.

For color pixels, the discharge gas mixture is modified to produce emissions in the VUV. In all other respects, the operational principals of the plasma discharge by the pixel are identical for color and for monochrome displays. Ideally in color plasma displays, no visible emissions are produced within the discharge itself and VUV-photostimulated luminous phosphors are used to produce the required RGB visible light. The ac color pixel design concept shown in Fig. 93.6 is that utilized by Fujitsu [18]. Long, straight barrier structures, each about $100 \mu\text{m}$ tall, are constructed parallel to and between each of the vertically oriented conductor wires on the rear glass plate. The sidewalls of these barriers are alternately coated with red, green, and blue photostimulated phosphors. Note that the Fujitsu panel employs a three-electrode, ac-driven surface discharge pixel design which is slightly more complicated than the opposed electrode ac design shown in Fig. 93.5b. This chapter will return to surface discharge configurations and other aspects of color pixel design and operation after reviewing fundamentals of the discharge physics and electrical behavior governing pixel operation.

GAS DISCHARGE REACTIONS

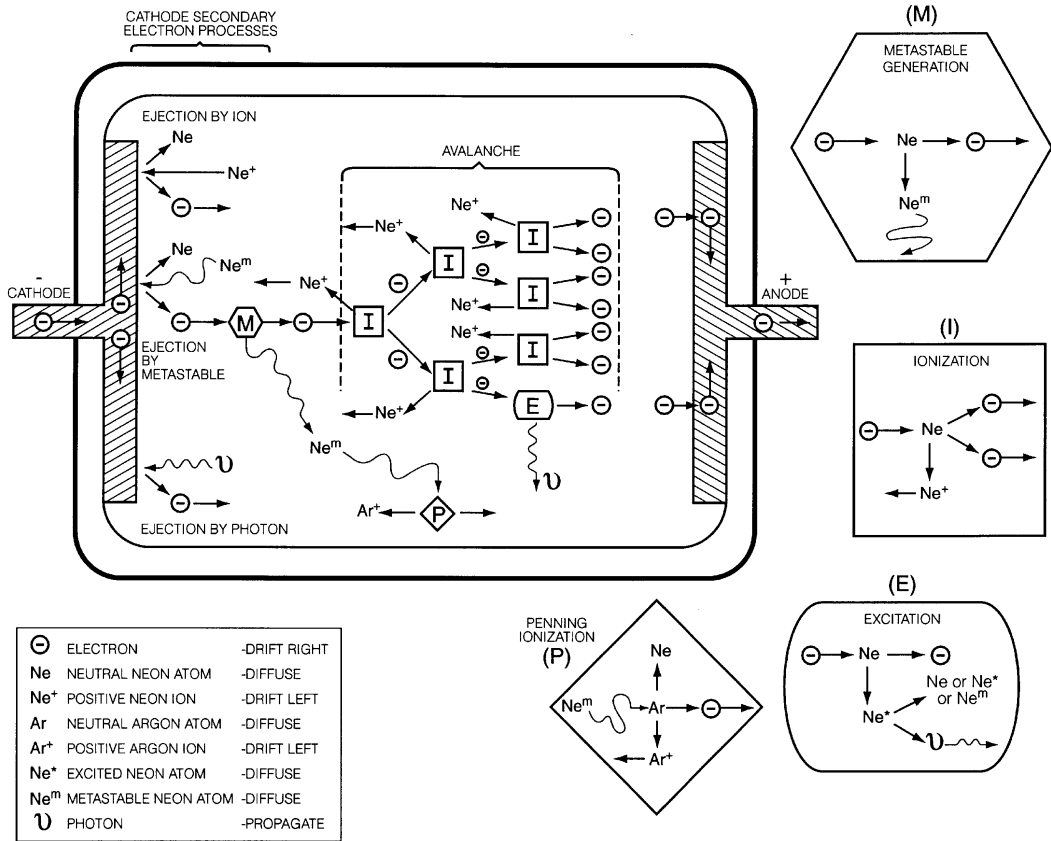

FIGURE 93.7 Collisional and surface interactions in a gas discharge. (From Weber, L.F. in *Flat Panel Displays and CRTs*, L.E. Tannas, Jr., Ed., Van Nostrand Reinhold, New York, 1985. With permission.)

93.2 Fundamentals of Plasma Pixel Operation

Atomic Physics Processes

Although simplistic in design, the plasma display pixel is a rich environment for study of basic atomic physics, electron collisional processes, photon production and transport, and plasma–surface interactions. The coupling of these processes for a neon–argon monochrome pixel discharge was nicely summarized in the diagram from Weber which is reproduced here as Fig. 93.7 [4]. The reader interested in additional information on fundamental discharge physics is directed to one of the excellent textbooks in this field [25-27].

The physical processes governing of the behavior of the pixel discharge are closely coupled and form a closed-loop system. The discussion begins by assuming that a seed electron is resident within the gas gap and is subjected to an electric field which results from application of an externally applied voltage to the two conductors forming that pixel. Some of the gas and surface processes for production of the seed electrons will become evident as the discussion progresses. In order to ensure reliable discharge progresses, seed particles, which are either electrons or electron-producing photons or metastable atoms, are often provided by a controlled source which may be external to the pixel being fired. Some display panels include electrodes for production of seed particles at the edges of the panel outside the field of

view or hidden behind opaque conductor wires. Other display panels use well-controlled temporal sequencing to ensure that nearest-neighbor pixels provide seed particles for one another [4,19,28]. Pixel addressing sequences are discussed further later in this chapter.

The transport of electrons or ions across the gas gap is a balance between field acceleration and collisional energy loss. In the example of Fig. 93.7, the gas is mostly neon (98 to 99.9%) and field-accelerated electrons will predominantly collide with Ne atoms. The quantum energy level diagram for excitation of the Ne atom is shown schematically in Fig. 93.7 [29]. Note that the lowest-lying excited state is 16.6 eV above the ground state, while the ionization energy is 21.6 eV. This means that electrons with energies less than 16.6 eV can only experience elastic collisions with the Ne atoms. When an electron is field-accelerated to an energy in excess of 16.6 eV, inelastic collisions which transfer energy from the incident electron to one of the outer-shell electrons in the Ne atom can take place. Incident electrons with kinetic energies in excess of 21.6 eV can drive ionization reactions:

Excitation and ionization collisions transfer energy from the electron population to the neutral atoms in the gas. At the same time, the electron population available to ionize the Ne further is increased with every ionizing event. The result is the discharge avalanche schematically shown in Fig. 93.7, which manifests itself experimentally as a rapid increase in electric current flowing in the pixel gas gap. In dc panels, an external resistor of about $R = 500 \text{ k}\Omega$ is placed in series with each pixel. The amplitude of the externally applied voltage provided by the driving electronics, V_a , is held constant and the total voltage across the gas gap, $V_g = V_a - IR$, decreases as the circuit current, I , increases. Very quickly, a steady-state dc current in the gas gap and in the circuit is established. Brightness and gray scale are controlled by frequency modulation of the pulsed dc pixel firing using a base frequency of about 50 kHz. In ac pixel discharges, electrons and ions are driven by the applied field to the dielectric-covered anode and cathode, respectively. The buildup of charge on the dielectric surfaces shields the gap region from the field produced by the externally applied voltage. Eventually, the electric field in the gap drops below a level sufficient to sustain the discharge and the pixel turns *off*.

For electron energies greater than 16.6 eV, collisions with Ne atoms can excite outer-shell electrons in the atom to one of the numerous excited energy states shown in Fig. 93.7.

Most of these excited states have short lifetimes ranging from fractions to tens of nanoseconds [30] and quickly decay to lower-lying atomic quantum states accompanied by the emission of a characteristic photon, indicated in Eq. 93.2 by $h\nu$, the product of Planck's constant times the photon frequency. As can be seen in Fig. 93.8, the characteristic red-orange Ne gas emissions result from electron transitions within the atom from higher-energy 2p quantum states to lower-lying 1s energy levels [30,31]. Two of the four 1s energy levels radiate to ground-emitting VUV photons with wavelengths of 74.4 and 73.6 nm. Due to quantum mechanical exclusion principles, electron decay from the other two 1s levels is more complex and depends upon fine details of the electronic wave function and upon very small perturbing interactions [31]. Consequently, decay lifetimes for these so-called metastable states are measured in seconds, which is very long relative to other dynamic physical processes governing pixel discharge behavior, such as charge or neutral particle transport. An Ne atom with an electron trapped in one of these metastable levels harbors 16.6 eV of latent energy. The metastable atom, Ne^* , is unable to dissipate its stored energy in collisions with ground-state Ne atoms, yet readily liberates its energy whenever a lower-lying energy configuration can be accessed. The principal channels in this system to lower energy configurations are Ne^* collisions with Ar or Ne^* incidence onto pixel interior surfaces.

FIGURE 93.8 Quantum energy level diagrams for He, Ne, Ar, Xe, and the Xe²⁺ dimer.

Figure 93.8 shows simplified energy-level diagrams for several inert gases. The relative positioning of the allowable energy levels provides insight into the energy exchange that occurs in collisional coupling. The ionization energy of the Ar atom is 15.8 eV and lies 0.8 eV below the metastable-state Ne*. Consequently, the Ne* has sufficient stored energy to ionize the Ar atom:

Ionizing reactions of this type are called Penning reactions, and gas mixtures that rely on metastable states of the majority gas constituent (Ne) for ionization of the minority gas constituent (Ar) are referred to as Penning gas mixtures [25,26,32]. Figure 93.9 shows the efficiency with which charge pairs are produced through ionization within Ne/Ar Penning gases containing various fractions of Ar. The curves show that for any given pressure, ion pair production per volt applied is optimal at low Ar gas fractions (0 to 10%) except for very large values of E/P , greater than 75 V/m/Pa (100 V/cm/torr), where E is the electric field strength and P is the gas pressure. Penning gas mixtures have been studied for many years. Figure 93.9 shows the original data on Ne/Ar gas breakdown published by Kruithof and Penning in 1937 [32]. An extensive volume of literature has been published on inert gas Penning processes since then, and the interested reader is referred to the excellent texts which have recently been re-released through the American Vacuum Society and MIT Press [25,26].

Plasma display pixels usually operate at pressures near 53.3 kPa (400 torr) in order to achieve sufficient photon production and brightness. Typical pixel fields are roughly 100 MV/m. Consequently, plasma pixels operate with E/P values near 18.8 V/m/Pa (25 V/cm/torr). Both charge pair production and luminous efficiency are then optimized with Ar gas fractions between 0.1 and 10%, depending upon the specifics of the pixel gas pressure, gap width, and driving voltage. For a given applied voltage, the product of the gas pressure (P) and the gas gap dimension (d) provides a measure of the balance between electron

FIGURE 93.9 Ionizing collisions plotted vs. electric field strength divided by pressure. The numbers on each curve indicate the ratio of the Ar partial pressure to the total gas pressure. (From Brown, S., *Basic Data of Plasma Physics — The Fundamental Data on Electrical Discharges in Gas*, American Institute of Physics Press, New York, 1993. With permission.)

acceleration by the electric field and electron energy loss due to collisions with the background gas. Paschen curves, which plot the gas breakdown voltage vs. the Pd product, for several inert gas mixtures are shown in Fig. 93.10 [26,33,45]. In each case, minimum voltage for breakdown occurs at a value of the Pd product which is dependent upon the ionization levels, collisionality, and energy channels within the gas. For example, in Ne atomic excitation and ionization processes dominate, while in air much of the energy absorbed by the gas goes into nonionizing molecular vibration, rotation, and dissociation. For fixed pressure, the Paschen curves show that increased gap dimension lowers the electric field strength per volt applied and a large voltage is required for breakdown. On the other hand, if d is reduced for a given pressure, the electric field strength can be large, but electrons transit the gap without initiating a sufficient number of collisions to drive the type of discharge avalanche shown in Fig. 93.7. If the gas gap, d , is held fixed while pressure is varied, the shapes of the Paschen curves are again explained by electron acceleration and collisional processes. For high pressures, the mean free paths between electron collisions with the background gas atoms are short and electrons are unable to accelerate to energies sufficient to initiate ionization unless the electric field is especially strong. At low pressures, the electrons may be accelerated by the field to energies sufficient to initiate ionization, but few collisions with the background gas occur and, again, the avalanche is difficult to initiate. Penning processes are especially efficient at driving ionization. Introduction of 0.1% Ar into the neon gas lowers the minimum breakdown voltage from the value near 250 V shown in Fig. 93.10, to about 150 V. The minimum breakdown voltage occurs at a Pd product of 40 Pa-m (30 torr-cm) for this gas mixture.

Discharge Physics for Plasma Pixels

Within any discharge, electrons move very quickly, while the more massive ions move relatively slowly in comparison. In a charge-neutral plasma that is subjected to an externally applied electric field, the

FIGURE 93.10 Breakdown voltage as a function of pressure — gas gap length product for various gases. (From Brown, S., *Basic Data of Plasma Physics — The Fundamental Data on Electrical Discharges in Gas*, American Institute of Physics Press, New York, 1993. With permission.)

mobile electrons quickly respond to the applied field and rush toward the anode. The inertia-laden ions, in a much slower fashion, begin their motion toward the cathode. Very quickly, a local charge imbalance is established as the electrons reach the anode faster than the rate of arrival of ions at the cathode. Poisson's equation

$$\nabla \cdot E(x) = 4\pi\rho(x) = 4\pi e(n_i(x) - n_e(x)) \quad (93.4)$$

shows that a local electric field is established in response to the net positive charge density, $\rho(x)$, in the plasma region. Here, $n_i(x)$ and $n_e(x)$ are the spatial profiles of the ion and electron densities, respectively, and e is the electron charge. The field established retards the rate at which electrons flow out of any volume within the plasma column and forces them to follow the net ion motion. The ion drift motion is correspondingly accelerated, but this acceleration is smaller by a factor proportional to the mass ratio of the electron to the ion. The net ion/electron motion is called ambipolar flow and is described in detail in many basic plasma physics texts [25-27].

In steady-state dc plasma pixel discharges, the amplitude of the current flowing in the circuit and in the gas gap is defined by the value of the applied voltage and the resistor in series with the pixel. Steady-state operation dictates that charge buildup within the gap region cannot occur. The rate at which charge particle pairs arrive at the electrodes must equal their rate of production due to ionization. At the same time, the rates at which ions and electrons leave the plasma volume, arriving at the cathode and anode, respectively, must be equal. Equilibrium is sustained by establishment of the spatial potential profile within the gas gap shown in Fig. 93.11a. Due to the high electron mobility, the plasma is extremely efficient in shielding out externally applied electric fields. As a result, the potential profile is flat across the gas gap of a pixel sustaining a fully developed discharge. The entire potential drop is localized in a small zone called the sheath adjacent to each electrode. The spatial extent of the sheath is determined by the effectiveness of the electron population in shielding out the electric fields produced by the electrode potentials. The Debye length,

FIGURE 93.11 Potential profiles in the pixel gap region for (a) high-electron-density and (b) low-electron-density discharges.

$$\lambda_D = \sqrt{kT_e / 4\pi e^2 n_e(x)} \tag{93.5}$$

provides a measure of the shielding distance. The expression for λ_D implies that the sheath thickness increases with increasing electron temperature, T_e , and decreases as the electron density, n_e , increases. For fully developed plasma pixel discharges, the product of Boltzmann's constant and the electron temperature, kT_e , is at most a few electron volts, and n_e is of order $10^{16}/\text{m}^3$. Thus, the sheath thickness is roughly $5 \mu\text{m}$. The potential within the plasma region adjusts, V_p , within the discharge volume rises to a value just above that of the applied voltage at the anode. Consequently, only the most energetic electrons can overcome the potential barrier at the anode which adjusts to a potential such that the rate of electron loss at the anode equals the rate of ion loss at the cathode. For ac plasma pixels, a similar potential profile is established, but changes dynamically as the pixel pulse evolves. Charge pairs incident upon the anode and cathode in ac pixels are trapped there by the dielectric film covering the conductor wires. Consequently, the potential at the discharge boundary is diminished as surface charge collects at each electrode, as shown in Fig. 93.11b. Ultimately, the discharge terminates as the electric field produced by the surface charge cancels that produced by the externally applied voltage. As the density of charge carriers is reduced near the termination of an ac pixel discharge pulse, the effectiveness of the electrons

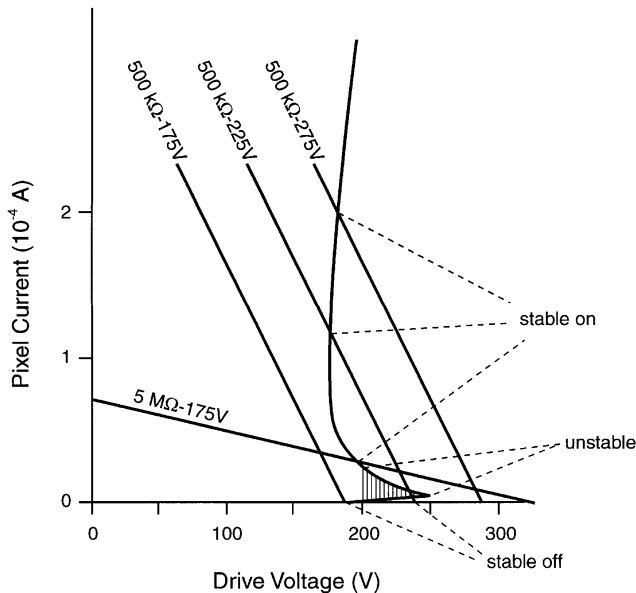

FIGURE 93.12 A representative current–voltage characteristic for gas breakdown. Load lines representative of plasma pixel operation are also shown. (From Weber, L.F., in *Flat Panel Displays and CRTs*, L.E. Tannas, Jr., Ed., Van Nostrand Reinhold, New York, 1985. With permission.)

to shield out electric fields within the gap is diminished. In this situation, the sheath potential drop is small but the sheath region occupies a large fraction of the gap [36,37].

Plasma Surface Interactions

Ion-Induced Secondary Electron Emission

Ions arriving at the cathode sheath are accelerated by the sheath potential drop. Incident ions strike the cathode with kinetic energies equal to the plasma potential, V_p , which is just over 200 V in the example shown in Fig. 93.12a. Ions incident on the cathode quickly capture an electron, additionally depositing on the cathode surface an energy equal to the recombination or ionization energy for that atom. Energy deposition on the cathode surface drives two important processes for plasma pixels — ion-induced secondary electron emission and sputtering. The first process significantly enhances the luminous efficiency of plasma pixels. The second shortens their operational lifetime as is discussed in subsequent sections.

Ion-induced secondary electron emission occurs when ion energy deposition on the surface results in electron ejection. Secondary electrons are exceptionally effective at driving discharge ionization since they gain large amounts of kinetic energy as they are accelerated across the cathode sheath and because they have ample opportunities for ionizing collisions as they traverse the entire width of the gas gap. The secondary electron emission coefficient, γ , is defined as the number of electrons ejected per incident ion [25,26]. As one would expect, γ varies with incident ion energy and with cathode material. Most ac plasma display panels take advantage of the strong secondary electron emission of MgO, which is also a good insulating material as required for surface charge storage in ac operation. Measurement of the MgO γ value is difficult, especially for low-energy ion incidence (<500 eV), and is complicated by charge buildup on the samples during the measurements [38]. Most often, relative values of secondary electron yields for different materials are deduced from discharge intensity measurements [11,12,39-42]. Chou directly measured the ion-induced secondary electron emission coefficient for MgO using a pulsed ion beam with sample surface neutralization between pulses. For ion incidence at 200 eV, he found $\gamma = 0.45$ and $\gamma = 0.05$ for Ne^+ and Ar^+ , respectively [39]. Note, too, that photons and metastable atoms incident

on the electrode surfaces are also capable of initiating secondary electron emission, as shown in Fig. 93.7. Since neither photons nor metastables are influenced by the electric fields within the gas gap, they propagate isotropically throughout the gas volume and are often utilized as seed particles.

Sputtering

Ions accelerated across the sheath deposit energy on the cathode surface. This often initiates sputtering, whereby an atom within the cathode material is ejected from the surface. Sputtering processes erode the cathode surface and degrade pixel performance. Contamination of the discharge by sputtered surface impurities can lead to reduction in luminous efficiency due to visible emissions from the contaminant atoms or molecules which compromise the color purity of the pixel. Unwanted surface coatings from redeposited materials can also degrade the electrical characteristics of the pixel or, in color applications, shield the phosphors from VUV photons, further degrading luminous efficiency. For argon ion, Ar^+ , bombardment of MgO surfaces at 2 keV, the measured sputtering yield is slightly greater than one ejected atom per incident ion [43]. Data on sputtering yields at lower energy ion incidence are difficult to obtain. Because yields are small, large incident ion currents are required to obtain measurable signals and sample charging is once again a problem. In spite of the lack of detailed data on low-energy MgO sputtering, manufactures of ac plasma panels have been able to demonstrate display lifetimes well in excess of 10,000 h [18,23]. Shone et al. [44] have demonstrated that Rutherford backscattering of high-energy (2.8 MeV) alpha particle can be used to measure the thickness of MgO film on a PbO substrate. The film thickness accuracy obtained was ± 1.5 nm. Because the technique requires a large (and expensive) particle accelerator, this technique is a very nice research tool but is ill suited for any fabrication line measurements.

93.3 Pixel Electrical Properties

Electrical Properties of dc Pixels

Figure 93.5 shows schematic diagrams and circuit models for dc and ac pixels. In the dc case, the pixel gas gap functions electrically as a variable impedance resistor. Prior to gas breakdown, the resistance is large and the pixel represents an open-circuit element. Once breakdown is initiated, the plasma is an excellent conductor and offers only modest resistance, R_p , to current flow. Since $R \gg R_p$, the circuit equation simplifies to

$$V_a = I(R + R_p) \approx IR \quad (93.6)$$

and the circuit current, I , is defined by the amplitude of the applied voltage and the size of the circuit series resistor, R . The externally applied voltage, V_a , is typically a 50-kHz square wave with a fast voltage rise time (~ 50 ns). The dc driving voltages range from 175 to 275 V and a typical value for the series resistor is $R = 500$ k Ω . Pixel currents then range from 0.35 to 0.55 mA. Note that without a large resistance in series with the pixel, the current is limited by some physical failure such as melting of the pixel electrodes.

Figure 93.12 shows the characteristic I - V behavior of a dc pixel which has a breakdown voltage of 250 V [4]. Only a very small current due to a few stray charge carriers flows across the gas gap as the voltage increases from 0 to 250 V and the pixel remains in the *off* state. At the breakdown voltage, the situation is dynamic with the current growing rapidly and the voltage across the gas gap dropping as a result. The steady-state operating point achieved is identified by the intersection of the load line, $V_a = IR$, with the discharge I - V characteristic as shown in Fig. 93.12. For an applied voltage of 175 V the pixel is always *off*, while for $V_a = 275$ V the pixel is always *on*. For a line resistance of 500 k Ω , the bimodal operation and memory of the dc pixel at $V = 225$ V is evident in the figure. If an applied voltage of 225 V is approached from the low-voltage direction, the pixel remains *off*. If, on the other hand, a large voltage is applied and subsequently lowered to $V_a = 225$ V, then the pixel will be in an *on* state. Note that the

region where the 225 V/500 k Ω load line intersects the negative resistance portion of the I - V characteristic is unstable. The pixel discharge will quickly transition to either the stable *on* or stable *off* operating point. As a practical matter, one should note that the negative resistance region of the I - V characteristic curve cannot be experimentally measured in a pixel circuit operating with a 500 k Ω series resistance. Instead, as shown in the figure, a much larger series resistor, $R = 5$ M Ω , provides a load line with slope small enough to produce stable operation in the negative resistance regime.

Electrical Properties of ac Pixels

The physical design of an opposed electrode ac pixel is shown in Fig. 93.5b. Electrically, the pixel functions as a breakdown capacitor and is described by the circuit equation:

$$V_a(t) = I(t)R + \frac{1}{C} \int_0^t I(t') dt' = I(t)R + Q(t)/C \quad (93.7)$$

where V_a is the externally applied voltage, I the circuit current, C the pixel capacitance, and Q the charge collected. For ac pixels the line resistance, R , is minimized in order to minimize power consumption and Eq. 93.7 simplifies to

$$V_a(t) = \frac{1}{C} \int_0^t I(t') dt' = Q(t)/C \quad (93.8)$$

The capacitance for each pixel is the series summation of the capacitance for each dielectric film and for the gas gap:

$$\frac{1}{C} = \frac{1}{C_{\text{PbO}}} + \frac{1}{C_{\text{MgO}}} + \frac{1}{C_{\text{gas}}} \quad (93.9)$$

In each case,

$$C_i = \frac{e_i A}{d_i} \quad (93.10)$$

where i is the material index and the surface area, A , is roughly equal to the square of the conductor wire width. As shown in Fig. 93.5b, an ac pixel is typically constructed with a PbO film of thickness $d = 25$ μm , while the thin-film MgO has thickness $d = 50$ to 200 nm. The lead oxide has a dielectric constant of roughly $\epsilon_{\text{PbO}} = 15\epsilon_0$, while that for MgO is $\epsilon_{\text{MgO}} = 6\epsilon_0$ with exact values dependent upon the film purity and microstructure [45]. Note that the MgO contribution to the total capacitance is negligible and that this material is incorporated into the design because of its excellent secondary electron emission properties. Prior to gas breakdown, the capacitance of the pixel is attributed largely to the gas gap. For 20- μm -thick conductor wires the capacitance of a pixel gas gap prior to breakdown is about 500 pF. The time derivative of Eq. 93.8 gives the circuit current:

$$I(t) = C \frac{dV(t)}{dt} \quad (93.11)$$

This charge displacement current appears as the initial large amplitude current peak in Fig. 93.13, which shows the temporal current response of a 45×45 ac pixel array to a single pulse within a 50-kHz square

FIGURE 93.13 Voltage and current traces for a 45×45 array of ac plasma pixels in the (a) *on* and (b) *off* states. Drive voltage amplitudes were 117 and 127 V, respectively.

wave applied voltage pulse train. The electrical measurement shown was made using a simple induction loop probe to measure the current and a high impedance voltage probe ($1 \text{ M}\Omega$, 3 pF) to monitor the applied voltage. The signals were captured using a high-speed (300 MHz) oscilloscope.

If the applied voltage amplitude is below the gas breakdown threshold, only the capacitor charging displacement current, defined by Eq. 93.11, is observed as shown in Fig. 93.13a. If the voltage for gas breakdown is exceeded, a second current pulse due to the plasma discharge current within the gas gap is observed in the circuit, Fig. 93.13b. The plasma pulse is accompanied, of course, by strong photon emission from the gas gap region. The total charge displacement in the discharge pulse as a function of amplitude of the square wave–applied voltage is plotted in Fig. 93.14 for a helium–xenon (2%) Penning gas mixture [35]. The hysteresis or inherent memory property of the ac pixel is apparent. As the applied voltage amplitude is increased from zero to 180 V , no measurable current flows across the pixel gas gap. When no surface charge is present, below 180 V the electric field within the gap region is insufficient to drive the electron collisions into the avalanche regime. For any voltage amplitude in excess of 180 V , a gas discharge is initiated and the pixel turns *on*. If a pixel is subjected to a single voltage pulse with amplitude less than 135 V , the pixel turns *off* even if a surface charge is present.

In ac pixels, charge pairs produced during one discharge pulse collect on the surfaces of the dielectric films at the boundaries of the gas gap and are available to assist formation of the next discharge pulse in the sequence. In a fully developed ac pixel discharge, the surface charge accumulation on the dielectric

FIGURE 93.14 Discharge charge displacement for operation of a 45×45 array of ac opposed electrode pixels with an He – Xe (2%) gas mixture at 53.3 kPa (400 torr).

film produces an electric field within the gas gap, which cancels the gap field produced by the externally applied voltage. This is shown in Fig. 93.15, which is a composite representation of experimental current measurements and computational model predictions of the surface charge accumulation producing the surface or wall voltage [34,36]. When the polarity of the applied voltage is reversed, the potential drop due to the surface charge and that due to the applied voltage suddenly are additive as shown in the figure. The gas gap is momentarily subjected to an intense electric field which results from a potential drop roughly equal to twice the applied voltage. The presence or absence of surface charge results in the bimodal current–voltage behavior shown in Fig. 93.14.

Addressing of ac pixels is easily accomplished by taking advantage of the inherent memory of the pixel that results from this bimodal I – V behavior. For the pixel electrical properties shown in Fig. 93.14, each pixel would be continuously supplied with an ac square wave applied voltage pulse train with an amplitude of 160 V, called the sustain voltage, V_{sustain} . If the pixel is initially in an *off* state, it will remain so indefinitely since no surface charge is available to enhance the field produced by the sustain voltage. To turn the pixel *on*, a single high-amplitude voltage pulse, called an address (or write) pulse is delivered across the pixel electrodes. In this example, an address pulse of 200 V initiates a discharge whose charge pairs collect on the internal dielectric surfaces of the pixel. The self-limiting nature of the ac pixel is such that the surface charge concentration produced for a fully developed pixel discharge completely shields the gap region from the externally applied field. When the next sustain polarity reversal occurs, the pixel gas gap experiences a voltage equal to the sum of the sustain voltage (160 V) plus the voltage due to the surface charge produced by the previous pulse, $V_{\text{surface}} = 200$ V in this case. The new gap voltage of 360 V is more than sufficient to initiate a second discharge and to establish a new surface charge whose polarity is opposite that of the preceding pulse. Once again, the surface charge adjusts to produce a voltage exactly canceling the field of the applied voltage. For this pulse, $V_{\text{wall}} = 160$ V, and the next sustain voltage polarity reversal subjects the gap to a potential difference of $V_{\text{gap}} = V_{\text{sustain}} + V_{\text{address}} = 160$ V + 160 V = 320 V, which is again sufficient to initiate a new discharge pulse. Consequently, the pixel remains in the *on* state

FIGURE 93.15 Sustain and address voltage waveforms for ac driven plasma pixels. The amplitude of the pixel current density and wall voltage resulting from the surface charge buildup provide a measure of the discharge intensity.

until action is taken to eliminate or diminish the surface charge buildup accompanying each discharge. This is accomplished by application of a single low-voltage pulse called an erase pulse with amplitude $V_{\text{erase}} = 120 \text{ V}$ for the example shown in Figs. 93.14 and 93.15. Application of the erase pulse produces a potential drop across the gas gap of $V_{\text{gap}} = V_{\text{applied}} + V_{\text{surface}} = V_{\text{erase}} + V_{\text{surface}} = 120 \text{ V} + 160 \text{ V} = 280 \text{ V}$. The erase pulse produces a discharge of lower intensity which is insufficient to reestablish a reversed polarity surface charge. Consequently, the erase discharge diminishes the concentration of the surface charge so that no discharge is initiated during the next pulse in the sustain applied voltage train. Ideally, the erase pulse drives the surface charge concentration identically to zero, but this rarely occurs in practice and is not essential for ac pixel operation, as can be seen in Fig. 93.15. Very low intensity discharges with negligible photon production drive the pixel to its ideal *off* state within a few ac cycles. Fortunately, these minor deviations from the ideal *off* condition have little effect on subsequent write pulses for frequency-modulated ac operation, and therefore do not affect the timing of pixel addressing and refresh which is covered in the next subsection.

93.4 Display Priming, Addressing, Refresh, and Gray Scale

Pixel priming is necessary to provide the initial source of electrons, or the priming current, required to initiate a discharge avalanche. Metastable atoms or photons can also be used as priming particles since these produce electrons via ionization of the background gas. Pilot cell priming and self-priming are two

options used in currently available commercial products. In pilot cell priming, a separate cell which generates electrons is located near the pixel to be addressed. Pilot cells are often located on the periphery of the display outside the viewing area, yet can produce seed electrons throughout the display. In self-priming, an auxiliary discharge created within each pixel provides the priming electron source for the main pixel discharge. These priming discharges are often hidden from view by positioning them behind opaque conductor wires. Introducing a trace amount of radioactive Kr^{85} into the gas mixture provides a passive priming option. The ionizing radiation from Kr^{85} generates priming electrons uniformly throughout the display interior. Because the required Kr concentration is low and because the beta radiation produced cannot penetrate the glass enclosure of the display, the radiation exposure risk to the display user is negligible. However, display manufacture using radioactive seeding involves potential health hazards associated with radioactive material handling. Consequently, this seeding approach, while very effective, is not at present employed in commercial products.

A simplistic scanning scheme for pixel illumination is shown in Fig. 93.2, reproduced here from Reference 4. The scan switches on one axis open and close sequentially in a repetitive fashion, while the data switches on the other axis determine if the pixel is fired on a given scan. This simplistic refresh and data update method fails to take advantage of the discharge properties or inherent memory functions available with plasma pixels. High-resolution dynamic displays utilizing this address scheme would not be cost-competitive since display drivers constitute a significant portion of the total cost of plasma displays. Driver circuit costs also increase with required output voltage. Thus, it is desirable to design plasma displays with operating voltages as low as possible and which require the fewest number of driver chips. Designers strive then to maximize the number of pixels driven by a single chip.

For nonmemory dc pixels, one option for reducing the number of external drive switches required is to sweep the firing of priming discharges repetitively across each pixel row, such as in the self-scan circuitry developed by Burroughs [46,47]. More recently, NHK has developed a pulse memory drive scheme for its 102-cm (40-in.) diagonal dc HDTV plasma display, which is being widely used [48]. Sustain operation at high frequency is used to take advantage of residual charge pairs and metastable atoms present in the pixel gas volume as result of the preceding discharge [49]. In this fashion, each pixel is self-seeding, with seed particle populations dependent upon the time elapsed since the termination of the preceding discharge. The high-frequency operation is fast enough to take advantage of the short duration memory characteristic of the dc pixel. As the sustain voltage pulse train is applied to the electrode of a pixel, it will remain in the *on* or *off* state indefinitely until an address or erase pulse is supplied. In the NHK scheme, an auxiliary anode is used to assist in the *address* access operations. Figure 93.16a shows the block diagram of such a system, while Fig. 93.16b shows the time sequences for the scheme [48]. Note that the pulses are dc and that *on* state pulses have larger gap voltages than erase pulses. The timing sequence is critical to address a pixel selectively within the matrix. Implementation of this scheme requires (1) display anode drivers, (2) auxiliary anode drivers, (3) cathode drivers, and (4) interfaces to decode the HDTV signals provided to the drivers.

For ac displays with memory, drivers need to provide (1) *address* (or *write*) pulses, (2) *sustain* pulses, and (3) *erase* pulses. A complex refresh scan signal is not required since a continuously supplied sustain signal, coupled with the ac pixels inherent memory, trivially maintains each pixel in either an *on* or *off* state. Pixels respond to address, sustain, and erase pulses as described in the preceding section. Similar to dc pixel dynamic control discussed above, ac pixel addressing requires well-timed application of voltage waveforms to the rows and columns of the display matrix so that the proper voltage appears across the electrodes for the pixel of interest without modifying the state of adjacent pixels. A more-detailed discussion of ac pixel addressing can be found in Reference 4 or 47.

Gray scale is achieved for dc or ac plasma displays either by modulation of the discharge current or by duty cycle modulation with fixed current. Modulating the applied voltage amplitude to vary the discharge current is not widely used because of practical limitations in effectively controlling the nonlinear response of the discharge current. However, duty cycle modulation is a viable technique both for pulse memory-driven dc displays and for ac memory displays. In either case, duty cycle modulation requires

FIGURE 93.16 Pulsed memory operation of the NHK dc plasma display. (a) Block diagram of the driver system and pixel array. (b) Temporal sequences for pulsed memory operation. (From Yamamoto, T. et al., *SID' 93 Sympos. Dig.*, 165–168, 1993. With permission.)

complex circuit design for the well-timed delivery of *on* and *off* pulses. Gray scale is achieved by varying the time a pixel is *on* compared with *off* during each refresh cycle. In 50-kHz operation, a sustain half cycle is 10 μ s. VUV photon emission occurs usually in less than 1 μ s. For color displays the visible light emission persists much longer, with the fastest phosphors having 10% persistence times of about 5 μ s. More typical phosphors have 10% persistence times in the 5 to 10 ms range [50]. If the image is updated every 40 ms, corresponding to a refresh rate of 25 images per second, then a 1/8-level brightness is achieved by having the pixel *on* for 5 ms and *off* for 35 ms during that refresh cycle. The time *on* is interspersed throughout the 40 ms refresh period by appropriate timing circuit design. For example, the NHK 102-cm (40-in.) display has a 2⁸ or 256 levels of gray scale per color, providing a total of 16 million (256³) color scale levels [48].

93.5 Color Plasma Flat Panel Displays

Color Pixel Structures

In color plasma display panels, photoluminescent phosphors provide the primary RGB optical emissions required for full-color image display. In this case, visible emissions from the discharge itself must be suppressed in order to avoid color contamination. A common approach is to utilize xenon as the minority species constituent in the Penning gas mixture of the panel. The structure and phosphor layout of the 102-cm (40-in.) diagonal color dc plasma display available from NHK is shown in Fig. 93.17, while that of the Fujitsu 53-cm (21-in.) diagonal ac color display is shown in Fig. 93.6. Each uses screen printing and hard mask or abrasive-resistant lithographic processes for conductor wire deposition, barrier structure definition, and phosphor deposition [51]. In the NHK design, the fourth section within the honeycomb color pixel structure houses a redundant green phosphor subpixel to compensate for the lower photoluminance of green phosphors relative to that of either red or blue phosphors. In a similar honeycomb dc color pixel structure, Panasonic instead incorporates a series resistor in this fourth subpixel position [20]. Printing the series resistor for each pixel on the display glass substrate complicates panel manufacturing but simplifies design requirements for the drive electronics. In the Fujitsu, the opposed electrode ac color pixel structure shown in Fig. 93.6, barrier or separation rib structures running between and parallel to each conductor wire are fabricated on the rear glass substrate. The barrier rib heights are typically 100 to 150 μ m. Ac barrier rib structures and dc pixel honeycomb lattice structures are usually composed of the same PbO thick-film dielectric used to cover the conductor wires.

FIGURE 93.17 Structure of the 40-in. color display manufactured by NHK. (From Yamamoto, T. et al., *SID' 93 Sympos. Dig.*, 165–168, 1993. With permission.)

VUV Photon Production and Utilization for Color Plasma Flat Panel Displays

Color plasma display gas mixtures utilizing xenon as the minority species are optimized for production of VUV emissions which are used to excite RGB photoluminescent phosphors. Both neon–xenon and helium–xenon combinations are popular. The ionization energy of xenon at 12.3 eV lies below the lowest excited atomic states of either neon or helium, as shown in Fig. 93.8. Consequently, electrons accelerated by electric fields within the pixel volume preferentially impart their kinetic energy to the xenon atoms. In addition, the excited states of He or Ne produced readily transfer stored energy to the xenon atoms through ionizing Penning collision processes. Consequently, the red-orange visible emissions typical of Ne discharges are suppressed as Xe concentration is increased. Fujitsu utilizes an Ne–10% Xe working gas in its color display [18], while Photonics Imaging prefers to use an He-based background gas in its panel [23] where suppression of unwanted optical emissions from the discharge can be accomplished at somewhat lower xenon concentrations.

The tendency of xenon to fill its outermost electronic shell results in the formation of the xenon dimer molecule, Xe_2^+ , whose energy states are also shown in Fig. 93.8 [52,53]. Radiative dissociation of the dimer produces photons with wavelengths near 173 and 150 nm. Figure 93.18 shows how the dimer emissions dominate the VUV spectra from He–Xe gas pixel discharges as the fraction of Xe is increased. Since VUV photons are completely absorbed by glass, the spectra shown in the figure were measured by mounting opposed electrode pixels inside of a vacuum chamber filled with the gas mix of interest. The boundaries of the panel glass were not sealed which then allowed on-edge viewing of the pixel discharges with a McPherson 0.2 m monochromator operating in conjunction with a Princeton Instrument CCD optical multichannel analyzer [34]. The background gas mix was varied to obtain the various Xe concentrations in He shown while maintaining a total gas pressure of 53.3 kPa (400 torr). At low Xe concentrations, photons from the atomic Xe $1s^4$ and $1s^5$ states dominate the emission spectra producing lines at 147 nm and, with much less intensity, at 129 nm. The Tachibana laser-induced spectroscopic measurements show the spatial and temporal evolution of the $1s^4$ Xe atomic state in He/Xe plasma display discharges [54]. Both of these atomic lines experience significant resonant absorption and reemission. Thus, the measured line intensities are strong functions of photon path length traveled and of Xe partial pressure in the background gas [55]. For the emission spectra shown in Fig. 93.18, the lithium fluoride (LiF) entrance window to the evacuated spectrometer chamber was positioned between 100 and 150 nm

FIGURE 93.18 VUV emission spectra from opposed electrode ac plasma pixel discharges in He/Xe gas mixtures. Each spectrum was collected near the minimum sustain (or first *on*) voltage for that gas mixture, which ranged from 150 V for 0.1% Xe to 350 V for 20% Xe.

from the nearest pixel discharges, which is roughly the location of the phosphors relative to the discharge in an opposed electrode ac color display panel; for an example, see Fig. 93.5.

Recall that the optimal charge pair production per volt applied in Penning gas discharges occurs at minority species concentrations as low as 0.1%; see Fig. 93.9. However, color plasma pixels must optimize usable photon production per watt while maintaining stringent color purity requirements. Consequently, color plasma pixels typically operate with xenon concentrations ranging between 2 and 10%. Figure 93.18 shows that increased xenon concentration results in significant dimer formation and radiative emission from dimer dissociation. Since the dimer dissociation is a three-body process involving a photon and two xenon atoms, the momentum and energy conservation equations do not demand unique solutions. Consequently, emissions lines produced cover a broad spectral range spanning several tens of nanometers. Increased dimer emission is accompanied by the suppression of xenon atomic emission as energy within the atomic manifolds continues to flow toward the lowest available atomic levels; see Fig. 93.8. Note, too, that the dimer emission lines are not subject to resonant absorption. Therefore, the measured intensities shown reflect dimer emission from all pixels rows within the line of site of the spectrometer (four for the data of Fig. 93.18). In contrast, due to the strong resonance absorption of the atomic lines, more than 90% of the measured intensity of the 147-nm line is produced in the pixel row adjacent to the spectrometer window [34,55]. Care must be taken to account for these large variations in photon mean free paths when analyzing emission data.

Phosphor Excitation and Emission for Color Plasma Flat Panels

A variety of photoluminous phosphors are commercially available. Efficiencies for conversion of VUV photons to visible emissions has a complex dependence on excitation photon wavelength as can be seen

FIGURE 93.19 Relative quantum efficiencies of a Tb-activated lanthanum phosphate compared to that of yttrium and gadolinium phosphate prepared by Sarnoff Research Center. (From Yocum, N. et al., *J. SID*, 4/3, 169–172, 1996. With permission.)

in Fig. 93.19, which shows quantum conversion efficiencies relative to a sodium salicylate standard for some of the available green phosphors [50]. Conversion efficiencies for red, blue, and other green phosphors can be found in References 56 and 57. Table 93.2 provides the compositions of some selected commercially available phosphors and lists their relative quantum efficiencies for the principal emission lines of xenon discharges. Note that quantum efficiencies listed are relative values and that phosphors that convert 8.4-eV photons to visible photons near 2.3 eV have absolute efficiencies of only 27%. In principle, it is possible to produce two or more visible photons from a single high energy photon, but to date no such phosphors have been developed [58]. Table 93.2 also lists the chromaticity diagram coordinates which provide a measure of the color purity of the visible RGB emission spectra produced. The chromaticity diagram can be found in many references including Reference 59. Another consideration is the plasma display phosphor selection is persistence. Most of the phosphors listed in Table 93.2 require 5 to 13 ms for the emission intensity to decay to 10% of maximum value. For ac pixel operation at 50 kHz, each sustain voltage half cycle lasts only 10 μs while the discharge produces VUV emissions for only a small fraction of that time. Efforts are continuing for development of phosphors with faster response times. For example, Eu^{2+} green phosphors with 10% decay times of only 5 to 10 μs and with good quantum efficiencies near 173 nm have been developed [50].

Color Plasma Display Lifetime Considerations

Phosphors for plasma flat panel displays must be tolerant of the harsh environment produced by the pixel discharge. Photoluminous phosphor degradation mechanisms are at present not well understood. Contamination of the discharge by phosphor materials is a serious concern. Discharge modeling indicates that damage results principally from the accumulated fluence of photon and metastable bombardment, although fringe electric fields and prolonged surface charge accumulations could also result in ion bombardment [37]. Most ac plasma displays take advantage of MgO for enhancement of the discharge intensity by coating dielectric surfaces above the electrodes with an additional thin film of MgO. For ease of fabrication, the MgO is most often deposited using electron beam evaporation as one of the final manufacturing steps before glass seal and gas fill. If no mask is used, the MgO can also cover the

phosphors. While providing the phosphors with a protective coating, the MgO film also attenuates the intensity of the VUV photon flux available to excite the phosphors. Figure 93.20 shows VUV photon transmission as a function of wavelength through MgO films [34,60]. The measurements show that the primary atomic Xe emission lines at 129 and 147 nm are nearly 95% attenuated by an MgO film only 75 nm thick. In contrast, the dimer emission lines centered near 173 nm are much less attenuated with transmission factors of 30 to 50%, respectively, for MgO films of 200 and 75 nm. Consequently, ac plasma display designers must often achieve a balance among discharge enhancement due to MgO secondary electron emission, discharge degradation due to MgO photon absorption, and fabrication complexity associated with MgO deposition, which impacts the final cost of the display. Additionally, the designer must consider the aging or brightness degradation with time of the display, which is influenced in part by the rate of MgO sputter erosion discussed briefly below.

FIGURE 93.20 Photon transmission through MgO films before and after bake-out to remove water vapor.

93.6 Inspection and Metrology

Plasma display panel manufacturing uses some process steps typically found in semiconductor device manufacturing. Although the feature sizes are much larger than those required in semiconductor manufacturing, the dimensions over which feature integrity must be assured are also much larger. Confirmation that a display manufacturing process is under control or rapid quantitative characterization of the deviation from acceptable process limits is essential to producing high-quality displays with high yield. Information on a variety of length scales is required. Blanket deposition of materials onto substrates should be uniform; large deviations in thickness of the deposited material from one point on the substrate to a widely separated point should be avoided. Similarly, roughness of the deposited layers must be kept within defined limits. Finally, chemical compositions of deposited layers and their spatial homogeneity need to be measured and controlled.

The three commercial profile measuring devices, the CyberOptics, Zygo, and Leitz units, are based on laser or white light triangulation or interferometry; see Table 93.3 [61-63]. These machines are well suited for determining the profile of metallization after patterning. They do not appear to be useful for measuring the thickness of opaque layers and cannot, for example, measure the thickness of the blanket metallization before patterning. The CyberOptics unit is in wide use in the electronic packaging industry because of the low noise in its signal. Improvements in vertical resolution would increase its value for display manufacturing process control. The Zygo instrument has better vertical resolution, but has no real scanning capability. The Leitz unit is designed specifically for metrology of unfinished liquid crystal display components, and is presumably optimized for that application. Both the CyberOptics and Zygo units have a variety of heads with differing resolutions and fields of view. However, the vertical distance over which the interference can take place in the Zygo unit is very limited, so it may not be suitable for measuring features with large vertical dimensions.

TABLE 93.3 Equipment for Noncontact Profiling and Chemical Characterization of Thin Films

	CyberOptics Point Range Sensor	Zygo NewView 200	Leitz FTM400
Physical principle	Laser triangulation	Scanning white light interferometry	Laser interferometry
Maximum thickness/step height	150 μm (high resolution head)	100 μm (standard) (to 5 mm with z-drive)	70 μm
Vertical resolution	0.38 μm	100 pm	150 pm or 0.5%
Spatial resolution	>0.5 μm	0.22 μm	0.5 μm
Spot diameter/FOV	5.1 μm	140 \times 110 μm	20 μm
Scan rate	10 points/s	2 or 4 $\mu\text{m/s}$	75 mm/s max.
Maximum sample size	Based on Table	10 cm \times 15 cm	47 cm \times 37 cm
Maximum sample weight	Based on Table	4.5 kg	4.5 kg (including holder)
Elemental detection	N.A.	N.A.	N.A.

Depending on system requirements, a useful laser metrology system can be purchased for as little as \$20,000. Full-featured systems can easily cost \$100,000. The bulk of the cost is, however, in the precision transport tables used for moving samples in a precisely controlled manner beneath stationary measurement heads. Since precision transport tables meeting the needs of the metrology equipment may already be part of the display production process or would require only minor upgrades to be brought in line with requirements, the cost to bring the metrology capability online may be much smaller than the figures mentioned above. Since laser head costs are low, it may also be desirable to use multiple fixed heads to speed up inspection and metrology.

Listed in Table 93.4 are the characteristics of two advanced measurement techniques for noncontact profiling and chemical analysis. To the authors' knowledge, systems of this type are not yet commercially available. They are being utilized, however, by researchers at Sandia National Laboratories and show promise for commercial usage. In beta backscattering measurements, the energy spectra of the backscattered beta particles provides an accurate measure of the elemental composition of a surface. This technique has been used to measure the thin-film thickness of trace-deposited metals on large-area surfaces (several square meters) in tokamaks [64]. With a depth resolution of about 100 pm, beta backscatter could serve as the physical basis for a high-sensitivity surface-profiling device. X-ray fluorescence measurements, routinely performed in air, can give information on film thickness and composition, and performance parameters for this technique are also listed in Table 93.4. Vacuum must be used when studying light elements like carbon, a potential undesired product of phosphor binder burnout, because the x rays produced are "soft". Although x-ray fluorescence equipment may have good lateral resolution, a larger spot size may prove useful when more averaged information such as film thickness is needed. Finally, eddy current measurements may provide a fast and reliable method for determining the thickness of the opaque, blanket metallization before patterning. This technique should be capable of providing 10% thickness measurement accuracy for conductor layers as thin as 1 μm .

TABLE 93.4 Advanced Techniques for Noncontact Profiling/Chemical Characterization of Thin Films

Physical Principle	β -Backscatter	X-Ray Microfluorescence
Maximum thickness/step height	A few mm	50 μm
Vertical resolution	About 0.1 nm	0.1 μm
Spatial resolution	Depends on pinhole size	50 μm to 2 mm
Spot diameter/FOV	Depends on pinhole size	100 μm
Scan rate	<1 min/measurement	1 spot/min
Maximum sample size	No restriction	24 cm \times 21.5 cm
Maximum sample weight	No restriction	4.5 kg
Elemental detection	N.A.	<10 – 300 ppm

Many of the devices for quantitative characterization of the thickness and chemistry of the deposited layers suffer from the fact that they have a rather limited field of view. Characterization techniques are needed that will allow rapid identification of visual defects in the blanket-deposited layers and in the patterned layers produced from them. Visual inspection equipment is available for defect identification in liquid crystal displays. Manufacturers include Minato Electronics, Advantest, ADS, Photon Dynamics, and Teradyne. All use CCD devices and special algorithms for the identification of line and area defects. The defects found during high-volume plasma display manufacturing may be sufficiently similar in appearance to those found in liquid crystal display manufacturing that this equipment will prove useful with appropriate adjustments. These devices, however, are expensive.

Although researchers and equipment manufacturers believe that the equipment and techniques described above will be suitable for online process control during plasma display manufacturing, all agree that more development is required. Real parts will need to be characterized extensively on specific commercial equipment in production environments before conclusions can be drawn about the suitability of the equipment and techniques for the intended application. This is particularly true for more difficult measurements, like that of the thickness of dielectric above conductor lines. It is clear that there is no single instrument that will meet all film and feature dimensional measurement requirements and those for chemical characterization. A number of instruments will be needed to measure confidently the parameters needed for inspection, and characterize and control the manufacturing processes for plasma displays.

Planar Systems

94.1 Introduction

Electroluminescence (EL) is the nonthermal generation of light resulting from the application of an electric field to a substance. The light-emitting substance is generally a luminescent crystal. Most commercially available monochrome EL displays utilize ZnS:Mn as the luminescent material. EL displays have become very important in certain display markets. These include medical instrumentation, industrial control equipment, portable instrumentation, and military vehicles. The attributes of EL displays that make them attractive in these types of applications are mechanical ruggedness, relative insensitivity to ambient temperature, rapid display response, essentially unlimited viewing angle, compactness, and light weight.

There are four types of EL devices: ac thin film, ac powder, dc thin film, and dc powder. The ac thin-film display is by far the dominant device type. Some liquid crystal displays use ac powder EL for backlights. There is currently little or no commercial application of dc EL devices, either thin film or powder [1]. The focus here is on ac thin-film EL (ACTFEL) devices. While there are no widely established standard measurement techniques for the other EL device types, measurements similar to those described herein for ACTFEL devices could be applied with appropriate modifications to the other methods of device excitation.

FIGURE 94.1 Schematic, cross-sectional diagram of the basic ACTFEL device structure.

94.2 Device Structure and Operation

A schematic, cross-sectional representation of the basic ACTFEL device structure [2] is shown in Fig. 94.1. The supporting substrate is usually made of very low sodium glass. If a suitable ion barrier layer is deposited between the substrate and lower electrode of the EL device, soda-lime glass can be used. The lower electrode, usually a transparent conductor such as indium tin oxide (ITO) is deposited next. The ITO is usually between 350 and 120 nm in thickness, providing sheet resistance in the range of 5 to 15 Ω /square. On top of the ITO electrode a lower insulator is deposited. This layer is typically SiON or aluminum titanium oxide (ATO). The thickness is normally around 200 nm. The phosphor layer, typically ZnS:Mn, is deposited between the lower insulator and a similar upper insulator. The phosphor thickness is typically in the range 200 to 1000 nm thickness, depending on the application. The upper electrode, typically aluminum, is deposited on top of the upper insulator. The aluminum is generally 100 to 200 nm thick.

A matrix-addressed monochrome display is created by dividing the upper and lower electrodes into orthogonal arrays of electrode stripes. The EL device is then excited locally by applying a voltage between a pair of crossing electrodes, causing an electric field to exist between them, which excites the phosphor. A color display can be created by dividing the phosphor into stripes of red-, green- and blue-emitting phosphors which are aligned with one of the sets of electrode stripes [3,4]. This is shown schematically in Fig. 94.2. Color displays can also be created by using an unpatterned phosphor which emits a broad spectrum including red, green, and blue and filtering the emission using either a patterned color filter which is aligned with the electrode stripes or a frame sequential color filter.

94.3 Device Fabrication

Thin-Film Deposition Methods

A wide variety of deposition techniques are used by various manufacturers and researchers in the fabrication of ACTFEL devices. The electrode materials ITO and aluminum are usually deposited by physical vapor deposition (PVD) techniques. ITO is almost universally deposited by dc magnetron

FIGURE 94.2 Schematic, cross-sectional diagram of a color ACTFEL device with the red, green, and blue primary colors produced by patterned color phosphor stripes. The color phosphor stripes are end on in this view.

sputtering from either a conductive ITO target or from a metal alloy target [5]. Optimum ITO conductivity is obtained by postdeposition annealing in a very low oxygen environment. Al is deposited either by dc magnetron sputtering from an Al metal target or by electron beam evaporation of Al metal. The insulator and phosphor layers are deposited by chemical vapor deposition (CVD) as well as PVD. Phosphor layers have been deposited by thermal as well as e-beam evaporation, sputtering, metal-organic CVD (MOCVD), and atomic layer epitaxy (ALE). Insulator layers have been deposited by e-beam evaporation, radio frequency (RF) sputtering, plasma-enhanced CVD (PECVD), and ALE.

Thin-Film Patterning Methods

Patterning of the electrodes is generally accomplished either through etching or liftoff, although some early workers patterned the upper aluminum electrodes by evaporating through a shadow mask. Aluminum is easily etched wet or dry. There are commercially available wet etches for Al. Dry etching of Al can be carried out using standard chlorine chemistries, e.g., Cl_2/BCl_3 . Al can also be patterned by evaporating onto a reversed photoresist pattern and lifting off excess metal. ITO can be etched wet or dry. ITO wet etches generally consist of mixtures of HCl and HNO_3 . ITO can be dry-etched in HI or HBr. Patterning of the phosphor layers is more problematic. Phosphor etches exist for most ACTFEL phosphor materials, but they are generally proprietary. Thin-film phosphors are difficult to etch because they are usually water sensitive, and some color phosphors contain heavy metals which are difficult to volatilize in a dry-etch process.

94.4 Device Operation

Luminescence Mechanisms

As the device structure shown in Fig. 94.1 indicates, ACTFEL devices are capacitively coupled. Since only displacement current can flow across the insulator layers, the drive signal must be an alternating polarity waveform. A typical alternating polarity, trapezoidal waveform is shown in Fig. 94.3. If the peak voltage, V_p , in Fig. 94.3 is larger than the **threshold voltage** of the device, V_{th} , then, when the positive pulse of the waveform is applied between the Al and ITO electrodes of the device structure shown in Fig. 94.1, the energy band diagram of the ACTFEL device will be as shown in Fig. 94.4. Electrons, which are the majority carriers in ACTFEL devices, tunnel out of the interface states on the left and into the conduction

band. Once in the conduction band the electrons are accelerated by the large electric field, which is approximately $1 \text{ MV/cm} = 100 \text{ kV/mm}$. The conduction electrons drift across the ZnS:Mn layer until they impact excite an Mn^{2+} center, transferring some energy to one of its electrons and causing it to undergo a transition to an excited state. The conduction electron may undergo additional collisions, eventually reaching the right interface and getting trapped in interface states there until the next voltage pulse, which is of the opposite polarity. This pulse causes the electrons to tunnel out and drift back across the ZnS:Mn layer, transferring energy to Mn^{2+} centers along the way, until eventually they are trapped again at the left interface. This transfer of charge back and forth between the interface states continues as long as the alternating polarity drive signal with a peak amplitude above the threshold voltage of the device continues to be applied. Light emission occurs when the Mn^{2+} centers, which have been impact excited by the hot electrons, relax [6-8]. The light emission thus results from transitions of the electrons within the Mn^{2+} centers, rather than electron-hole pair recombination near a *pn* junction as occurs in a light-emitting diode (LED).

FIGURE 94.3 Typical alternating polarity, pulse drive waveform. Letters A–L mark points on the drive waveform which are referenced later in Figs. 94.5 and Fig. 94.6. The pulse width would generally be about $30 \mu\text{s}$ and the frequency would be between 60 and 500 Hz for a passive matrix-addressed display.

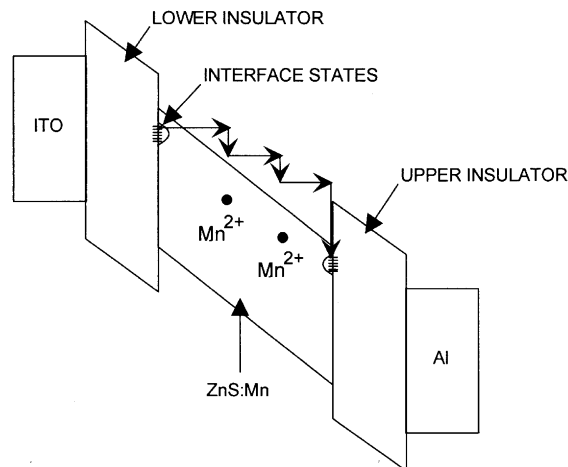

FIGURE 94.4 Energy band diagram of an ACTFEL device during the peak of the applied voltage pulse. Electrons tunnel out of insulator/phosphor interface states into the conduction band, are swept across the phosphor layer, and impact exciting emission centers as they go until they are finally thermalized and trapped at the opposite interface.

FIGURE 94.5 Idealized QV loop with no charge leakage from interface states between drive pulses. Letters A–L mark points on the QV loop which are coincident in time with the points labeled A–L on the drive waveform in Fig. 94.3. The dashed line is the QV loop for the case just below threshold. The solid line is the open loop above threshold. The area of the QV loop represents the energy dissipated by the device per cycle of the drive waveform.

Description of Charge Flow

If the external charge, Q , flowing into the ACTFEL device is plotted vs. the externally applied voltage, V , the resulting curve is called a **QV loop** [9,10]. If the amplitude of the applied voltage pulses is less than the threshold voltage of the device, the QV loop is simply a straight line with slope equal to the total capacitance of the insulator/phosphor/insulator stack. If the amplitude of the applied voltage pulses is greater than the threshold voltage of the device, the QV loop opens up. QV loops below and above threshold are shown in Fig. 94.5. Above threshold, power is dissipated in the ACTFEL device. The area encompassed by the QV loop is equal to the energy delivered to the device per period of the drive waveform.

The QV loop is measured directly. A theoretical extension of the QV loop that is sometimes used by researchers studying the physics of ACTFEL devices is a plot of the actual charge flow across the phosphor layer, Q_p , vs. the electric field across the phosphor layer, F_p . The quantities required for a plot of $Q_p F_p$ can be calculated from the QV data if the thicknesses and dielectric constants of the insulator layers and phosphor layer are known. The actual charge flow across the phosphor is calculated by subtracting the reactive charge from the total charge. The field in the phosphor layer is calculated by adding the externally applied field to the internal **polarization field** due to the actual flow of charges across the phosphor layer. A $Q_p F_p$ loop corresponding to the above threshold QV loop of Fig. 94.5 is shown in Fig. 94.6. The $Q_p F_p$ loop is useful because it expresses the internal electrical characteristics of the phosphor layer during device operation.

Device Excitation

Whether the device under test is a test dot or a matrix display, the drive waveform must be ac coupled. Passively addressed matrix displays are scanned one row at a time. Data are loaded into the column drivers for a single row of pixels and the selected pixels in the row are all turned on simultaneously. The row pulse brings the voltage across each pixel in the row to a level just below threshold. The columns of selected pixels are then pulsed to bring the voltage across selected pixels to a level above threshold and the pixels are turned on. During the following frame the voltage polarities across the pixels are reversed.

FIGURE 94.6 $Q_p F_p$ loop corresponding to the above threshold QV loop in Fig. 94.5. This loop represents the charge flow across the phosphor layer as a function of the electric field across the phosphor layer.

Each individual pixel is subjected to a drive signal similar to that shown in Fig. 94.3. To activate a pixel fully requires the voltage to be held above V_{th} for 10 to 20 μs . Since each row must be scanned in sequence, a typical display with approximately 500 rows requires at least 5 ms to scan one frame. The maximum frame rate is thus approximately 200 Hz. Displays that are addressed by an active matrix of transistors are not scanned a line at a time as passively addressed displays are, but instead are bulk driven. They have one unpatterned common electrode, usually an upper layer of ITO, to which an ac drive signal is applied. Each pixel is connected to ground through a transistor which drops a portion of the applied drive voltage when the pixel is not selected. In this type of display the drive waveform can be any ac signal of the appropriate voltage. Sine, trapezoid, and triangle waveforms have been used. An active matrix display can be driven with a frame rate higher than a passive matrix-addressed display by a factor equal to the number of rows in the display, since row-at-a-time scanning is not required. Since a light pulse is emitted for each voltage pulse, the average luminance is proportional to the frame rate, resulting in much higher luminance capability for active matrix-addressed displays.

94.5 Standard Measurements

Measurable quantities of interest include luminance, luminous efficiency, emission spectrum, latent image, and defects. The luminance of an ACTFEL display is a function of the peak voltage and frequency of the drive waveform, the intrinsic efficiency of the insulator/phosphor/insulator stack, and the operating history (aging). The efficiency is a function of the drive waveform shape and frequency as well as various device parameters. The emission spectrum is primarily determined by the phosphor host material and activators, although it is also affected by deposition and anneal conditions and in some cases by the drive voltage and frequency. **Latent image** is the burning in of a permanent image of a fixed pattern which is displayed for long periods. It can appear as a faint dark image superimposed on a bright background or as a faint bright image superimposed on a dark background. Formation of latent image is affected primarily by drive waveform symmetry and device processing parameters. Display defects include pixel, line, and mura defects.

94.6 Time-Resolved Measurements

Measurements of luminance, efficiency, and emission spectra as introduced so far involve time-averaged light emission. There are two fairly common time-resolved measurements of ACTFEL light emission:

light emission decay time and time-resolved light emission spectroscopy. The **light emission decay time**, τ , is the time it takes for the light emission from one excitation pulse to fall to $1/e$ times its initial value. The measurement of τ is started just after the trailing edge of the excitation pulse. This is necessary in order that the measured value of τ not be affected by the continuing excitation of additional emission centers, so that it represents the intrinsic relaxation time of the emission center. In devices with evaporated ZnS:Mn phosphor, τ is a strong function of the Mn concentration. It can thus be used as an analytical technique to determine the Mn concentration. Time-resolved spectroscopy is the measurement of the emission spectrum occurring during specific portions of the excitation and emission process. An example of the application of this technique is the study of the separate light pulses emitted during the leading and trailing edges of the excitation pulse with the blue-emitting phosphor SrS:Ce. Both of these techniques are frequently used to help elucidate the excitation and emission mechanisms in ACTFEL phosphors.

94.7 Test Dot Characterization

Luminance and Efficiency

A schematic representation of a measurement system for collecting luminance and efficiency vs. voltage data on a test dot is shown in Fig. 94.7. An arbitrary waveform generator provides a drive signal with the waveshape, frequency, and peak voltage determined by a control computer. The waveform generator output signal is amplified from a ± 5 V range to a ± 300 V range. A photometer, also under computer control, measures the luminance, L , of the test dot. An oscilloscope measures the voltage across the test dot and the voltage across the sense resistor. The current is calculated by dividing the voltage across the sense resistor by its resistance. The control computer can thus adjust the peak voltage up and down and collect the luminance data, as well as the waveforms representing the voltage across the test dot and the current through it. The energy dissipated, E_p , during each drive pulse is calculated as

$$E_p = \int_D I(t) \times V(t) dt \quad (94.1)$$

where $I(t)$ and $V(t)$ are the current and voltage waveforms, respectively, and D is the duration of either the positive or negative drive pulse. This integration can be carried out by most oscilloscopes or the $I(t)$ and $V(t)$ data can be transferred to the control computer for the calculation, although this approach is generally slower. The average energy dissipated per period of the drive waveform, E , is the average of E_p for a positive pulse and a negative pulse. The average power dissipated, P , can be calculated by multiplying E by the frequency of the drive waveform. The efficiency, η , is calculated as follows:

$$\eta = \frac{\pi LA}{P} \quad (94.2)$$

where L is the luminance in cd/m^2 , A is the area of the test dot in m^2 , and P is the average power in watts. Values of L and η are collected for peak voltages ranging from 10 V below threshold to 40 or 50 V above threshold. Plots of L and η vs. peak voltage for a typical device are shown in Fig. 94.8.

Charge Flow and Electric Field

The QV loop is measured using a circuit identical to that in Fig. 94.7, except that the sense resistor is replaced by a sense capacitor and the photometer is not used. The sense capacitor value is chosen to be much larger than the capacitance of the ACTFEL device so that the voltage dropped by the sense capacitor is small. Since the sense capacitor and the ACTFEL device are in series, the charges stored on them are equal. The charge, Q , on the ACTFEL device is thus

FIGURE 94.7 Schematic diagram of a system for measuring luminance and efficiency as functions of the peak drive voltage. The voltage waveform, $V(t)$, is measured by the oscilloscope at the Al electrode of the device under test. The current waveform, $I(t)$, is measured by the oscilloscope as the voltage across the sense resistor divided by its resistance. The luminance is measured by the photometer.

FIGURE 94.8 Plots of luminance and efficiency as functions of peak drive voltage. The solid line is the luminance and the dashed line is the efficiency.

$$Q = C_S V_S \quad (94.3)$$

where C_S is the capacitance of the sense capacitor and V_S is the voltage appearing across it. When $Q(t)$ is plotted vs. $v(t)$, the QV loop results. In the idealized QV loop shown in Fig. 94.5, V_{th} (C) is the threshold voltage, V_{to} (B) is the **turn on voltage**, and V_p (D,E) is the peak voltage of the drive waveform. Threshold voltage is the voltage at which the first knee in the LV curve occurs. If C_T is the total capacitance of the device below threshold, this is also the voltage at which the line $Q = C_T V$ intersects the open, above-threshold QV loop (C). In practice, it is sometimes defined as the voltage at which a certain luminance value occurs at a given frequency, e.g., the voltage at which the luminance is 1 cd/m^2 at 60 Hz. V_{to} is the

voltage at which the slope of the QV loop changes from C_T to C_I , where C_I is the capacitance of the insulator layers.

Since a differential element of energy delivered to the ACTFEL device is $dE = V(t)dQ$, then

$$E = \int V(t)dQ \quad (94.4)$$

The energy delivered per period of the drive waveform is thus equal to the area encompassed by the QV loop. The power dissipated is just the energy per period multiplied by the frequency. In practice, the area of the QV loop is measured by numerical integration. The calculation can be carried out on the oscilloscope if it has analysis capabilities or the data can be transferred to the control computer for integration.

Generation of the $Q_p F_p$ loop does not require any electrical measurements other than those required for the QV loop. Q_p is the charge separation across the phosphor layer and F_p is the electric field across the phosphor layer. If the thicknesses and dielectric constants of the insulator and phosphor layers are known, Q_p and F_p can be calculated from the values of $Q(t)$ and $V(t)$ on the QV loop. This is accomplished by applying the following equations [11,12]:

$$Q_p(t) = \frac{C_i + C_p}{C_i} Q(t) - C_p V(t) \quad (94.5)$$

and

$$F_p(t) = \frac{1}{d_p} \left(\frac{Q(t)}{C_i} - V(t) \right) \quad (94.6)$$

where C_i is the capacitance of the insulators, C_p is the capacitance of the phosphor layer, and d_p is the thickness of the phosphor layer.

Time-Resolved Measurements

The apparatus for measuring τ is shown in Fig. 94.9. A photomultiplier tube (PMT) is used to detect the light emission as a function of time. The drive system is set to provide relatively narrow drive pulses, typically 10 μ s pulse width, at relatively low frequency, typically 60 Hz. This approach works well for phosphors with relatively long decay times, on the order of 100 μ s to a few milliseconds. This is the case for many common ACTFEL phosphors such as ZnS:Mn and ZnS:Tb. Phosphors such as SrS:Ce, however, have very fast decay times and cannot be measured in this manner. In such cases the photoluminescent decay time must be measured using a pulsed laser to excite the phosphor and appropriately low RC response time of the light detection system.

The general setup for measuring time-resolved emission spectra from ACTFEL devices is shown schematically in Fig. 94.10. The oscilloscope is triggered on the drive waveform and the signal integration period is set to the region of interest. A boxcar integrator can also be used to integrate the light signal during the desired time window. The monochromator wavelength is scanned and the emission spectrum is collected for the selected portion of the emission process.

Aging

ACTFEL devices tend to stabilize after a few tens of hours of burn-in, but can exhibit complex aging behavior during the burn-in process. The luminance vs. voltage curves for ZnS:Mn devices in which the phosphor layer is deposited by evaporation, for example, tend to shift to slightly higher voltage during burn-in [2]. Luminance vs. voltage curves for devices in which the ZnS:Mn is deposited by ALE tend to shift to slightly lower voltage [13]. Aging data is collected by measuring luminance vs. voltage at selected

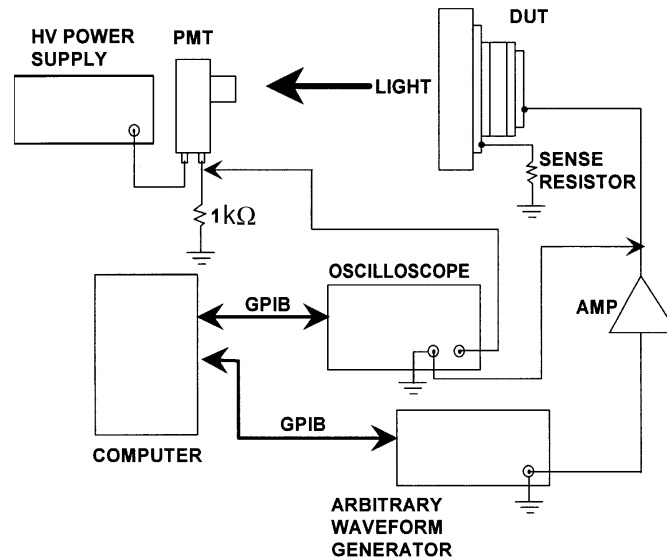

FIGURE 94.9 Apparatus for measuring the luminescent decay time of the ACTFEL phosphor. The light signal is measured by the oscilloscope across the sense resistor on the output of the PMT. The oscilloscope is triggered on the drive pulse.

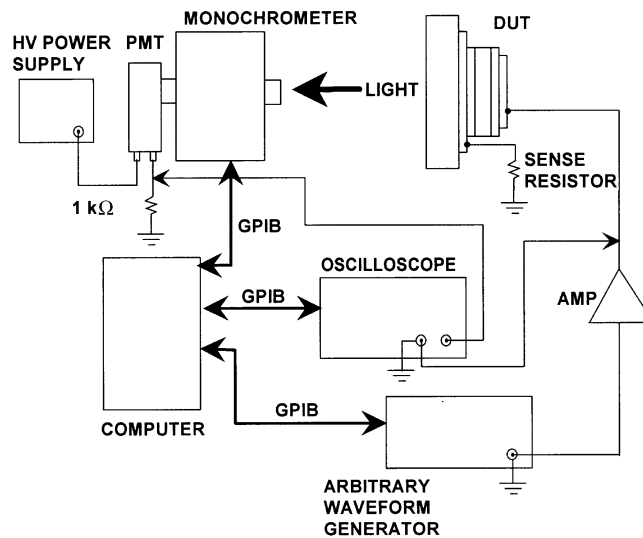

FIGURE 94.10 System for measuring the time-resolved emission spectrum of an ACTFEL device. The oscilloscope is set to integrate the light signal from the PMT during a selected time window. The monochromator wavelength is scanned over the entire spectral range and the emission intensity data is collected from the oscilloscope.

time intervals during aging. The measurement is carried out as described earlier for luminance vs. voltage measurements. The aging is done by continuously operating the device at a fixed voltage or at a fixed voltage above threshold. The aging process can be accelerated by operating the device at higher frequency.

94.8 Characterization of Matrix-Addressed Displays

The characterization of matrix-addressed displays differs from characterization of test dots because less control of the drive waveform is readily available. The row and column drivers do not provide great

flexibility, although some control can be exercised by varying the composite drive waveform and the control signals to the driver chips. These types of modifications, however, require detailed knowledge of the addressing and control electronics involved and are best left to the original display manufacturer. Measurements that are more accessible and of more general interest involve characterization of the luminance, chromaticity, uniformity, display life, latent image, and defects. For these measurements the display under test is controlled by a computer through a standard video output or a custom video display interface provided with the display. The display operating voltage and frequency are fixed. The display is placed in a dark room or enclosure. Luminance is measured with a photometer. Chromaticity is measured with a spectrophotometer or a photometer equipped with tristimulus filters. Uniformity can be measured by mounting either the display or the photometer/spectrophotometer on a translation system and collecting data at points in a regular array of locations throughout the display surface. Display life is characterized by operating the display in a full-on pattern, cycling through checkerboard patterns, etc., and making luminance measurements at exponentially increasing time intervals. Latent image is formed by displaying small blocks in various fixed locations and various fixed gray levels (if available) continuously for long periods. It is characterized by setting the entire screen to each gray level available and measuring the luminance in the locations which had blocks displayed during aging as well as unaged areas nearby. Latent image is the percent luminance difference between aged blocks and nearby unaged areas. Latent image is typically measured after aging the block pattern for 1000 h. Defects are classified into pixel, line, and mura defects. They are characterized by visual inspection with the aid of an eye loupe or by an automated flat panel inspection system.

94.9 Excitation and Measurement Equipment

Excitation of Test Dots

Test dots can be excited by any signal source that provides bipolar pulses up to a peak voltage of 300 V and sufficient current sourcing and sinking capability to charge and discharge the device capacitance. Bipolar pulse drivers with sufficient voltage and current output can be built with commercially available components. A hybrid circuit op amp, produced by Apex Microtechnology, provides sufficient voltage output and frequency response. A current boosting stage can be added to the output if the DUT capacitance is too large to drive directly. This amplifier approach is very flexible since any waveform that can be generated by the arbitrary waveform generator can be used. There are also some commercial amplifiers available that are effective for driving test dots for some measurements. They tend to have limited bandwidth and must be used with caution in situations in which the measurement is sensitive to the exact shape of the drive pulse. This would be the case, for example, in *QV* measurements and often in efficiency measurements.

Excitation of Matrix-Addressed Displays

Excitation of matrix-addressed displays is straightforward since the drive electronics are integrated with the display. Generally, only a standard ac power outlet and a computer with an appropriate video card are required. Test patterns for measurement can be created using simple computer programs.

94.10 Measurement Instruments

Measurement of Drive Voltage and Current

Digital oscilloscopes are used for all of the electrical measurements described in this chapter. Suitable instruments are available from several manufacturers, including Tektronix and Hewlett-Packard. A bandwidth of 100 MHz is more than sufficient. Waveform analysis capabilities are very helpful but not absolutely necessary. RS 232 or IEEE 488 interfaces are required for computer control and data transfer.

Measurement of Emitted Light

Several types of instruments are used for measuring light emission from ACTFEL displays. Photometers are used for luminance measurements. Spectrophotometers are used for measuring the emission spectrum and with suitable software can also provide luminance measurements. Time-resolved measurements are accomplished by using photomultiplier tubes or photodiode detectors. [Table 94.1](#) lists some examples of photometers, spectroradiometers, photomultipliers, and photodiodes along with the names of the companies that manufacture them. A relatively new development for characterizing the light emission characteristics of flat panel displays, including ACTFEL displays, is the flat panel inspection system. This is a large measurement system comprising a CCD camera detector, light-tight enclosure, control computer, image processor, and specialized software. This type of system images an entire flat panel display on the CCD camera and measures luminance, chromaticity, and various defects by analyzing the image. These systems are intended for high throughput manufacturing environments and cost several hundred thousand dollars. An example of this type of system is also included in [Table 94.1](#). Contact information for the companies listed in [Table 94.1](#) is provided in [Table 94.2](#).

Defining of Terms

Electroluminescence: The nonthermal generation of light resulting from the application of an electric field to a substance, usually a luminescent crystal.

Latent image: The ghost image of a previously displayed pattern which can sometimes be seen in a full field on an electronic display screen.

Light emission decay time: The time it takes for the light emission from one excitation pulse to fall to $1/e$ times its initial value.

Polarization charge: The charge trapped at the phosphor/insulator interface following the application of a drive pulse.

- Polarization field:** The field across the phosphor layer resulting from the polarization charge.
- $Q_p F_p$ loop:** The closed curve which results from plotting the internal charge flow across the phosphor layer (Q_p) vs. the electric field across the phosphor layer (F_p).
- QV loop:** The closed curve which results from plotting the external charge (Q) flowing into a TFEL device vs. the externally applied voltage (V).
- Threshold voltage:** The voltage amplitude of the drive waveform above which current flows across the phosphor layer and light is emitted from a TFEL device.
- Turn-on voltage:** The voltage corresponding to the first knee in the QV loop of a TFEL device. This is the voltage at which charge begins to flow across the phosphor layer. This voltage is generally less than the threshold voltage because the internal field across the phosphor layer is enhanced by the polarization field once the polarization charge has built up in the steady state.

Light-Emitting Diode Displays

Mohammad A. Karim

University of Tennessee, Knoxville

A light-emitting diode (LED) is a particular solid-state p - n junction diode that gives out light upon the application of a bias voltage. The luminescence process in this case is electroluminescence, which is associated with emission wavelengths in the visible and infrared regions of the spectrum. When a forward bias is applied to the p - n junction diode, carriers are injected into the depletion region in large numbers. Because of their physical proximity, the electron-hole pairs undergo a recombination that is associated with the emission of energy. Depending on the semiconductor band-gap characteristics, this emitted energy can be in the form of heat (as phonons) or light (as photons).

The solution of the Schrödinger equation for a typical crystal reveals the existence of Brillouin zones. A plot between the energy E of an electron in a solid and its wave vector \mathbf{k} represents the allowed energy bands. It may be noted that the lattice structure affects the motion of an electron when k is close to $n\pi/l$ (where n is any integer and l is the crystal periodicity) and the effect of this constraint is to introduce an energy band gap between the allowed energy bands. Figure 95.1a shows portions of two E vs. k curves for neighboring energy bands within the regions $k = \pi/l$ and $k = -\pi/l$ (also known as the reduced zone).

While the upper band of Fig. 95.1 represents the energy of conduction band electrons, the curvature of the lower band can be associated with electrons having negative effective mass. The concept of negative effective mass can readily be identified with the concept of holes in the valence band. While the majority of the electrons are identified with the minima of the upper E - k curve, the majority of the holes are identified with the maxima of the lower E - k curve. The minimum value of the conduction band and the maximum value of the valence band in Fig. 95.1a both have identical k values. A semiconductor having such a characteristic is said to have a direct band gap, and the associated recombination in such a semiconductor is referred to as direct.

The *direct recombination* of an electron-hole pair always results in the emission of a photon. In a direct band-gap semiconductor, the emitted photon is not associated with any change in momentum (given by $hk/2\pi$) since $\Delta k = 0$. However, for some semiconducting materials, the E vs. k curve may be somewhat different, as shown in Fig. 95.1b. While the minimum conduction band energy can have a nonzero k , the maximum valence band energy can have $k = 0$. The electron-hole recombination in such a semiconductor is referred to as indirect.

An *indirect recombination* process involves a momentum adjustment. Most of the emission energy is thus expended in the form of heat (as phonons). Very little energy is left for the purpose of photon emission, which in most cases is a very slow process. Furthermore, since both photons and phonons are involved in this energy exchange, such transitions are less likely to occur. The interband recombination rate is basically given by

FIGURE 95.1 E versus k for semiconductors having (a) a direct band gap and (b) an indirect band gap.

$$dn/dt = B_r np \quad (95.1)$$

where B_r is a recombination-dependent constant which for a direct band-gap semiconductor is $\sim 10^6$ times larger than that for an indirect band-gap semiconductor. For direct recombination, B_r value ranges from 0.46×10^{-10} to 7.2×10^{-10} cm^3/s .

All semiconductor crystal lattices are alike, being dissimilar only in terms of their band characteristics. Si and Ge both have indirect band transitions, whereas GaAs, for example, is a semiconductor that has a direct band transition. Thus, while Si and Ge are preferred for fabrication of transistors and integrated circuits, GaAs is preferred for the fabrication of LEDs.

The direct recombination (when $k = \text{constant}$) results in a photon emission whose wavelength (in micrometers) is given by

$$\lambda = hc/E_g = 1.24/E_g \text{ (eV)} \quad (95.2)$$

where E_g is the band-gap energy. The LEDs under proper forward-biased conditions can operate in the ultraviolet, visible, and infrared regions. For the visible region, however, the spectral luminous efficiency curves of Fig. 95.2, which account for the fact that the visual response to any emission is a function of wavelength, should be of concern. It is unfortunate that there is not a single-element semiconductor suitable for fabrication of LEDs, but there are many binary and ternary compounds that can be used for fabrication of LEDs. Table 95.1 lists some of these binary semiconductor materials. The ternary semiconductors include GaAlAs, CdGeP₂, and ZnGeP₂ for infrared region operation, CuGaS₂ and AgInS₂ for visible region operation, and CuAlS₂ for ultraviolet region operation. Ternary semiconductors are used because their energy gaps can be tuned to a desired emission wavelength by picking appropriate composition.

Of the ternary compounds, gallium arsenide–phosphide (written as GaAs_{1-x}P_x) is an example that is basically a combination of two binary semiconductors, namely, GaAs and GaP. The corresponding band-gap energy of the semiconductor can be varied by changing the value of x . For example, when $x = 0$, $E_g = 1.43$ eV. E_g increases with increasing x until $x = 0.44$ and $E_g = 1.977$ eV, as shown in Fig. 95.3. However for $x \geq 0.45$, the band gap is indirect. The most common composition of GaAs_{1-x}P_x used in LEDs has $x = 0.4$ and $E_g \approx 1.3$ eV. This band-gap energy corresponds to an emission of red light. Calculators and watches often use this particular composition of GaAs_{1-x}P_x.

Interestingly, the indirect band gap of GaAs_{1-x}P_x (with $1 \geq x \geq 0.45$) can be used to output light ranging from yellow through green provided the semiconductor is doped with impurities such as nitrogen. The dopants introduced in the semiconductor replace phosphorus atoms which, in turn, introduce electron trap levels very near the conduction band. For example, $x = 0.5$, the doping of nitrogen increases the LED efficiency from 0.01 to 1%, as shown in Fig. 95.4. It must be noted, however, that nitrogen doping

FIGURE 95.2 Spectral luminous efficiency curves. The photopic curve $V_{d\lambda}$ corresponds to the daylight-adapted case while the scotopic curve $V_{n\lambda}$ corresponds to the night-adapted case.

TABLE 95.1 Binary Semiconductors Suitable for LED Fabrication

	Material	E_g (eV)	Emission Type
III–V	GaN	3.5	UV

II–VI	CdTe	1.5	IR
III–VI	GaSe	2.1	Visible

shifts the peak emission wavelength toward the red. The shift is comparatively larger at and around $x = 0.05$ than $x = 1.0$. The energy emission in nitrogen-doped GaAs_{1-x}P_x devices is a function of both x and the nitrogen concentration.

Nitrogen is a different type of impurity from those commonly encountered in extrinsic semiconductors. Nitrogen, like arsenic and phosphorus, has five valence electrons, but it introduces no net charge carriers in the lattice. It provides active radiative recombination centers in the indirect band-gap materials. For an electron, a recombination center is an empty state in the band gap into which an electron falls and, then, thereafter, falls into the valence band by recombining with a hole. For example, while a GaP LED emits green light (2.23 eV), a nitrogen-doped GaP LED emits yellowish green light (2.19 eV), and a heavily nitrogen-doped GaP LED emits yellow light (2.1 eV).

The injected excess carriers in a semiconductor may recombine either radiatively or nonradiatively. Whereas nonradiative recombination generates phonons, radiative recombination produces photons.

FIGURE 95.3 Band-gap energy versus x in $\text{GaAs}_{1-x}\text{P}_x$. (From Casey, H.J., Jr. and Parish, M.B., Eds., *Heterostructure Lasers*, Academic Press, New York, 1978. With permission.)

FIGURE 95.4 The effects of nitrogen doping in $\text{GaAs}_{1-x}\text{P}_x$: (a) quantum efficiency vs. x and (b) peak emission wavelength vs. x .

Consequently, the internal quantum efficiency η , defined as the ratio of the radiative recombination rate R_r to the total recombination rate, is given by

$$\eta = R_r / (R_r + R_{nr}) \quad (95.3)$$

where R_{nr} is the nonradiative recombination rate. However, the injected excess carrier densities return to their value exponentially as

$$\Delta p = \Delta n = \Delta n_0 e^{-t/\tau} \quad (95.4)$$

where τ is the carrier lifetime and Δn_0 is the excess electron density at equilibrium. Since $\Delta n/R_r$ and $\Delta n/R_{nr}$ are, respectively, equivalent to the radiative recombination lifetime τ_r and the nonradiative recombination lifetime τ_{nr} , we can obtain the effective minority carrier bulk recombination time τ as

$$(1/\tau) = (1/\tau_r) + (1/\tau_{nr}) \quad (95.5)$$

such that $\eta = \tau/\tau_r$. The reason that a fast recombination time is crucial is that the longer the carrier remains in an excited state, the larger the probability that it will give out energy nonradiatively. In order for the internal quantum efficiency to be high, the radiative lifetime τ_r needs to be small. For indirect band-gap semiconductors, $\tau_r \gg \tau_{nr}$ so that very little light is generated, and for direct band-gap semiconductors, τ_r increases with temperature so that the internal quantum efficiency deteriorates with the temperature.

As long as the LEDs are used as display devices, it is not too important to have fast response characteristics. However, LEDs are also used for the purpose of optical communications, and for those applications it is appropriate to study their time response characteristics. For example, an LED can be used in conjunction with a photodetector for transmitting optical information between two points. The LED light output can be modulated to convey optical information by varying the diode current. Most often, the transmission of optical signals is facilitated by introducing an optical fiber between the LED and the photodetector.

There can be two different types of capacitances in diodes that can influence the behavior of the minority carriers. One of these is the *junction capacitance*, which is caused by the variation of majority charge in the depletion layer. While it is inversely proportional to the square root of bias voltage in the case of an abrupt junction, it is inversely proportional to the cube root of bias voltage in the case of a linearly graded junction. The second type of capacitance, known as the *diffusion capacitance*, is caused by the minority carriers.

Consider an LED that is forward biased with a dc voltage. Consider further that the bias is perturbed by a small sinusoidal signal. When the bias is withdrawn or reduced, charge begins to diffuse from the junction as a result of recombination until an equilibrium condition is achieved. Consequently, as a response to the signal voltage, the minority carrier distribution contributes to a signal current.

Consider a one-dimensional p -type semiconducting material of cross-sectional area A whose excess minority carrier density is given by

$$\delta \Delta n_p / \delta t = D_n \delta^2 \Delta n_p / \delta x^2 - \Delta n_p / \tau \quad (95.6)$$

As a direct consequence of the applied sinusoidal signal, the excess electron distribution fluctuates about its dc value. In fact, we may assume excess minority carrier density to have a time-varying component as described by

$$\Delta n_p(x, t) = \langle \Delta n_p(x) \rangle + n'_p(x) e^{j\omega t} \quad (95.7)$$

where $\langle \Delta n_p(x) \rangle$ is a time-invariant quantity. By introducing Eq. 95.7 into Eq. 95.6, we get two separate differential equations:

$$\delta^2 / \delta x^2 \left(\langle \Delta n_p(x) \rangle \right) = \langle \Delta n_p(x) \rangle / (L_n)^2 \quad (95.8a)$$

and

$$\delta^2/\delta x^2 [\Delta n'_p(x)] = \Delta n'_p(x) / [L_n^*]^2 \quad (95.8b)$$

where

$$L_n^* = L_n / (1 + j\omega\tau)^{1/2} \quad (95.9a)$$

and

$$L_n = (D_n \tau)^{1/2} \quad (95.9b)$$

The dc solution of Eq. 95.8a is well known. Again, the form of Eq. 95.8b is similar to that of Eq. 95.8a and, therefore, its solution is given by

$$\Delta n'_p(x) = \Delta n'_p(0) e^{-x/L} \quad (95.10)$$

Since the frequency-dependent current $I(\omega)$ is simply a product of eAD_n and the concentration gradient, we find that

$$\begin{aligned} I(\omega) &= \left| eAD_n \frac{dn'_p(x)}{dx} \right|_{x=0} \\ &= I(0) / (1 + \omega^2\tau^2)^{1/2} \end{aligned} \quad (95.11)$$

where $I(0)$ is the intensity emitted at zero modulation frequency. We can determine the admittance next by dividing the current by the perturbing voltage. The real part of the admittance, in this case, will be equivalent to the diode conductance, whereas its imaginary part will correspond to the diffusion capacitive susceptance.

The modulation response as given by Eq. 95.11 is, however, limited by the carrier recombination time. Often an LED is characterized by its modulation bandwidth, which is defined as the frequency band over which signal power (proportional to $P(\omega)$) is half of that at $\omega = 0$. Using Eq. 95.11, the 3-dB modulation bandwidth is given by

$$\Delta\omega \approx 1/\tau_r \quad (95.12)$$

where the bulk lifetime has been approximated by the radiative lifetime. Some times the 3-dB bandwidth of the LED is given by $I(\omega) = 1/2 I(0)$, but this simplification contributes to an erroneous increase in the bandwidth by a factor of 1.732.

Under conditions of thermal equilibrium, the recombination rate is proportional to the product of initial carrier concentrations, n_0 and p_0 . Then, under nonequilibrium conditions, additional carriers $\Delta n = \Delta p$ are injected into the material. Consequently, the recombination rate of injected excess carrier densities is given by initial carrier concentrations and injected carrier densities as

$$\begin{aligned} R_{\Delta r} &= [B_r (n_0 + \Delta n)(p_0 + \Delta p) - B_r n_0 p_0] \\ &= B_r (n_0 + p_0 + \Delta n) \Delta n \end{aligned} \quad (95.13)$$

where B_r is the same constant introduced in Eq. 95.1. For p -type GaAs, for example, $B_r = 1.7 \times 10^{-10}$ cm³/s when $p_0 = 2.4 \times 10^{18}$ holes/cm³. Equation 95.13 is used to define the radiative carrier recombination lifetime by

$$\tau_r = \Delta n / R_{\Delta r} = \left[B_r (n_o + p_o + \Delta n) \right]^{-1} \quad (95.14)$$

In the steady-state condition, the excess carrier density can be calculated in terms of the active region width d by

$$\Delta n = J \tau_r / ed \quad (95.15)$$

where J is the injection current density.

The radiative recombination lifetime is found by solving Eq. 95.14 after having eliminated Δn from it using Eq. 95.15:

$$\tau_r = \left[\left\{ (n_o + p_o)^2 + (4J/B_r ed) \right\}^{1/2} - (n_o + p_o) \right] / (2J/ed) \quad (95.16)$$

Thus, while for the low carrier injection (i.e., $n_o + p_o \gg \Delta n$), Eq. 95.16 reduces to

$$\tau_r \approx \left[B_r (n_o + p_o) \right]^{1/2} \quad (95.17a)$$

for the high carrier injection (i.e., $n_o + p_o \ll \Delta n$), it reduces to

$$\tau_r \approx (ed/JB_r)^{1/2} \quad (95.17b)$$

Equation 95.17a indicates that in highly doped semiconductors, τ_r is small. But the doping process has its own problem, since in many of the binary LED compounds higher doping may introduce nonradiative traps just below the conduction band, thus nullifying Eq. 95.12. In comparison to Eq. 95.17a, Eq. 95.17b provides a better alternative whereby τ_r can be reduced by decreasing the active region width or by increasing the current density. For the case of p -type GaAs, the radiative lifetimes vary between 2.6 and 0.35 ns, respectively, when p_0 varies between 1.0×10^{18} holes/cm³ and 1.5×10^{19} holes/cm³.

Usually, LEDs are operated at low current (≈ 10 mA) and low voltages (≈ 1.5 V), and they can be switched on and off in the order of 10 ns. In addition, because of their small sizes, they can be reasonably treated as point sources. It is, therefore, not surprising that they are highly preferred over other light sources for applications in fiber-optic data links.

Two particular LED designs are popular: *surface emitters* and *edge emitters*. They are shown in Fig. 95.5. In the former, the direction of major emission is normal to the plane of the active region, whereas in the latter the direction of major emission is in the plane of the active region. The emission pattern of the surface emitters is very much isotropic, whereas that of the edge emitters is highly directional.

As the LED light originating from a medium of refractive index n_1 goes to another medium of refractive index n_2 ($n_2 < n_1$), only a portion of incident light is transmitted. In particular, the portion of the emitted light corresponds to only that which originates from within a cone of semiapex angle θ_c , such that

$$\theta_c = \sin^{-1}(n_2/n_1) \quad (95.18)$$

FIGURE 95.5 LED type: (a) surface emitter and (b) edge emitter.

In the case of an LED, n_1 corresponds to the refractive index of the LED medium and n_2 corresponds to that of air (or vacuum). Light originating from *beyond* angle θ_c undergoes a total internal reflection. However, the light directed from *within* the cone of the semiapex angle θ_c will be subjected to Fresnel loss. Thus, the overall transmittance T is given by

$$T = 1 - \left\{ \frac{(n_1 - n_2)}{(n_1 + n_2)} \right\}^2 \quad (95.19)$$

Accordingly, the total electrical-to-optical conversion efficiency in LEDs is given by

$$\begin{aligned} \eta_{\text{LED}} &= T \left[\frac{\text{solid angle within the cone}}{4\pi} \right] \\ &= \left(\frac{T}{2} \right) (1 - \cos \theta_c) \\ &= \left(\frac{T}{4} \right) \sin^2 \theta_c \\ &= \left(\frac{1}{4} \right) \left(\frac{n_2}{n_1} \right)^2 \left[1 - \left\{ \frac{(n_1 - n_2)}{(n_1 + n_2)} \right\}^2 \right] \end{aligned} \quad (95.20)$$

Only two schemes increase the electrical-to-optical conversion efficiency in an LED. The first technique involves guaranteeing that most of the incident rays strike the glass-to-air interface at angles less than θ_c . It is accomplished by making the semiconductor–air interface hemispherical. The second method involves schemes whereby the LED is encapsulated in an almost transparent medium of high refractive index. The latter means is comparatively less expensive. If a glass of refractive index 1.5 is used for encapsulation, the LED efficiency can be increased by a factor of 3. Two of the possible encapsulation arrangements and the corresponding radiation patterns are illustrated in [Fig. 95.6](#).

LEDs are often used in conjunction with a phototransistor to function as an optocoupler. The optocouplers are used in circumstances when it is desirable to have a transmission of signals between electrically isolated circuits. They are used to achieve noise separation by eliminating the necessity of having a common ground between the two systems. Depending on the type of coupling material, these miniature devices can provide both noise isolation as well as high voltage isolation. [Figure 95.7](#) shows a typical case where two optocouplers are used to attain a chopper circuit. The two optocouplers chop either the positive or the negative portion of the input signals with a frequency of one half that of the control signal that is introduced at the T flip-flop. The operational amplifier provides an amplified version of the chopped output waveform. In comparison, a chopper circuit that uses simple bipolar transistors produces noise spikes in the output because of its inherent capacitive coupling.

The visible LEDs are best known for their uses in displays and indicator lamps. In applications where more than a single source of light is required, an LED array can be utilized. An LED array is a device

FIGURE 95.6 LED encapsulation geometries and their radiation patterns.

FIGURE 95.7 A chopping circuit with an amplifier.

consisting of a row of discrete LEDs connected together within or without a common reflector cavity. [Figure 95.8a](#) shows different LED arrangements for displaying hexadecimal numeric and alphanumeric characters, whereas [Fig. 95.8b](#) shows, for example, the possible alphanumeric characters using 16-segment displays. In digital systems, the binary codes equivalent to these characters are usually decoded and, consequently, a specific combination of LED segments are turned on to display the desired alphanumeric character.

The dot matrix display provides the most desirable display font. It gives more flexibility in shaping characters and has a lower probability of being misinterpreted in case of a display failure. However, these displays involve a large number of wires and increased circuit complexity. LED displays, in general, have an excellent viewing angle, high resonance speed (≈ 10 ns), long life, and superior interface capability with electronics with almost no duty cycle limitation. LEDs with blue emission are not available commercially. When compared with passive displays, LED displays consume more power and involve complicated wiring with at least one wire per display element.

96.1 Graphic Recorders

Herman Vermariën

A **graphic recorder** is essentially a measuring apparatus that is able to produce in real time a hard copy of a set of time functions with the purpose of immediate and/or later visual inspection. The curves are mostly drawn on a (long) strip of paper (from a roll or Z-fold); as such, the instrument is indicated as a strip chart recorder. The independent variable time (t) then corresponds to the strip length axis and the physical variables measured are related to the chart width. Tracings are obtained by a writing process at sites on the chart short axis (y) corresponding to the physical variables magnitudes with the strip being moved at constant velocity to generate the time axis. Graphs cannot be interpreted if essential information is absent; scales and reference levels for each physical variable recorded and for time are all a necessity. Additional information concerning the experimental conditions of the recording is also necessary and is preferably printed by the apparatus (data, investigated item, type of experiment, etc.). The capacity of the graphic recorder is thus determined by its measuring accuracy, its ability to report additional information and its graphical quality, including the sharpness of tracings, the discriminability of tracings (e.g., by different colors), and the stability of quality with respect to long-term storage. Simple chart recorders only produce tracings on calibrated paper; more-advanced graphic recorders generate tracings and calibration lines, display additional information in alphanumeric form on charts, store instrument settings and recorded data in memory (which can be reproduced on charts in diverse modes), have a built in waveform monitor screen, and can communicate with a PC via standard serial interfacing. The borderlines between these types of intelligent graphic recorders and, on the one hand, digital storage oscilloscopes equipped with a hard copy unit and, on the other hand, PC-based data acquisition systems

with a laser printer or a plotter, become very unclear. The property of producing the hard copy in real time is probably the most discriminating factor between the graphic recorder and other measuring systems that produce hard copies. Graphic recorders are used for test and measurement applications in laboratory and field conditions and for industrial process monitoring and control. Graphic recorders are intensively used in biomedical measurement applications [1].

Whereas the time axis is generated by moving the chart at constant velocity, the ordinate can be marked in an analog or a digital manner. Analog recorder transducers generate a physical displacement of the writing device, e.g., a pen or a printhead. With digital transducers, moving parts are absent and the writing device is a stationary rectilinear array of equidistant writing points covering the complete width of the chart; the writing act then consists in activating the point situated at the site corresponding to the signal magnitude and putting a dot on the paper. Analog recorders thus can produce continuous lines, whereas digital recorders generate dotted lines. If ordinate and time axis resolutions are sufficient, digital recordings have excellent graphic quality regarding visual impression of continuity. Analog transducers can be used in a discontinuous mode and thus handle a set of slowly varying signals; during the scanning cycle a dot is set on the paper by the moving writing device at the sites corresponding to the magnitudes of the signal. A single digital transducer and a single analog transducer applied in the scanning mode can handle a set of signals; a single analog transducer can process only one signal in the continuous mode. For a digital transducer the number of signals recorded is essentially unlimited; it is thus programmed to draw the necessary calibration lines. With analog transducers calibrated paper is used. In this case, generally ink writing is applied and different colors ensure excellent tracing identifiability. With the digital array, dot printing can be more or less intensified for different channels or more than one adjacent points can be activated, resulting in more or less increased line blackness and thickness. However, tracing identification is usually performed by alphanumeric annotations.

In **analog graphic recorders**, the transducer can be designed in a direct mode or in a servo mode. In the direct mode the signal magnitude is directly transduced to a position of the writing device (e.g., the simple galvanometric type). In the servo mode (also called *feedback* or *compensation*) the position of the writing device is measured by a specific sensor system and the difference between the measured value and the value of the signal to be traced is applied to the transducer motor, resulting in a movement tending to zero the difference value and thus to correct the position [2,3]. In both methods the moving parts set a limit to the system frequency bandwidth. Moreover, in the feedback mode velocity and acceleration limitations may be present; thus linear system theory description of the apparatus behavior with respect to signal frequency may not be applicable. As such, the bandwidths of servo systems can be dependent on the writing width. Movement of the writing device can be generated by a rotation or by a translation. In the latter case the writing part is mechanically guided; primarily, the servo method is applied [3]. A rotation is generally obtained with a galvanometric motortype [3,4]; the galvanometer may rotate a pen, an ink jet, a light beam. The inertia of the moving part is the major parameter determining the bandwidth of the system. Translational devices allow a bandwidth of a few hertz. Higher bandwidths can be obtained with galvanometric pen types (about 100 Hz), ink jets (up to 1 kHz), and optical systems (up to 10 kHz) [1], but, being replaced by dot array recorders or data acquisition systems, these types are disappearing from the market. Major reasons are inherent errors and limitations of these analog types, maintenance needs of moving parts and ink devices, cost of photographic paper, and the lack of the possibilities of digital types.

Whereas moving parts restrict the analog recorder bandwidth, a corresponding capacity of **digital graphic recorders** is determined by the sampling frequency and the writing frequency. According to the sampling criterion the sampling frequency should be twice the highest signal frequency. This implies two samples to display a complete sine wave period, which can hardly be called a good graphic representation. Ten samples may be a minimum. The sampling frequency is a pure electronic matter; the maximal writing frequency of the dot array is the limiting factor in real time. Alternatively, if the signal spectrum exceeds the real-time bandwidth of the recorder, data can be stored at a sufficient sampling rate in memory and reproduced off-line at a slower rate which can be handled by the apparatus. Most digital recorders have

this memory facility; some recorders are specifically referred to as “memory” recorders when their off-line capabilities largely exceed their online performance.

Real-time recording is primarily performed as a function of time (t - y recorders). On the other hand, x - y recording is another way of representing the data. In this case the relation between two physical variables is traced and the independent variable time is excluded (apart from the fact that, if a dashed line is used, each dash can represent a fixed time interval). In standard analog x - y recorders the chart is stationary (e.g., electrostatically fixed to the writing table); two similar analog writing transducers with identical input circuitry are assembled in the recorder. The first transducer (y) translates a long arm covering the width of the paper at which the second transducer (x) carrying the pen is moved. Evidently, recorders with memory facilities and appropriate software may produce an x - y recording in off-line mode by setting dots while the paper progresses. Recording accuracy can be formulated in similar terms as for any measuring instrument [5]. This accuracy is determined, on the one hand, by the input signal conditioning, similar for digital as well as for analog types and, on the other hand, by the accuracy of the recording transducer and its driver electronics. In the digital type, digitization bit accuracy, sampling frequency, dot array resolution, and dot writing frequency are major parameters. In the analog type, typical inconveniences of analog transducer systems can be found (such as static nonlinearity, noise and drift, dead zone and hysteresis, limited dynamic behavior); servo systems are known to be more accurate as compared with direct systems. For example, drift in analog recording can be the result of a small shift of the calibrated chart along the y -axis; the latter is excluded if the recorder draws its own calibration lines.

With respect to graphic quality, clarity and sharpness of the tracings are important (within a large range of writing velocities). Tracing quality depends on the writing velocity, i.e., the velocity of the writing device with respect to the moving paper. Evidently, the flow of writing medium (e.g., ink or heat) should be more or less adapted to this writing velocity to prevent poorly visible tracings at high velocities and thick lines at low velocities. Good identifiability of overlapping curves is essential. Sufficient dot resolution (with adequate interpolation techniques) is important in discontinuous types for easy visual inspection. A graphic recorder can be designed as a single-channel instrument or can have a multichannel input. Inputs can be standard or modular, so that the user can choose the specific signal conditioners for the application and the number of channels. A recorder can be called “general purpose” or can be assembled in a specific measuring apparatus (e.g., in biomedical applications such as electrocardiography and electroencephalography). The recorder can be portable for operation in the field or can be mounted in a laboratory rack or in a control panel. The paper can be moved vertically or horizontally on a writing table (“flat bed” recorder) and can be supplied from a roll or in Z-fold. Besides strip chart recorders and x - y recorders, circular chart recorders exist. In this case the chart rotates, one rotation corresponds to a complete measurement interval, and the chart is provided with appropriate calibration lines adapted to movement of the pens writing on it.

Apart from the low-bandwidth translational pen devices there is a decreasing interest in analog graphic recorders. They are being replaced by thermal dot array recorders or by data acquisition systems. Nevertheless, as some of them may still be manufactured and a number of apparatus may still be in use, different techniques are mentioned. A description of analog recorder principles and performances can be found in Reference 1. Galvanometric recorders apply rotational transducers. The direct as well as the servo principles are used. The direct type makes use of the d’Arsonval movement as applied in ordinary galvanometers [1, 2, 4]. Dynamically, the galvanometer acts as a mechanical resonant system and the bandwidth is thus determined by its resonant frequency, the latter being dependent on the inertia of the moving parts. Evidently, rotation gives rise to inherent errors in graphic recorders. If pen tips (perpendicular to the pen arm, thermal or ink) are used, the rotation of the pen arm fixed to the galvanometer coil occurs in a plane parallel to the chart plane, so the recording is curvilinear instead of rectilinear, introducing an error with respect to the time axis and to the ordinate axis (the ordinate value being proportional to the tangent of the rotation angle). Calibrated paper with curvilinear coordinate lines may solve this problem; nevertheless, the tracing is deformed and zero offset is critical. Rectilinear recording can be realized with pen systems, ink jets, and light beams. Rectilinear pen recording can be

approximated with pen tips in case of “long-arm” pens and by mechanical rectilinearization; alternatively “knife-edge” recording is a solution [1]. In the case of ink jet and light beam recorders the rotation plane and the chart plane do not have to be parallel; writing then occurs at the intersecting line of both planes and is thus essentially rectilinear. In ink jet recording a miniature nozzle through which ink is pumped is mounted in a direction perpendicular to the axis of the galvanometer. In optical recording a sharp light beam is reflected by a small mirror connected to the galvanometric moving coil toward the photosensitive paper. In these methods miniaturization of the moving parts gives rise to higher resonant frequencies and thus higher bandwidths. Whereas a typical bandwidth for a galvanometric pen system is 100 Hz, the bandwidth for an ink jet system can be 1000 Hz and for an optical system 10 kHz may be reached. In the fiber-optic cathode ray tube (FO-CRT) no mechanical moving parts are present and thus there are no mechanical limits on bandwidth. The FO-CRT is essentially a one-dimensional CRT. A phosphor layer at the inside of the screen converts the cathode ray into ultraviolet (UV) light. This UV light is guided by an outer faceplate composed of glass fibers onto the photosensitive chart. As in ordinary oscilloscopes, the deflection of the spot is directly proportional to the signal applied at the input of the deflection unit. The bandwidth is determined by the driving electronics. The system can be used in scanning mode as the beam intensity is easily controlled. In the following paragraphs further details will be given on translational pen recorders and thermal dot array recorders.

Translational Pen Recorders

In **translational pen recorders** the writing device is usually a fiber-tip pen with an ink cartridge. In discontinuous applications the writing device can be a printhead with different color styli or with a colored ribbon. A manual or automatic pen lift facility is included. During recording, the writing device is translated along the y -axis as it is linked to a mechanical guidance and a closed-loop wire system. A motor and wheels system pulls the wire and thus the writing device. In some designs a motor and screw system is applied. Translational recorders are primarily designed as a servo type. The position of the pen is accurately measured, and the difference voltage between the input signal and the position magnitude (following appropriate amplification and conditioning) drives the servomotor. Servo motors can be dc or stepper types; servo electronics can be analog or digital. Position sensing can be potentiometric (“potentiometric” recorders): the pen carriage is equipped with a sliding contact on the resistor (wire wound or thick film) which covers the complete width of the paper. More recently developed methods use optical or ultrasonic principles for position sensing; with these methods contacts are absent resulting in less maintenance and longer lifetime. For example, in the ultrasonic method the pen position is sensed by a detector coil from the propagation time of an ultrasound pulse, which is imparted by a piezoelectric transducer to a magnetostrictive strip covering the chart width. Accordingly, brushless dc-motors are used in some apparatuses. In the servo system accuracy is determined for the larger part by the quality of the sensing system. A poor contact with the resistor can give rise to noise; there may be a mechanical backlash between pen tip and the sliding contact on the potentiometer. The velocity of the pen carriage is limited, about 0.5 to 2 m/s dependent on motor and mechanics design. This results in a bandwidth of the recorder depending on the amplitude of the tracing: the -3 dB frequency fits in the range from 1 to 5 Hz for a full-scale width of 200 to 250 mm. Alternatively, the pen response time to a full-scale step input is given (5 to 95% of full-scale tracing): 0.1 to 0.5 s. Overshoot of the pen step response is extremely small in accurate designs.

In most pen recorders each tracing can cover the complete width. As such, pens must have the possibility to pass each other resulting in a small shift between adjacent pens (a few millimeters) along the time axis. In some apparatus, tracings can be synchronized with a POC-system (“pen offset compensation”); signals are digitized, stored in memory, and reproduced after a time delay correcting for the physical displacement of the pen. If immediate visual inspection is required, applying POC can be inconvenient as a consequence of this time delay. In process monitoring, slowly varying signals such as temperature, pressure, flow, etc. are followed. These signals can be handled by a single transducer in a discontinuous way; all input signals are scanned during the scanning cycle and for each signal a dot is

printed (“multipoint” recorder). The minimum scanning time is dependent on the moving writing device. For chart progression, dc and stepper motors are used. Calibrated paper is pulled by sprocket wheels seizing in equidistant perforations at both sides of the chart. Translational pen recorders range from simple purely analog design to intelligent microprocessor-controlled types handling a large number of channels with a broad range of control and monitor facilities (e.g., printing of a report after alarm).

Table 96.1 displays a set of translational pen recorders; some of them are equipped with a printhead. Under “Description” the major application is given: test and measurement or process monitoring. Furthermore the following are indicated: the number of continuous (c. ch.) and scanned (s. ch.) channels; the availability of POC, a printer (for additional information or for trace printing), a display for alphanumeric information (such as calibration values for each channel), or even a waveform display, data memory (allowing memory recorder functioning), $x-y$ recording facility, alarm generation (after reaching thresholds of recorded variables), and standard serial interface options allowing communication with a PC (introduction of recorder settings, storage, and processing of recorded data, etc.). Table 96.2 gives a summary of pen recorder specifications (multipoint types also included).

Thermal Dot Array Recorders

In **thermal dot array recorders**, apart from the chart-pulling system, no moving parts are present; the writing transducer is essentially a rectilinear array of equidistal writing points which covers the total width of the paper. Although some apparatuses apply an electrostatic method [1], the thermal dot array

and thermosensitive paper are generally used. In this array the writing styli consist of miniature electrically heated resistances; thermal properties of the resistances (in close contact with the chart paper) and the electric activating pulse form determine the maximal writing frequency. The latter ranges in real-time recorders from 1 to 6.4 kHz. Heating of the thermosensitive paper results in a black dot with good long-term stability. The heating pulse is controlled in relation to the chart velocity in order to obtain sufficient blackness at high velocities. Tracing blackness or line thickness is seldom used for curve identification; alphanumeric annotation is mostly applied. With the dot array a theoretically unlimited number of waveforms can be processed; the apparatus is thus programmed to draw its own calibration lines. Different types of grid patterns can be selected by the user. Moreover, alphanumeric information can be printed for indicating experimental conditions.

Ordinate axis resolution is determined by the dot array: primarily, 8 dots/mm; exceptionally, 12 dots/mm (as in standard laser printers). The resolution along the abscissa depends on the thermal array limitations and programming. Generally, a higher resolution is used (mostly 32 dots/mm, maximally 64 dots/mm) except for the highest chart velocities (100, 200, 500 mm/s). At these high velocities and consequently short chart contact times, dots become less sharp and less black. Most of the dot array instruments are intended for high-signal-frequency applications: per channel sampling frequencies of 100, 200, and even 500 kHz are used in real time. These sampling frequencies largely exceed the writing frequencies; during the writing cycle, data are stored in memory and for each channel within each writing interval a dotted vertical line is printed between the minimal and the maximal value. For example, a sine wave with a frequency largely exceeding the writing frequency is represented as a black band with a width

equal to the sine amplitude. In this way the graphs indicate the presence of a phenomenon with a frequency content exceeding the writing frequency. As data are stored in memory they can be reproduced at a lower rate thus revealing the actual high-frequency waveform captured. Some apparatuses use a much lower sampling rate in real time and only perform off-line: in this case the apparatus is indicated as a “memory” recorder. Digitization accuracy ranges from 8 to 16 bit, whereas the largest number of dots full scale is 4800. In this way the useful signal may be superposed on a large dc-offset: it can be written or reproduced with excellent graphic quality with the offset digitally removed and the scale adapted.

In a high-performance recorder a waveform display is extremely useful to avoid paper spoiling, in real-time and in off-line recording as well. The display is also used for apparatus settings. Signals can be calibrated and real physical values and units can be printed at the calibration lines. Via memory $x-y$ plots can be obtained. Some apparatuses allow application of mathematical functions for waveform processing and analysis: original and processed waveforms can be drawn together off-line. A few types are equipped with FFT software. Computer interfacing, a large set of triggering modes (including recording at increased velocity after a specific trigger), event channels, etc. are standard facilities. Table 96.3 shows a set of thermal dot array recorders (under “Description”: number of analog channels (a. ch.) and digital channels (d. ch.); waveform monitor; signal data memory, $x-y$ facility, mathematical analysis, FFT) and Table 96.4 gives specifications.

Concluding Remarks

Table 96.5 gives addresses and fax and phone numbers of manufacturers of recorders mentioned in Tables 96.1 and 96.3. It should be remarked that prices mentioned in these tables hold for purchasing a complete functioning apparatus (number of channels indicated) from firms in Belgium representing the manufacturers and having provided the data sheets from which specifications were derived. With the expression “a complete functioning” apparatus a standard system is meant, thus including simple input couplers (in case of a modular design), standard RAM and analysis software, no specific options. Obviously, the list of manufacturers is incomplete. It should be mentioned that the number of manufacturers of graphic recorders is decreasing; a significant and increasing amount of applications has been taken over by

“paperless” recorders, i.e., data acquisition systems. Nevertheless, the possibility of generating graphs in real time remains an important feature, e.g., to provide evidence of the presence of a specific phenomenon. In recent years analog recorders have become less used and manufactured (apart from the translational pen types, especially in industrial process monitoring). Thermal array recorders have become more important: the quality and long-term stability of thermal paper have improved and cost levels are comparable with calibrated paper for ink recording. In new designs, recorders provide more capabilities

and appear more intelligent, obviously leading to increased complications with respect to instrument settings and thus increased need for training and experience in the use of the instrument.

Defining Terms

Analog graphic recorder: A graphic recorder that makes use of an analog transducer system (e.g., a moving pen).

Analog recorder bandwidth: The largest frequency that can be processed by the analog recorder (−3 dB limit).

Digital graphic recorder: A graphic recorder that makes use of a digital transducer system (e.g., a fixed dot array).

Graphic recorder: A measuring apparatus that produces in real time a hard copy of a set of time-dependent variables.

Maximal sampling frequency: Maximal number of data points sampled by the digital recorder per time unit (totally or per channel).

Maximal writing frequency: Maximal number of writing (or printing) acts executed by the digital recorder per time unit.

Thermal dot array recorder: A digital recorder applying a fixed thermal dot array perpendicular to the time axis.

Translational pen recorder: An analog recorder with one or several pens being translated perpendicularly to the time axis.

96.2 Data Acquisition Systems

Edward McConnell

The fundamental task of a **data acquisition system** is the measurement or generation of real-world physical signals. Before a physical signal can be measured by a computer-based system, a sensor or transducer is used to convert the physical signal into an electrical signal, such as voltage or current. Often only a plug-in data acquisition (DAQ) board is considered the data acquisition system; however, a board is only one of the components in the system. A complete DAQ system consists of sensors, signal conditioning, interface hardware, and software. Unlike stand-alone instruments, signals often cannot be directly connected to the DAQ board. The signals may need to be conditioned by some signal-conditioning accessory before they are converted to digital information by the plug-in DAQ board. Software controls the data acquisition system — acquiring the raw data, analyzing the data, and presenting the results. The components are shown in [Fig. 96.1](#).

Signals

Signals are physical events whose magnitude or time variation contains information. DAQ systems measure various aspects of a signal in order to monitor and control the physical events. Users of DAQ systems need to know the relation of the signal to the physical event and what information is available in the signal. Generally, information is conveyed by a signal through one or more of the following signal parameters: state, rate, level, shape, or frequency content. The physical characteristics of the measured signals and the related information help determine the design of a DAQ system..

All signals are, fundamentally, analog, time-varying signals. For the purpose of discussing the methods of signal measurement using a plug-in DAQ board, a given signal should be classified as one of five signal types. Because the method of signal measurement is determined by the way the signal conveys the needed information, a classification based on this criterion is useful in understanding the fundamental building blocks of a DAQ system.

As shown in the [Fig. 96.2](#), any signal can generally be classified as analog or digital. A digital, or binary, signal has only two possible discrete levels of interest — a high (on) level and a low (off) level. The two digital signal types are on–off signals and pulse train signals. An analog signal, on the other hand, contains information in the continuous variation of the signal with time. Analog signals are described in the time or frequency domains depending upon the information of interest. A dc type signal is a low-frequency signal, and if the phase information of a signal is presented with the frequency information, then there is no difference between the time or frequency domain representations. The category to which a signal belongs depends on the characteristic of the signal to be measured. The five types of signals can be closely paralleled with the five basic types of signal information — state, rate, level, shape, and frequency content.

Basic understanding of the signal representing the physical event being measured and controlled assists in the selection of the appropriate DAQ system.

FIGURE 96.1 Components of a DAQ system.

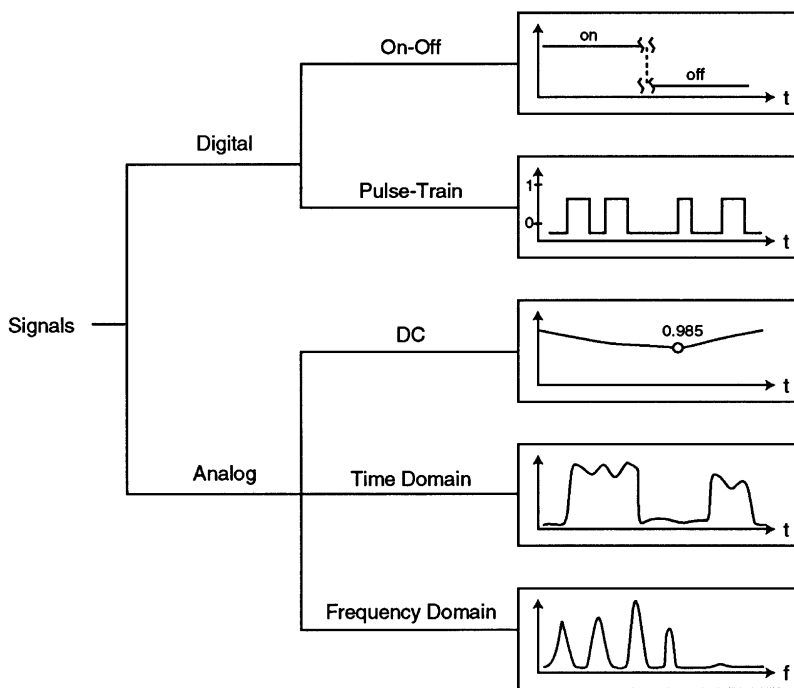

FIGURE 96.2 Classes of signals.

Plug-In DAQ Boards

The fundamental component of a DAQ system is the plug-in DAQ board. These boards plug directly into a slot in a PC and are available with analog, digital, and timing inputs and outputs (I/O). The most versatile of the plug-in DAQ boards is the multifunction I/O board. As the name implies, this board typically contains various combinations of analog-to-digital converters (ADCs), digital-to-analog converters (DACs), digital I/O lines, and counters/timers. ADCs and DACs measure and generate analog voltage signals, respectively. The digital I/O lines sense and control digital signals. Counters/timers measure pulse rates, widths, delays, and generate timing signals. These many features make the multifunction DAQ board useful for a wide range of applications.

Multifunction boards are commonly used to measure analog signals. This is done by the ADC, which converts the analog voltage level into a digital number that the computer can interpret. The analog multiplexer (MUX), the instrumentation amplifier, the sample-and-hold (S/H) circuitry, and the ADC compose the analog input section of a multifunction board (see Fig. 96.3).

FIGURE 96.3 Analog input section of a plug-in DAQ board. *Note:* FIFO = first-in first-out buffer, S/H = sample-and-hold, Inst. Amp = instrumentation amplifier, and Mux = analog multiplexer.

Typically, multifunction DAQ boards have one ADC. Multiplexing is a common technique for measuring multiple channels (generally 16 single-ended or 8 differential) with a single ADC. The analog MUX switches between channels and passes the signal to the instrumentation amplifier and the S/H circuitry. The MUX architecture is the most common approach taken with plug-in DAQ boards. While plug-in boards typically include up to only 16 single-ended or 8 differential inputs, the number of analog input channels can be further expanded with external MUX accessories.

Instrumentation amplifiers typically provide a differential input and selectable gain by jumpers or software. The differential input rejects small common-mode voltages. The gain is often software programmable. In addition, many DAQ boards also include the capability to change the amplifier gain while scanning channels at high rates. Therefore, one can easily monitor signals with different ranges of amplitudes. The output of the amplifier is sampled, or held at a constant voltage, by the S/H device at measurement time so that voltage does not change during digitization.

The ADC transforms the analog signal into a digital value which is ultimately sent to computer memory. There are several important parameters of A/D conversion. The fundamental parameter of an ADC is the number of bits. The number of bits of an A/D determines the range of values for the binary output of the ADC conversion. For example, many ADCs are 12-bit, so a voltage within the input range of the ADC will produce a binary value that has one of $2^{12} = 4096$ different values. The more bits that an ADC has, the higher the resolution of the measurement. The resolution determines the smallest amount of change that can be detected by the ADC. Resolution is expressed as the number of digits of a voltmeter or dynamic range in decibels, rather than with bits. [Table 96.6](#) shows the relation among bits, number of digits, and dynamic range in decibels.

TABLE 96.6 Relation Among Bits, Number of Digits, and Dynamic Range (dB)

Bits	Digits	dB
20	6.0	120
16	4.5	96
12	3.5	72
8	2.5	48

The resolution of the A/D conversion is also determined by the input range of the ADC and the gain. DAQ boards usually include an instrumentation amplifier that amplifies the analog signal by a gain factor prior to the conversion. This gain amplifies low-level signals so that more accurate measurements can be made.

Together, the input range of the ADC, the gain, and the number of bits of the board determine the minimum resolution of the measurement. For example, suppose a low-level ± 30 mV signal is acquired

using a 12-bit ADC that has a ± 5 V input range. If the system includes an amplifier with a gain of 100, the resulting resolution of the measurement will be $\text{range}/(\text{gain} * 2^{\text{bits}}) = \text{resolution}$, or $10 \text{ V}/(100 * 2^{12}) = 0.0244 \text{ mV}$.

Finally, an important parameter of digitization is the rate at which A/D conversions are made, referred to as the sampling rate. The A/D system must be able to sample the input signal fast enough to measure the important waveform attributes accurately. In order to meet this criterion, the ADC must be able to convert the analog signal to digital form quickly enough.

When scanning multiple channels with a multiplexing DAQ system, other factors can affect the throughput of the system. Specifically, the instrumentation amplifier must be able to settle to the needed accuracy before the A/D conversion occurs. With multiplexed signals, multiple signals are being switched into one instrumentation amplifier. Most amplifiers, especially when amplifying the signals with larger gains, will not be able to settle to the full accuracy of the ADC when scanning channels at high rates. To avoid this situation, consult the specified settling times of the DAQ board for the gains and sampling rates required by the application.

Types of ADCs

Different DAQ boards use different types of ADCs to digitize the signal. The most popular type of ADC on plug-in DAQ boards is the successive approximation ADC, because it offers high speed and high resolution at a modest cost.

Subranging (also called half-flash) ADCs offer very high speed conversion with sampling speeds up to several million samples per second.

The state-of-the-art technology in ADCs is sigma–delta modulating ADCs. These ADCs sample at high rates, are able to achieve high resolution, and offer the best linearity of all ADCs.

Integrating and flash ADCs are mature technologies still used on DAQ boards today. Integrating ADCs are able to digitize with high resolution but must sacrifice sampling speed to obtain it. Flash ADCs are able to achieve the highest sampling rate (gigahertz) but are available only with low resolution. The different types of ADCs are summarized in [Table 96.7](#).

TABLE 96.7 Types of ADCs

Type of ADC	Advantages	Features
Successive approximation	High resolution High speed Easily multiplexed	1.25 MS/s sampling rate 12-bit resolution 200 kS/s sampling rate 16-bit resolution
Subranging	Higher speed	1 MHz sampling rate 12-bit resolution
Sigma–delta	High resolution Excellent linearity Built-in antialiasing State-of-the-art technology	48 kHz sampling rate 16-bit resolution
Integrated	High resolution Good noise rejection Mature technology	15 kHz sampling rate
Flash	Highest speed Mature technology	125 MHz sampling rate

Analog Input Architecture

With a typical DAQ board, the multiplexer switches among analog input channels. The analog signal on the channel selected by the multiplexer then passes to the programmable gain instrumentation amplifier (PGIA), which amplifies the signal. After the signal is amplified, the sample and hold (S/H) keeps the analog signal constant so that the ADC can determine the digital representation of the analog signal. A

good DAQ board will then place the digital signal in a first-in first-out (FIFO) buffer, so that no data will be lost if the sample cannot transfer immediately over the PC I/O channel to computer memory. Having a FIFO becomes especially important when the board is run under operating systems that have large interrupt latencies, such as Microsoft Windows.

Basic Analog Specifications

Almost every DAQ board data sheet specifies the number of channels, the maximum sampling rate, the resolution, and the input range and gain.

The number of channels, which is determined by the multiplexer, is usually specified in two forms — differential and single ended. Differential inputs are inputs that have different reference points for each channel, none of which is grounded by the board. Differential inputs are the best way to connect signals to the DAQ board because they provide the best noise immunity.

Single-ended inputs are inputs that are referenced to a common ground point. Because single-ended inputs are referenced to a common ground, they are not as good as differential inputs for rejecting noise. They do have a larger number of channels, however. Single-ended inputs are used when the input signals are high level (greater than 1 V), the leads from the signal source to the analog input hardware are short (less than 5 m), and all input signals share a common reference.

Some boards have pseudodifferential inputs which have all inputs referenced to the same common — like single-ended inputs — but the common is not referenced to ground. These boards have the benefit of a large number of input channels, like single-ended inputs, and the ability to remove some common-mode noise, especially if the common-mode noise is consistent across all channels. Differential inputs are still preferable to pseudodifferential, however, because differential is more immune to magnetic noise.

Sampling rate determines how fast the analog signal is converted to a digital signal. When measuring ac signals, sample at least two times faster than the highest frequency of the input signal. Even when measuring dc signals, oversample and average the data to increase the accuracy of the signal by reducing the effects of noise.

If the physical event consists of multiple dc-class signals, a DAQ board with interval scanning should be used. With interval scanning, all channels are scanned at one sample interval (usually the fastest rate of the board), with a second interval (usually slow) determining the time before repeating the scan. Interval scanning gives the effects of simultaneously sampling for slowly varying signals without requiring the additional cost of input circuitry for true simultaneous sampling.

Resolution is the number of bits that are used to represent the analog signal. The higher the resolution, the higher the number of divisions the input range is broken into, and therefore the smaller the possible detectable voltage. Unfortunately, some DAQ specifications are misleading when they specify the resolution associated with the DAQ board. Many DAQ board specifications state the resolution of the ADC without stating the linearities and noise, and therefore do not give the information needed to determine the resolution of the entire board. Resolution of the ADC, combined with the settling time, **integral nonlinearity (INL)**, **differential nonlinearity (DNL)**, and noise will give an understanding of the accuracy of the board.

Input range and gain determine the level of signal that should be connect to the board. Usually, the range and gain are specified separately, so the two must be combined to determine the actual signal input range as

$$\text{signal input range} = \text{range/gain}$$

For example, a board using an input range of ± 10 V with a gain of 2 will have a signal input range of ± 5 V. The closer the signal input range is to the range of the signal, the more accurate the readings from the DAQ board will be. If the signals have different input ranges, use a DAQ board with the feature of different gains per channel.

Data Acquisition Software

The software is often the most critical component of the DAQ system. Users of DAQ systems usually program the hardware in one of two ways — through register programming or through high-level device drivers.

Board Register-Level Programming

The first option is not to use vendor-supplied software and program the DAQ board at the hardware level. DAQ boards are typically register based; that is, they include a number of digital registers that control the operation of the board. The developer may use any standard programming language, such as C, C++, or Visual BASIC, to write series of binary codes to the DAQ board to control its operation. Although this method affords the highest level of flexibility, it is also the most difficult and time-consuming, especially for the inexperienced programmer. The programmer must know the details of programming all hardware, including the board, the PC interrupt controller, the DMA controller, and PC memory.

Driver Software

Driver software typically consists of a library of function calls usable from a standard programming language. These function calls provide a high-level interface to control the standard functions of the plug-in board. For example, a function called SCAN_OP may configure, initiate, and complete a multiple-channel scanning DAQ operation of a predetermined number of points. The function call would include parameters to indicate the channels to be scanned, the amplifier gains to be used, the sampling rate, and the total number of data points to be collected. The driver responds to this one function call by programming the plug-in board, the DMA controller, the interrupt controller, and CPU to scan the channels as requested.

What Is Digital Sampling?

Every DAQ system has the task of gathering information about analog signals. To do this, the system captures a series of instantaneous “snapshots” or samples of the signal at definite time intervals. Each sample contains information about the signal at a specific instant. Knowing the exact time of each conversion and the value of the sample, one can reconstruct, analyze, and display the digitized waveform.

Real-Time Sampling Techniques

In real-time sampling, the DAQ board digitizes consecutive samples along the signal (Fig. 96.4). According to the **Nyquist sampling theorem**, the ADC must sample at least twice the rate of the maximum frequency component in that signal to prevent aliasing. **Aliasing** is a false lower-frequency component that appears in sampled data acquired at too low a sampling rate. The frequency at one half the sampling frequency is referred to as the Nyquist frequency. Theoretically, it is possible to recover information about those signals with frequencies at or below the Nyquist frequency. Frequencies above the Nyquist frequency will alias to appear between dc and the Nyquist frequency.

For example, assume the sampling frequency, f_s , is 100 Hz. Also assume the input signal to be sampled contains the following frequencies — 25, 70, 160, and 510 Hz. Figure 96.5 shows a spectral representation of the input signal.

The mathematics of sampling theory show us that a sampled signal is shifted in the frequency domain by an amount equal to integer multiples of the sampling frequency, f_s . Figure 96.6 shows the spectral content of the input signal after sampling. Frequencies below 50 Hz, the Nyquist frequency ($f_s/2$), appear correctly. However, frequencies above the Nyquist appear as aliases below the Nyquist frequency. For example, F1 appears correctly; however, F2, F3, and F4 have aliases at 30, 40, and 10 Hz, respectively.

FIGURE 96.4 Consecutive discrete samples recreate the input signal.

FIGURE 96.5 Spectral of signal with multiple frequencies.

The resulting frequency of aliased signals can be calculated with the following formula:

$$\text{Apparent (Alias) Freq.} = \text{ABS (Closest Integer Multiple of Sampling Freq. - Input Freq.)}$$

For the example of Figs. 96.5 and 96.6:

$$\text{Alias F2} = |100 - 70| = 30 \text{ Hz}$$

$$\text{Alias F3} = |(2)100 - 160| = 40 \text{ Hz}$$

$$\text{Alias F4} = |(5)100 - 510| = 10 \text{ Hz}$$

Preventing Aliasing

Aliasing can be prevented by using filters on the front end of the DAQ system. These antialiasing filters are set to cut off any frequencies above the Nyquist frequency (half the sampling rate). The perfect filter would reject all frequencies above the Nyquist; however, because perfect filters exist only in textbooks, one must compromise between sampling rate and selecting filters. In many applications, one- or two-pole passive filters are satisfactory. The rule of thumb is to oversample (5 to 10 times) and use these antialiasing filters when frequency information is crucial.

Alternatively, active antialiasing filters with programmable cutoff frequencies and very sharp attenuation of frequencies above the cutoff can be used. Because these filters exhibit a very steep roll-off, the DAQ system can sample at two to three times the filter cutoff frequency. Figure 96.7 shows a transfer function of a high-quality antialiasing filter.

Alias F2 = $|100 - 70| = 30$ Hz
 Alias F3 = $|2 \cdot 100 - 160| = 40$ Hz
 Alias F4 = $|5 \cdot 100 - 510| = 10$ Hz

FIGURE 96.6 Spectral of signal with multiple frequencies after sampling at $f_s = 100$ Hz.

FIGURE 96.7 Magnitude portion of transfer function of an antialiasing filter.

The computer uses digital values to recreate or to analyze the waveform. Because the signal could be anything between each sample, the DAQ board may be unaware of any changes in the signal between samples. There are several sampling methods optimized for the different classes of data; they include software polling, external sampling, continuous scanning, multirate scanning, simultaneous sampling, interval scanning, and seamless changing of the sample rate.

Software Polling

A software loop polls a timing signal and starts the A/D conversion via a software command when the edge of the timing signal is detected. The timing signal may originate from the internal clock of the computer or from a clock on the DAQ board. Software polling is useful in simple, low-speed applications, such as temperature measurements.

The software loop must be fast enough to detect the timing signal and trigger a conversion. Otherwise, a window of uncertainty, also known as jitter, will exist between two successive samples. Within the window of uncertainty, the input waveform could change enough to reduce the accuracy of the ADC drastically.

Suppose a 100-Hz, 10-V full-scale sine wave is digitized (Fig. 96.8). If the polling loop takes 5 ms to detect the timing signal and to trigger a conversion, then the voltage of the input sine wave will change

as much as 31 mV, $[\Delta V = 10 \sin(2\pi \times 100 \times 5 \times 10^{-6})]$. For a 12-bit ADC operating over an input range of 10 V and a gain of 1, one least significant bit (LSB) of error represents 2.44 mV:

$$\left(\frac{\text{Input range}}{\text{gain} \times 2^n} \right) = \left(\frac{10 \text{ V}}{1 \times 2^{12}} \right) = 2.44 \text{ mV}$$

But because the voltage error due to jitter is 31 mV, the accuracy error is 13 LSB.

$$\left(\frac{31 \text{ mV}}{2.44 \text{ mV}} \right)$$

This represents uncertainty in the last 4 bits of a 12-bit ADC. Thus, the effective accuracy of the system is no longer 12 bits but rather 8 bits.

External Sampling

Some DAQ applications must perform a conversion based on another physical event that triggers the data conversion. The event could be a pulse from an optical encoder measuring the rotation of a cylinder. A sample would be taken every time the encoder generates a pulse corresponding to n degrees of rotation. External triggering is advantageous when trying to measure signals whose occurrence is relative to another physical phenomenon.

Continuous Scanning

When a DAQ board acquires data, several components on the board convert the analog signal to a digital value. These components include the analog MUX, the instrumentation amplifier, the S/H circuitry, and the ADC. When acquiring data from several input channels, the analog MUX connects each signal to the ADC at a constant rate. This method, known as continuous scanning, is significantly less expensive than having a separate amplifier and ADC for each input channel.

Continuous scanning is advantageous because it eliminates jitter and is easy to implement. However, it is not possible to sample multiple channels simultaneously. Because the MUX switches between channels, a time skew occurs between any two successive channel samples. Continuous scanning is appropriate for applications where the time relationship between each sampled point is unimportant or where the skew is relatively negligible compared with the speed of the channel scan.

If samples from two signals are used to generate a third value, then continuous scanning can lead to significant errors if the time skew is large. In Fig. 96.9, two channels are continuously sampled and added together to produce a third value. Because the two sine waves are 90° out-of-phase, the sum of the signals should always be zero. But because of the skew time between the samples, an erroneous sawtooth signal results.

FIGURE 96.8 Jitter reduces the effective accuracy of the DAQ board.

FIGURE 96.9 If the channel skew is large compared with the signal, then erroneous conclusions may result.

Multirate Scanning

Multirate scanning, a method that scans multiple channels at different scan rates, is a special case of continuous scanning. Applications that digitize multiple signals with a variety of frequencies use multirate scanning to minimize the amount of buffer space needed to store the sampled signals. Channel-independent ADCs are used to implement hardware multirate scanning; however, this method is extremely expensive. Instead of multiple ADCs, only one ADC is used. A channel/gain configuration register stores the scan rate per channel and software divides down the scan clock based on the per-channel scan rate. Software-controlled multirate scanning works by sampling each input channel at a rate that is a fraction of the specified scan rate.

Suppose the system scans channels 0 through 3 at 10 kS/s, channel 4 at 5 kS/s, and channels 5 through 7 at 1 kS/s. A base scan rate of 10 kS/s should be used. Channels 0 through 3 are acquired at the base scan rate. Software and hardware divide the base scan rate by 2 to sample channel 4 at 5 kS/s, and by 10 to sample channels 5 through 7 at 1 kS/s.

Simultaneous Sampling

For applications where the time relationship between the input signals is important, such as phase analysis of ac signals, simultaneous sampling must be used. DAQ boards capable of simultaneous sampling typically use independent instrumentation amplifiers and S/H circuitry for each input channel, along with an analog MUX, which routes the input signals to the ADC for conversion (as shown in Fig. 96.10).

To demonstrate the need for a simultaneous-sampling DAQ board, consider a system consisting of four 50-kHz input signals sampled at 200 kS/s. If the DAQ board uses continuous scanning, the skew between each channel is $5 \mu\text{s}$ ($1\text{s}/200 \text{ kS/s}$) which represents a 270° [$(15 \mu\text{s}/20 \mu\text{s}) \times 360^\circ$] shift in phase between the first channel and fourth channel. Alternatively, with a simultaneous-sampling board with a maximum 5 ns interchannel time offset, the phase shift is only 0.09° [$(5 \mu\text{s}/20 \mu\text{s}) \times 360^\circ$]. This phenomenon is illustrated in Fig. 96.11.

Interval Scanning

For low-frequency signals, interval scanning creates the effect of simultaneous sampling, yet maintains the cost benefits of a continuous-scanning system. This method scans the input channels at one rate and

FIGURE 96.10 Block diagram of DAQ components used to sample multiple channels simultaneously.

FIGURE 96.11 Comparison of continuous scanning and simultaneous sampling.

uses a second rate to control when the next scan begins. If the input channels are scanned at the fastest rate of the ADC, the effect of simultaneously sampling the channels is created. Interval scanning is appropriate for slow-moving signals, such as temperature and pressure. Interval scanning results in a jitter-free sample rate and minimal skew time between channel samples. For example, consider a DAQ system with ten temperature signals. By using interval scanning, a DAQ board can be set up to scan all channels with an interchannel delay of $5\ \mu\text{s}$, then repeat the scan every second. This method creates the effect of simultaneously sampling ten channels at 1 S/s, as shown in Fig. 96.12.

To illustrate the difference between continuous and interval scanning, consider an application that monitors the torque and RPMs of an automobile engine and computes the engine horsepower. Two signals, proportional to torque and RPM, are easily sampled by a DAQ board at a rate of 1000 S/s. The values are multiplied together to determine the horsepower as a function of time.

A continuously scanning DAQ board must sample at an aggregate rate of 2000 S/s. The time between which the torque signal is sampled and the RPM signal is sampled will always be 0.5 ms (1/2000). If either signal changes within 0.5 ms, then the calculated horsepower is incorrect. But using interval scanning at a rate of 1000 S/s, the DAQ board samples the torque signal every 1 ms, and the RPM signal is sampled as quickly as possible after the torque is sampled. If a 5- μ s interchannel delay exists between the torque and RPM samples, then the time skew is reduced by 99% $[(0.5 \text{ ms} - 5 \mu\text{s})/0.5 \text{ ms}]$, and the chance of an incorrect calculation is reduced.

Factors Influencing the Accuracy of Measurements

How does one determine if a plug-in DAQ will deliver the required measurement results? With a sophisticated measuring device like a plug-in DAQ board, significantly different accuracies can be obtained depending on the type of board used. For example, one can purchase DAQ products on the market today with 16-bit ADCs and get less than 12 bits of useful data, or one can purchase a product with a 16-bit ADC and actually get 16 bits of useful data. This difference in accuracies causes confusion in the PC industry where everyone is used to switching out PCs, video cards, printers, and so on, and experiencing similar results between equipment.

The most important thing to do is to scrutinize more specifications than the resolution of the ADC that is used on the DAQ board. For dc-class measurements, one should at least consider the settling time of the instrumentation amplifier, DNL, **relative accuracy**, INL, and noise. If the manufacturer of the board under consideration does not supply these specifications in the data sheets, ask the vendor to provide them or run tests to determine these specifications.

Defining Terms

Alias: A false lower frequency component that appears in sampled data acquired at too low a sampling rate.

Asynchronous: (1) Hardware — A property of an event that occurs at an arbitrary time, without synchronization to a reference clock. (2) Software — A property of a function that begins an operation and returns prior to the completion or termination of the operation.

Conversion time: The time required, in an analog input or output system, from the moment a channel is interrogated (such as with a read instruction) to the moment that accurate data are available.

DAQ (data acquisition): (1) Collecting and measuring electric signals from sensors, transducers, and test probes or fixtures and inputting them to a computer for processing; (2) Collecting and measuring the same kinds of electric signals with ADC and/or DIO boards plugged into a PC, and possibly generating control signals with DAC and/or DIO boards in the same PC.

DNL (differential nonlinearity): A measure in LSB of the worst-case deviation of code widths from their ideal value of 1 LSB.

INL (integral nonlinearity): A measure in LSB of the worst-case deviation from the ideal A/D or D/A transfer characteristic of the analog I/O circuitry.

Nyquist sampling theorem: A law of sampling theory stating that if a continuous bandwidth-limited signal contains no frequency components higher than half the frequency at which it is sampled, then the original signal can be recovered without distortion.

Relative accuracy: A measure in LSB of the accuracy of an ADC. It includes all nonlinearity and quantization errors. It does not include offset and gain errors of the circuitry feeding the ADC.

96.3 Magnetic and Optical Recorders

Yufeng Li

The heart of recording technology is for the process of information storage and retrieval. In addition to its obvious importance in different branches of science and engineering, it has become indispensable to our daily life. When we make a bank transaction, reserve an airplane ticket, use a credit card, watch a movie from a video tape, or listen to music from a CD, we are using the technology of recording. The general requirements for recording are information integrity, fast access, and low cost. Among the different techniques, the most popularly used ones are magnetic and optical recording.

Typical recording equipment consists of a read/write head, a medium, a coding/decoding system, a data access system, and some auxiliary mechanical and electronic components. The head and medium are for data storage and retrieval purposes, and the coding/decoding system is for data error correction. The data access system changes the relative position between the head and the medium, usually with a servo mechanism for data track following and a spinning mechanism for on-track moving. While the data access system and the auxiliary components are important to recording equipment, they are not considered essential in this chapter to the understanding of recording technology, and will not be covered. Interested readers are referred to Reference 1.

Magnetic Recording

At present, magnetic recording technology dominates the recording industry. It is used in the forms of hard disk, floppy disk, removable disk, and tape with either digital or analog mode. In its simplest form, it consists of a magnetic head and a magnetic medium, as shown in Fig. 96.13. The head is made of a piece of magnetic material in a ring shape (core), with a small gap facing the medium and a coil away from the medium. The head records (writes) and reproduces (reads) information, while the medium stores the information. The recording process is based on the phenomenon that an electric current i generates a magnetic flux ϕ as described by Ampere's law. The flux ϕ leaks out of the head core at the gap, and magnetizes the magnetic medium which moves from left to right with a velocity V under the head gap. Depending on the direction of the electric current i , the medium is magnetized with magnetization M pointing either left or right. This pattern of magnetization is retained in the memory of the medium even after the head moves away.

Two types of head may be used for reproducing. One, termed the *inductive head*, senses magnetic flux change rate, and the other, named the *magnetoresistive (MR) head*, senses the magnetic flux. When an inductive head is used, the reproducing process is just the reverse of the recording process. The flux coming out of the magnetized medium surface is picked up by the head core. Because the medium magnetization under the head gap changes its magnitude and direction as the medium moves, an electric

FIGURE 96.13 Conceptual diagrams illustrating the magnetic recording principle (a), and recording/reproducing process (b).

voltage is generated in the coil. This process is governed by Faraday's law. Figure 96.13b schematically shows the digital recording/reproducing process. First, all user data are encoded into a binary format — a serial of 1s and 0s. Then a write current i is sent to the coil. This current changes its direction whenever a 1 is being written. Correspondingly, a change of magnetization, termed a *transition*, is recorded in the medium for each 1 in the encoded data. During the reproducing process, the electric voltage induced in the head coil reaches a peak whenever there is a transition in the medium. A pulse detector generates a pulse for each transition. These pulses are decoded to yield the user data.

The minimum distance between two transitions in the medium is the flux change length B , and the distance between two adjacent signal tracks is the track pitch W , which is wider than the signal track width w . The flux change length can be directly converted into bit length with the proper code information. The reciprocal of the bit length is called *linear density*, and the reciprocal of the track pitch is termed

track density. The information storage areal density in the medium is the product of the linear density and the track density. This areal density roughly determines how much information a user can store in a unit surface area of storage medium, and is a figure of merit for a recording technique. Much effort has been expended to increase the areal density. For example, it has been increased 50 times during the last decade in hard disk drives, and is expected to continue increasing 60% per year in the foreseeable future. At present, state-of-the-art hard disk products feature areal densities of more than 7 Mbits/mm² ($B < 0.1 \mu\text{m}$ and $W < 1.5 \mu\text{m}$). This gives a total storage capacity of up to 6 Gbytes for a disk of 95 mm diameter.

Magnetism and Hysteresis Loop

Magnetism is the result of uncompensated electron spin motions in an atom. Only transition elements exhibit this property, and nearly all practical interest in magnetism centers on the first transition group of elements (Mn, Cr, Fe, Ni, and Co) and their alloys. The strength of magnetism is represented by magnetization M , and is related to magnetic field H and magnetic flux density B by

$$B = \mu_0(H + M) \quad (96.1)$$

where μ_0 is the permeability of vacuum. Since M is a property of a magnetic material, it does not exist outside the magnetic material. H represents the strength acting on a magnetic material from a magnetic field which is generated either by a magnetic material or by an electric current. B is the flux density which determines the induced electric voltage in a coil. The ratio of B with and without a magnetic material is the relative permeability μ of that magnetic material.

When a magnetic field H is applied to a piece of demagnetized magnetic material, the magnetization M starts increasing with H from zero. The rate of increase gradually slows down and M asymptotically approaches a value M_s at high H . If H is reduced to zero, then M is reduced to a lower value M_r . Continuous reduction of H to a very high negative value will magnetize the material to $-M_s$. In order to bring the material to demagnetized state, a positive field H_c is required. Further increase in the H field will bring the trace of M to a closed loop. This loop is the major hysteresis loop, as shown in Fig. 96.14. The hysteresis loop shows that a magnetic material has memory. It is this memory that is used in the medium for storing information. H_c is the coercivity, indicating the strength of magnetic field required to erase the memory of a magnetic material. Magnetic materials with high H_c are “hard” magnets, and are suitable for medium applications if they have high M_r . On the other hand, magnetic materials with low H_c are “soft” magnets, and are candidates for head core materials if they have high M_s and high μ . M_r and M_s are the remanent and saturation magnetization, respectively, and their ratio is the remanent squareness. The flux density corresponding to M_s is B_s .

Magnetic Media

Magnetic media are used to store information in a magnetic recording system. In order to increase the areal density, we need to reduce flux change length B and track width w . Since B is limited by the term $M_r\delta/H_c$, where δ is the magnetic layer thickness, we can reduce B by either decreasing $M_r\delta$ or increasing H_c . However, the amplitude of the magnetic signal available for reproducing head is proportional to the term $M_r\delta w$. If we reduce track width w to increase areal density, we must increase $M_r\delta$ to avoid signal deterioration. In addition, if the magnetic layer is so thin that it causes thickness nonuniformity, more noise will appear in the reproducing process. Therefore, the major requirements for magnetic layer are high H_c , high M_r , and ease of making a uniform thin layer. Additional requirements include good magnetic and mechanical stability.

There are two groups of magnetic media. The first group is called particulate media because the magnetic materials are in the form of particles. This group includes iron oxide ($\gamma\text{-Fe}_2\text{O}_3$), cobalt-modified iron oxide ($\gamma\text{-Fe}_2\text{O}_3+\text{Co}$), chromium dioxide (CrO_2), metal particles, and barium ferrite ($\text{BaFe}_{12}\text{O}_{19}$). Some of these have been used in the magnetic recording for several decades. More recently, another group of media has been developed largely due to the ever-increasing demand for higher storage capacity

FIGURE 96.14 Hysteresis loop of a magnetic material shows the nonlinear relationship between M and H which results in magnetic memory.

TABLE 96.8 Remanence (M_r) and Coercivity (H_c) Values of Some Commonly Used Magnetic Media (some values are from Reference 5)

Group	Material	M_r (kA/m)	H_c (kA/m)	Application
Particulate	γ -Fe ₂ O ₃	56–140	23–32	Floppy disk, audio, video, and instrumentation tapes
	γ -Fe ₂ O ₃ +Co	60–140	44–74	Floppy disk, audio, video, and instrumentation tapes
	CrO ₂	110–140	38–58	Floppy disk, audio, video, and instrumentation tapes
Thin film	BaFe ₁₂ O ₁₉	56	58	Floppy disk
	Co–Ni	600–1100	30–85	Hard disk
	Co–Fe	1100–1500	60–150	Hard disk
	Co–P	600–1000	36–120	Hard disk
	Co–Ni–Pt	600–1100	60–175	Hard disk
	Co–Cr–Ta	350–900	55–190	Hard disk
	Co–Cr–Pt	300–750	56–200	Hard disk

in the computer industry. This group of media is the thin-film media, where the magnetic layer can be made as a continuous thin film. Most materials in this group are cobalt-based metal alloys. Compared with particulate media, the thin-film media usually have a higher coercivity H_c , a higher remanence M_r , and can be deposited in a very thin continuous film. Table 96.8 lists H_c and M_r for some of the most popularly used particulate and thin-film media. Note that magnetic properties are affected by the fabrication process and film structure. Therefore, their values can be out of the ranges of Table 96.8 if different processes are used.

Magnetic media can be classified into three general forms of applications. Tape is the oldest form and remains an important medium today. It is central to most audio, video, and instrumentation recording, although it is also used in the computer industry for archival storage. Tape is economical and can hold a large capacity, but suffers slow access time. Hard disk is primarily used as the storage inside a computer, providing fast data access for the user, but having poor transportability. Flexible disk is designed for easy data transportation, but is limited in capacity. Besides these three general forms of applications, a hybrid of flexible and hard disk is being gradually accepted. It is a removable rigid disk capable of holding up to several gigabytes of digital data. In addition, magnetic stripes are getting wide use in different forms of cards.

The magnetic layer alone cannot be used as a medium. It needs additional components to improve its chemical and mechanical durability. Typical cross sections of a particulate magnetic tape and a thin-film hard disk are shown in Fig. 96.15. In the case of tape application, iron particles with typical size of 0.5 μm long and 0.1 μm wide are dispersed in a polymeric binder, together with solvents, lubricants, and other fillers to improve magnetic and mechanical stability. This dispersed material is then coated on an abaxially oriented polyethylene terephthalate substrate. An optional back coat may also be applied to the other side of the substrate. The cross section of a hard disk is more complex. A high-purity aluminum–magnesium (5 wt%) substrate is diamond turned to a fine surface finish, and then electrolessly plated with a nonmagnetic nickel–phosphorus (10 at%) undercoat. This layer is used to increase the

hardness, reduce the defects, and improve the finish of the Al-Mg alloy, and is polished to a super surface finish. Next, an underlayer of chromium is sputtered to control the properties of the magnetic film, followed by sputtering the magnetic film. Finally, a layer of hydrogenated or nitrogenated carbon is overcoated on the magnetic film, and an ultrathin layer of perfluorinated hydrocarbon liquid lubricant is applied on top. The carbon and lubricant layers are used to improve the corrosion and mechanical resistance of the disk. For a 95-mm disk the finished product should have a surface flatness better than $10\ \mu\text{m}$ and a tightly control surface roughness. In some applications, an arithmetic average roughness (R_a) of less than 0.5 nm is required.

Magnetic Heads

Magnetic heads have three functions: recording, reproducing, and erasing. Usually for stationary head applications such as tape drives, multiple heads are used to perform these functions. For moving head applications such as disk drives, a single head is employed because of the requirements of simple connections and small head mass for fast data access. Most of these heads are the inductive type, where the fundamental design is an inductive coil and a magnetic core. The general requirements for the core materials are high relative permeability μ , high saturation flux density B_s , low coercivity H_c , high electric resistivity ρ , and low magnetostriction coefficient λ . Some of the properties for the commonly used core materials are listed in Table 96.9.

The evolution of the magnetic head follows the selection of core materials, as shown in Fig. 96.16. Early heads used laminated molybdebum Permalloy (Ni-Fe-Mo, 79-17-4 wt%). These heads are inex-

FIGURE 96.16 Schematic illustrations of (a) a laminated head, (b) cross-section of a MIG head, (c) cross-section of a thin film head, and (d) an MR sensor with leads.

expensive to make, and have low H_c and high μ and B_s . The primary drawbacks are frequency limitation, gap dimension inaccuracy, and mechanical softness. Frequency limitation is caused by the difficulty of making the lamination layer thinner than $25 \mu\text{m}$. Eddy current loss, which is proportional to layer thickness and square root of frequency, reduces the effective permeability. As a result, laminated heads are seldom used for applications exceeding 10 MHz. Gap dimension inaccuracy is associated with the head fabrication process, and makes it unsuitable for high areal density applications. Lack of mechanical hardness reduces its usable life.

One way to reduce eddy current loss is to increase core material electric resistivity. Two types of ferrite material have high resistivity (four to nine orders higher than Permalloy) and reasonable magnetic properties: Ni-Zn and Mn-Zn. These materials are also very hard, elongating head life during head/medium contacts. The major deficiency of ferrite materials is their low B_s values. In order to record in high H_c media, high flux density B is needed in the head core. When the flux density in the core

material reaches its saturation B_s , it will not increase despite the increase of recording current or coil turns. This saturation starts from the corners of the gap due to its geometry. To remedy this deficiency, a layer of metallic alloy material with much higher B_s is deposited on the gap faces. This type of head is called the metal-in-gap (MIG) head. Sendust (Fe–Si–Al, 85–9.6–5.4 wt%) is one of the materials used for the deposition. MIG heads are capable of recording up to 100 MHz frequency and 180 kA/m medium coercivity.

Thin-film heads capitalize on semiconductor-like processing technology to reduce the customized fabrication steps for individual heads. The core, coil, gap, and insulator layers are all fabricated by electroplating, sputtering, or evaporation. Due to the nature of the semiconductor process, the fabrication is accurate for small dimensions. Small gap dimensions are suitable for high linear and track density, and small core dimensions allow the use of high B_s Permalloy material (Ni–Fe, 80–20 wt%) as core with low inductance for high data rate applications. Thin-film heads are used for high medium H_c , high areal density applications. The high cost of the semiconductor-like process is offset by high throughput: a 150 × 150 mm wafer can produce 16,000 nanoslider heads. One disadvantage is the limited-band recording capability because the small pole length limits low-frequency response and introduces undershoots. A second disadvantage the Barkhausen noise, which is caused by the relatively small number of magnetic domains in the core. At present, thin-film heads are used up to frequencies of 80 MHz and medium coercivity of 200 kA/m. MIG thin-film heads are also being used for high-coercivity applications.

An inductive head is often used for both recording and reproducing. The optimal performance cannot be achieved because recording and reproducing have contradictory requirements for head design. To solve this problem, the MR head has been developed. The MR head is for reproducing only, and an inductive head is used for recording. As schematically shown in Fig. 96.16, an MR head has a magnetoresistive element (MRE) and two electric leads. The MRE is a Permalloy stripe (Ni–Fe, 80–20 wt%), with thickness t , width w , and height h . An electric current, with density J , passes through the MRE through the leads. The electric resistivity of the MRE is a function of the angle θ between J and MRE magnetization M :

$$\rho_\theta = \rho \left(1 + \frac{\Delta\rho}{\rho} \cos^2 \theta \right) \quad (96.2)$$

where ρ_θ is the resistivity at θ , ρ is the resistivity at $\theta = 90^\circ$, and $\Delta\rho$ is the resistivity difference between $\theta = 0^\circ$ and $\theta = 90^\circ$. $\Delta\rho/\rho$ is the anisotropic MR ratio (AMR) of the MRE. Usually a transverse magnetic field is applied to the MRE so that $\theta = \theta_0$ when the head is not reading a magnetic signal. Assume that a magnetic signal from the medium rotates M from θ_0 to θ , then an electric voltage change v will be detected across the MRE as the output signal:

$$v = Jw\rho \frac{\Delta\rho}{\rho} (\sin^2 \theta_0 - \sin^2 \theta) \quad (96.3)$$

where θ_0 is the bias angle and is set to 45° for good linearity. In practice, a longitudinal bias is also used along the MRE width direction to stabilize the magnetic domain and reduce large Barkhausen noise. To compare the output between an MR head and an inductive head, we write the inductive head output using Faraday's equation:

$$v = -nV \frac{d\phi}{dx} \quad (96.4)$$

where n is the number of the coil turns, V is the medium velocity, ϕ is the magnetic flux, and x is the coordinate axis fixed on the medium surface. Equations 96.3 and 96.4 tell us that while inductive head

output is proportional to medium velocity and not suitable for low-velocity applications, the MR head can be used for either high- or low-velocity applications.

Recording Process

We can imagine the recording process in two steps. First, the magnetic flux flowing in the head core generates a fringe magnetic field around the gap. Then the magnetic field magnetizes the magnetic medium and leaves a magnetization transition in it. Partly due to the nonlinear nature of the hysteresis loop, the recording process is so complex that there has been no rigorous explanation. However, we can still obtain significant insights into the recording process by using simple models if we keep in mind the limitations.

If we set the origin of a coordinate system at the center of the gap with x axis on the head surface and y axis pointing away from the head, then the longitudinal magnetic field H_x and perpendicular magnetic field H_y of this head can be expressed by the Karlqvist approximation [2]:

$$H_x = \frac{ni}{\pi(g + lA_g/\mu A_c)} \tan^{-1} \left[\frac{yg}{x^2 + y^2 - (g^2/4)} \right] \quad (96.5)$$

$$H_y = \frac{ni}{2\pi(g + lA_g/\mu A_c)} \ln \left[\frac{(x - g/2)^2 + y^2}{(x + g/2)^2 + y^2} \right] \quad (96.6)$$

where n is the number of coil turns, i is the current in the coil, g is the gap length, l is the core length, A_g is the core cross-sectional area, μ is the relative permeability of core material, and A_c is the gap cross-sectional area. Both Eqs. 96.5 and 96.6 give accurate results for points 0.25 g away from gap corners. Since longitudinal recording mode dominates the magnetic recording industry, we will focus on the field H_x . Equation 96.5 shows that the contours of constant H_x field are circles nesting on the two gap corners, as shown in Fig. 96.17. The greater the diameter of the circle, the weaker the magnetic field. Assume a magnetic medium, moving from left to right with a distance d above the head, has a thickness δ and a magnetization M pointing to right. At some instant the recording current turns on and generates the magnetic field H_x above the gap as depicted in Fig. 96.17. On the circumference of $H_x = H_c$, half of medium material has its magnetization reversed and half remains the same, resulting in a zero total magnetization. Since H_x has a gradient, the medium closer to the gap (inside a smaller circle) gets its magnetization reversed more completely than the medium farther away from the gap (outside a bigger circle). Therefore, magnetic transition is gradual in the medium even if the change of recording current follows a step function. Assume the original magnetization is M_r and the completely reversed magnetization is $-M_r$, this gradual change of magnetization for an isolated transition can be modeled by [3]:

$$M = \frac{2}{\pi} M_r \tan^{-1} \frac{x}{a} \quad (96.7)$$

where x is the distance from the center of transition and a is a parameter characterizing the sharpness of the transition as shown in Fig. 96.18. Assuming a thin-film medium and using the Karlqvist approximation for the head field, a is found to be [4–6]:

$$a = \frac{(1 - S^*)(d + \delta/2)}{\pi Q} + \sqrt{\left[\frac{(1 - S^*)(d + \delta/2)}{\pi Q} \right]^2 + \frac{M_r \delta (d + \delta/2)}{\pi Q H_c}} \quad (96.8)$$

FIGURE 96.17 The constant horizontal fields of Karlqvist approximation are circles resting on the gap corners of a head, and the change of magnetization in the medium is gradual.

FIGURE 96.18 An isolated arctangent magnetization transition from negative M_r to positive M_r .

where S^* is the medium loop squareness and Q is the head-field gradient factor. For a reasonably well designed head, $Q \approx 0.8$. It is obvious that we want to make parameter a as small as possible so that we can record more transitions for a unit medium length. If the head gap length g and medium thickness δ are small compared with head/medium separation d , and the medium has a squareness of one, then the minimum possible value of a is [7]

$$a_m = \begin{cases} \frac{M_r \delta}{2\pi H_c} & \frac{M_r \delta}{4\pi H_c d} \geq 1 \\ \sqrt{\frac{M_r \delta d}{\pi H_c}} & \frac{M_r \delta}{4\pi H_c d} < 1 \end{cases} \quad (96.9)$$

In order to decrease the value of a and therefore increase areal density, we need to reduce medium remanence M_r , thickness δ , head/medium separation d , and to increase coercivity H_c .

Reproducing Process

In contrast to the recording process, the reproducing process is well understood. The flux density induced in the head core is on the order of a few millitesla, yielding a linear process for easier mathematical treatment. The head fringe field is the Karlqvist approximation (Eq. 96.5) and the foundation is the reciprocity theorem. For an isolated transition (Fig. 96.18) with a thin magnetic layer $\delta \ll d$, the induced electric voltage v for an inductive head is [7]:

$$v(x) = \frac{-2\mu_0 V w M_r \delta n}{\pi(g + lA_g / \mu A_c)} \left[\tan^{-1} \left(\frac{g/2 + x}{a + d} \right) + \tan^{-1} \left(\frac{g/2 - x}{a + d} \right) \right] \quad (96.10)$$

where μ_0 is the permeability of vacuum, μ is the relative permeability of the core, V is the medium velocity, w is the track width, n is the number of coil turns, g is the head gap length, d is the head/medium

FIGURE 96.19 The reproducing voltage of an inductive head over an isolated arctangent transition shows the effects of gap length g , parameter a , and head/medium separation d .

FIGURE 96.20 Schematic diagram of a shielded MR head with a shield to MRE distance g .

separation, and x is the distance between the center of the medium transition and the center of the head gap. The term $lA_g/\mu A_c$ is closely related to g for head efficiency. When a transition passes under the head, its voltage starts with a very low value, reaches a peak, then falls off again, as shown in Fig. 96.19, where the following typical values for a hard disk drive are used: $V = 20$ m/s, $w = 3.5$ μm , $M_r = 450$ kA/m, $\delta = 50$ nm, $n = 50$, $lA_g/\mu A_c = 0.1g$. The effects of g and $a + d$ are shown in Fig. 96.19. Since a greater peak voltage and a narrower spatial response are desired for the reproducing process, smaller g and $a + d$ values are helpful.

When an MR head is used for reproducing, the MRE is usually sandwiched between two magnetic shields to increase its spatial resolution to medium signals, as shown in Fig. 96.20. Since the MR head is flux sensitive, the incident flux ϕ_i on the bottom surface of the MRE should be derived as a function of the distance (x) between the center of MRE and the center of the transition [7, 8]:

$$\phi_i(x) = \frac{2\mu_0 w M_r \delta (a+d)}{\pi g} \left\{ f\left[\frac{x+(g+t)/2}{a+d}\right] - f\left[\frac{(x+t)/2}{a+d}\right] + f\left[\frac{x-(g-t)/2}{a+d}\right] - f\left[\frac{(x-t)/2}{a+d}\right] \right\} \quad (96.11)$$

where g is the distance between the MRE and the shield, t is the MRE thickness, and

$$f(\beta) = \beta \tan^{-1} \beta - \ln \sqrt{1 + \beta^2} \quad (96.12)$$

The angle between magnetization and current varies along the MRE height h . To find out the variation, we need to calculate the signal flux decay as a function of y by

$$\phi_s(y) = \phi_i \frac{\sinh\left[\frac{(h-y)}{l_c}\right]}{\sinh\left(\frac{h}{l_c}\right)} \quad (96.13)$$

where

$$l_c = \sqrt{\mu g t / 2} \quad (96.14)$$

Then the bias angle θ_0 and signal angle θ can be calculated by

$$\sin \theta_0(y) = \frac{\phi_b(y)}{M_s t} \quad (96.15)$$

and

$$\sin \theta(y) = \frac{\phi_s(y) + \phi_b(y)}{M_s t} \quad (96.16)$$

where ϕ_b is the biasing flux in the MRE and M_s is the saturation magnetization of the MRE. Application of Eqs. 96.15 and 96.16 to Eq. 96.3 and integration over height h lead to

$$v = J_w \rho \frac{\Delta \rho}{\rho} \frac{1}{h} \left[\int_0^h \sin^2 \theta_0(y) dy - \int_0^h \sin^2 \theta(y) dy \right] \quad (96.17)$$

For an MR head with a 45° bias at the center and small height $h \ll l_c$, the peak voltage is [6]

$$v_p \approx \frac{9 \Delta \rho J_w M_r \delta (g+t)}{8 \sqrt{2} t g M_s} \tan^{-1} \left[\frac{g}{2(a+d)} \right] \quad (96.18)$$

The general shape of the reproducing voltage from an MR head is similar to that in Fig. 96.19.

The study of an isolated transition reveals many intrinsic features of the reproducing process. However, transitions are usually recorded closely in a magnetic medium to achieve high linear density. In this case, the magnetization variation in the medium approaches a sinusoidal wave. That is,

$$M(x) = M_r \sin \frac{2\pi}{\lambda} x \quad (96.19)$$

where λ is the wavelength. The reproducing voltage in an inductive head becomes [9, 10]

FIGURE 96.21 Spacing, thickness, and gap losses of an inductive head vs. frequency for the reproducing of a sinusoidal medium magnetization.

$$v(x) = \frac{-\mu_0 V w M_r n g}{g + l A_g / \mu A_c} \left(e^{-2\pi d/\lambda} \right) \left(1 - e^{-2\pi \delta/\lambda} \right) \left(\frac{\sin \frac{\pi g}{\lambda}}{\pi g/\lambda} \right) \cos \frac{2\pi}{\lambda} x \quad (96.20)$$

This equation presents all the important features of the high-linear-density reproducing process. The term $\exp(-2\pi d/\lambda)$ is the spacing loss. It shows that the reproducing voltage falls exponentially with the ratio of head/medium spacing to wavelength. The second term $1 - \exp(-2\pi \delta/\lambda)$ is the thickness loss. The name of this term is misleading because its value increases with a greater medium thickness. However, the rate of increase diminishes for thicker medium. In fact, 80% of the maximum possible value is achieved by a medium thickness of 0.25λ . The last term $\sin(\pi g/\lambda)/(\pi g/\lambda)$ is the gap loss. This term is based on the Karqvist approximation. If a more accurate head fringe field is used, this term is modified to $\sin(\pi g/\lambda)/(\pi g/\lambda) \cdot (1.25g^2 - \lambda^2)/(g^2 - \lambda^2)$ [11]. It shows a gap null at $\lambda = 1.12g$, and limits the shortest wavelength producible. These three terms are plotted in Fig. 96.21. The most significant loss comes from the spacing loss term, which is 54.6 dB for $d = \lambda$. Therefore, one of the biggest efforts spent on magnetic recording is to reduce the head/medium spacing as much as possible without causing mechanical reliability issues. For an MR head, the reproducing voltage is [11]

$$v \propto \frac{4M_r i \Delta \rho w \lambda}{ht} \left(e^{-2\pi d/\lambda} \right) \left(1 - e^{-2\pi \delta/\lambda} \right) \left(\frac{\sin \frac{\pi g}{\lambda}}{\pi g/\lambda} \right) \sin \frac{\pi(g+t)}{\lambda} \cos \frac{2\pi}{\lambda} x \quad (96.21)$$

Digital vs. Analog Recording

Due to the nonlinearity of the hysteresis loop, magnetic recording is intrinsically suitable for digital recording, where only two states (1 and 0) are to be recognized. Many physical quantities, however, are received in analog form before they can be recorded, such as in consumer audio and instrumentation recording. In order to perform such recording, we need to either digitize the information or use the analog recording technique. In the case of digitization, we use an analog-to-digital converter to change a continuous signal into binary numbers. The process can be explained by using the example shown in Fig. 96.22. An electric signal V , normalized to the range between 0 and 1, is to be digitized into three bits. The signal is sampled at time $t = 1, 2, \dots, 6$. At each sampling point, the first bit is assigned a 1 if the value of the continuous signal is in the top half (>0.5), otherwise assigned a 0. The second bit is assigned a 1 if the value of the continuous signal is in the top half of each half ($0.25 \leq V < 0.5$, or >0.75),

FIGURE 96.22 Schematic illustration of the quantization of a continuous signal to three bits.

otherwise assigned a 0. The third bit is assigned similarly. The first bit is the most significant bit (MSB), and the last bit is the least significant bit (LSB). The converted binary numbers are listed below each sampling point in Fig. 96.22. This process of digitization is termed *quantization*. In general, the final quantization interval is

$$\Delta V = \frac{V}{2^N} \quad (96.22)$$

Where V is the total voltage range and N is the number of bits. Because we use a finite number of bits, statistically there is a difference between the continuous signal and the quantized signal at the sampling points. This is the quantization error. It leads to a signal-to-quantization-noise ratio (SNR) [12]:

$$\text{SNR} = \frac{12P_s}{\Delta V^2} \quad (96.23)$$

where P_s is the mean square average signal power. For a signal with uniform distribution over its full range, this yields

$$\text{SNR} = 2^{2N} \quad (96.24)$$

For a sinusoidal signal, it changes to

$$\text{SNR} = 1.5 \times 2^{2N} \quad (96.25)$$

The SNR can be improved by using more bits. This improvement, however, is limited by the SNR of the incoming continuous signal. The quantized signal is then pulse code modulated (PCM) for recording.

For analog recording, a linear relationship between the medium magnetization and the recording signal is required. This is achieved through the anhysteretic magnetization process. If we apply an alternating magnetic field and a unidirectional magnetic field to a previously demagnetized medium, and then reduce the amplitude of the alternating field to zero before we remove the unidirectional field, the remanent magnetization shows a pseudolinear relationship with the unidirectional field strength H_u up to some level. Figure 96.23 shows such an anhysteretic curve. The linearity deteriorates as H_u gets greater. In applications, the recording signal current is biased with an ac current of greater amplitude and higher frequency. Therefore, it is also termed ac-biased recording. Analog recording is easy to implement, at the price of a lowered SNR because remanent magnetization is limited to about 30% of the maximum possible M_r to achieve good linearity.

FIGURE 96.23 An anhysteretic remanent magnetization shows a pseudo-linear relationship with the applied unidirectional magnetic field to some H_u level.

FIGURE 96.24 Comparison of some early developed codes.

Recording Codes

PCM is a scheme of modifying input binary data to make them more suitable for a recording and reproducing channel. These schemes are intended to achieve some of the following goals: (1) reducing the dc component, (2) increasing linear density, (3) providing self-clocking, (4) limiting error propagation, and (5) achieving error-free detection. There are numerous code schemes, only three of the ones developed early are shown in Fig. 96.24. The earliest and most straightforward one is the return-to-zero (RZ) code. In this scheme a positive and negative pulse is used to represent each 1 and 0, respectively, of the data. The main drawback is that direct recording over old data is not possible due to the existence of zero recording current between two data. It also generates two transitions for each bit, therefore reducing the linear density. In addition, it only uses half of the available recording current range for a transition. The non-return-to-zero-invert (NRZI) method was developed to alleviate some of these problems. It changes the recording current from one direction to the other for each 1 of the data, while making no changes for all 0s. However, it has a strong dc component and may lose reproducing synchronization if there is a long string of 0s in the input data. In addition, reproducing circuits are usually not designed for dc signal processing. In frequency modulation (FM) code there is always a transition at the bit-cell boundary which acts as a clock. There is also an additional transition at the bit-cell center for each 1 and no transition for 0s. It reduces the dc component significantly. The primary deficiency is the reduction of linear density since there are two transitions for each 1 in the data.

The most popularly used codes for magnetic recording are the run-length-limited (RLL) codes. They have the general form of $m/n(d, k)$. In these schemes, data are encoded in groups. Each input group has m bits. After encoding, each group contains n bits. In some schemes multiple groups are coded together. d and k are the minimum and maximum 0s, respectively, between two consecutive 1s in the encoded sequence. While d is used to limit the highest transition density and intersymbol interference, k is employed to ensure adequate transition frequency for reproducing clock synchronization. The encoding is carried out by using a lookup table, such as Table 96.10 for a $1/2(2,7)$ code [13].

Head/Medium Interface Tribology

As expressed in Eq. 96.20, the most effective way to increase signal amplitude, therefore areal density, is to reduce head/medium spacing d . However, wear occurs when a moving surface is in close proximity to another surface. The amount of wear is described by Archard's equation:

$$V = k \frac{Ws}{H} \quad (96.26)$$

where V is the volume worn away, W is the normal load, s is the sliding distance, H is the hardness of the surface being worn away, and k is a wear coefficient. In order to increase medium hardness H , hard Al_2O_3 particles are dispersed in particulate media and a thin layer of hard carbon (≈ 10 nm) with either hydrogenation or natrogenation is coated on thin-film media of hard disks. A layer of liquid lubricant, typically perfluoropolyethers with various end groups and additives, is applied on top of the carbon film to reduce the wear coefficient k . Load is minimized to reduce wear while keeping adequate head/medium dynamic stability. For applications where the sliding distance s is modest over the lifetime of the products such as floppy disk drives and consumer tapes drives, the head physically contacts the medium during operations. In the case of hard disk application, heads are separated nominally from the media by a layer of air cushion. The head is carried on a slider, and the slider uses air-bearing surfaces (ABS) to create the air film based on hydrodynamic lubrication theory. Figure 96.25 shows two commonly used ABS. Tapers are used to help the slider take off and maintain flying stability. ABS generates higher-than-ambient pressure to lift the slider above the medium surface during operations. The tripod slider is for pseudo-contact applications while the subambient-pressure (SAP) slider is for flying (such as MR head) applications. Because the relative linear velocity between the slider and the medium changes when the head moves to different radii, a cavity region is used in the SAP slider to generate suction force to reduce flying height variation. The ABS is designed based on the modified Reynolds equation:

$$\frac{\partial}{\partial X} \left(PH^3 Q \frac{\partial P}{\partial X} \right) + \frac{\partial}{\partial Y} \left(PH^3 Q \frac{\partial P}{\partial Y} \right) = \Lambda_x \frac{\partial(PH)}{\partial X} + \Lambda_y \frac{\partial(PH)}{\partial Y} + \sigma \frac{\partial(PH)}{\partial T} \quad (96.27)$$

where X and Y are coordinates in the slider longitudinal and transverse directions normalized by the slider length and width, respectively, P is the hydrodynamic pressure normalized by the ambient pressure, H is the distance between the ABS and medium surface normalized by the minimum flying height, Q is the molecular slip factor, T is time normalized by the characteristic squeeze period, Λ_x and Λ_y are the bearing numbers in the x and y directions, respectively, and σ is the squeeze number. A full derivation and explanation of the Reynolds equation can be found in Reference 14. At present, high end hard disk drives feature a flying height on the order of 20 to 50 nm.

When power is turned off, the slider in the popularly used Winchester-type drives rests on the medium surface. Although the ABS and medium surface look flat and smooth, they really consist of microscopic peaks and valleys. If we model an ABS/medium contact by a flat surface and a sphere tip, the liquid lubricant on the medium surface causes a meniscus force F_m as depicted in Fig. 96.26 [15]:

(a)

(b)

FIGURE 96.25 The ABS of (a) a tri-pad slider for pseudo-contact recording and (b) a SAP slider for conventional flying recording.

FIGURE 96.26 Formation of meniscus between a sphere tip and a flat surface.

$$F_m = \frac{4\pi R\gamma \cos \theta}{1 + y/(h - y)} \quad (96.28)$$

where R is the radius of the sphere, γ is the surface tension of the lubricant, θ is the contact angle between the lubricant and the surfaces, y is the sphere to flat surface distance, and h is the lubricant thickness. Detailed analysis [16] shows that the static friction F at a head/medium interface is a function of several parameters:

$$F = f(h, R, A, \eta, \gamma, \theta, E', \phi, \sigma, s) \quad (96.29)$$

where A is the ABS area, η is the peak density, E' is the effective modulus of elasticity, ϕ is the peak height distribution, σ is the rms peak roughness, and s is the solid-to-solid shear strength. If friction F is too large, either the drive cannot be started or the head/medium interface is damaged. While friction can be reduced practically by reducing A , γ , and increasing θ , the most effective ways are to control h , σ , η , and ϕ . Too thin a lubricant layer will cause wear, and too thick will induce high friction. This limits h to the range of 1 to 3 nm. σ is controlled by surface texture. Historically, texture is created by mechanical techniques using either free or fixed abrasives. This leaves a surface with a random feature and is unsuitable for controlling η and ϕ . Recently, people started to use lasers [17]. This technique generates a surface texture with well-defined η and ϕ to improve wear and friction performance. Figure 96.27 shows AFM images of a mechanical and a laser texture.

Optical Recording

The major obstacle to achieving higher areal density in magnetic recording is the spacing loss term. It is a great engineering challenge to keep heads and media in close proximity while maintaining the head/medium interface reliable and durable. Care must also be taken in handling magnetic media since even minute contamination or scratches can destroy the recorded information. In addition, the servo technique of using magnetic patterns limits the track density to about one order lower than the linear density. Optical recording, on the other hand, promises to address all these concerns.

Optical recording can be categorized into three groups. In the first group, information is stored in the media during manufacturing. Users can reproduce the information, but cannot change or record new information. CD-ROM (compact disk–read only memory) belongs to this group. The second group is WORM (write once read many times). Instead of recording information during manufacturing, it leaves this step to the user. This is usually achieved by creating physical holes or blisters in the media during the recording process. Once it is recorded, however, the medium behaves like the first group: no further recording is possible. The third group is similar to magnetic recording. Recording can be performed infinitely on the media by changing phase or magnetization of the media. The most noticeable example in this group is the magneto-optic (MO) technique [18]. Only CD-ROM and the magneto-optic recording are described in the following.

CD-ROM

Figure 96.28 shows the CD-ROM reproducing principle. Data are pressed as physical pits and lands on one surface of a plastic substrate, usually polycarbonate. A layer of aluminum is deposited on this surface to yield it reflective. Lacquer is then coated to protect the aluminum layer. During the reproducing process, an optical lens is used to focus a laser beam on the reflective pit and land surface. The diameter of the lens is D , the distance between the lens and the substrate is h_3 , and the substrate thickness is h_2 . The diameter of the laser beam is d_2 when entering the substrate, and becomes d_1 when focused on the reflective surface. The width of the pits are designed smaller than d_1 . The reflected light consists of two portions: I_1 from the land and I_2 from the pit. According to the theory of interference, the intensity of the reflected light is

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos \frac{4\pi h_1}{\lambda} \quad (96.30)$$

where λ is the wavelength of the laser and $h_1 \approx \lambda/4$ is the pit height. This leads to

$$I = \begin{cases} I_1 + I_2 - 2\sqrt{I_1 I_2} & \text{if there is a pit } (h_1 = \lambda/4) \\ I_1 + I_2 + 2\sqrt{I_1 I_2} & \text{if there is no pit } (h_1 = 0) \end{cases} \quad (96.31)$$

(a)

(b)

FIGURE 96.28 Schematic representation of the CD-ROM reproducing principle.

This change of light intensity is detected and decoded to yield the recorded data. The reflected light is also used for focusing and track following.

The fundamental limit on optical recording density is the focused beam diameter d_1 . For a Gaussian (TEM_{00}) laser, this is the diffraction-limited diameter at which the light intensity is reduced to $1/e^2$ of the peak intensity:

$$d_1 \approx \frac{2\lambda}{\pi\theta} \quad (96.32)$$

where θ is the aperture angle. The following values are typical for a CD-ROM system: λ (gallium arsenide laser) = 780 nm, $\theta = 27^\circ$, $h_2 = 1.2$ mm, $D = 5$ mm, $h_3 = 4.2$ mm. This yields $d_1 \approx 1.0$ μm and $d_2 \approx 0.7$ mm, and sets the areal density limit of optical (including magneto-optic) recording to about 1 Mbit/ mm^2 . For most CD-ROM applications, the areal density is smaller than this limit, and a disk with 120 mm diameter holds about 600 Mbyte information. In order to increase areal density, we can either reduce light wavelength or increase numerical aperture. Much of the effort has been to adopt a new light source with short wavelength such as a blue laser. Increasing numerical aperture is more difficult because increasing lens diameter is cost prohibitive and reducing h_2 or h_3 is reliability limited. Note that although the beam size on the focus plane is on the order of 1 μm (d_1), it is two to three orders greater at the air/substrate interface (d_2). This means that optical recording can tolerate disk surface contamination and scratches much better than magnetic recording. However, the performance of optical recording does not match magnetic recording in general. The data transfer rate of CD-ROM drives is expressed as multiple (\times) of 150 kB/s. Even for a 12 \times CD-ROM drive, the data access time and data transfer rate are still on the order of 100 ms and 1.8 MB/s, respectively, while for a high-performance rigid disk drive these values are less than 10 ms and greater than 30 MB/s, respectively.

Magneto-optic Recording

The primary drawback of a CD-ROM to an end user is its inability to record. This deficiency is remedied by MO recording technology, as depicted in Fig. 96.29. A linearly polarized laser beam is focused on a layer of magnetic material, and a coil provides a dc magnetic field on the other side of the medium. This dc magnetic field is too weak to affect the medium magnetization at normal temperature. The recording process utilizes the thermomagnetic property of the medium, and the reproducing process is achieved by using the Kerr effect. During recording, the medium is initially magnetized vertically in one direction, and the dc magnetic field is in the opposite direction. The laser heats up the medium to its Curie temperature, at which the coercivity becomes zero. During the cooling process, the dc magnetic field aligns the medium magnetization of the heated region to the magnetic field direction. In the process of reproducing, the same laser is used with a smaller intensity. The medium is heated up to its compensation temperature, at which the coercivity becomes extremely high. Depending on the direction of the mag-

TABLE 96.11 Digital Magnetic and Optical Storage Devices

Description	Manufacturers	Approximate Price, \$
Thin-film head for hard disk drive	AMC, Read-Rite, SAE	6.00–9.00
MR head for hard disk drive	AMC, Read-Rite, SAE, Seagate	8.00–12.00
Thin-film hard disk	Akashic, HMT, Komag, MCC, Stormedia	7.00–10.00
Hard disk drive	IBM, Maxtor, Quantum, Samsung, Seagate, WD	0.02–0.20/Mbytes
Floppy drive	Panasonic, Sony	20.00–40.00
Floppy disk	3M, Fuji, Memorex, Sony	0.15–0.50
Removable rigid disk drive	Iomega, Syquest	100.00–400.00
Removable rigid disk	Iomega, Maxell, Sony	5.00–20.00/100 Mbytes
Tape drive	Exabyte, HP, Seagate	100.00–400.00
Backup tape	3M, Sony, Verbatim	4.00–25.00/Gbytes
8 × CD-ROM drive	Goldstar, Panasonic	100.00–200.00
Recordable optical drive	JVC, Philips	300.00–500.00
Recordable optical disk	3M, Maxell, Memorex	3.00–15.00/650 Mbytes

netization, the polarization of the reflected light is rotated either clockwise or counterclockwise (Kerr rotation). This rotation of polarization is detected and decoded to get the data. The main disadvantage of MO recording is that a separate erasing process is needed to magnetize the medium in one direction before recording. Recently some technologies have been developed to eliminate this separate erasing process at the cost of complexity.

The medium used in MO recording must have a reasonable low Curie temperature ($<300^{\circ}\text{C}$). The materials having this property are rare earth transition metal alloys, such as $\text{Tb}_{23}\text{Fe}_{77}$ and $\text{Tb}_{21}\text{Co}_{79}$. Unfortunately, the properties of these materials deteriorate in an oxygen and moisture environment. To protect them from air and humidity, they are sandwiched between an overlayer and a underlayer, such as SiO , AlN , SiN , and TiO_2 . Another issue with the rare earth transition metal alloys is their small Kerr rotation, about 0.3° . To increase this Kerr rotation, multiple layers are used. In the so-called quadrilayer structure (Fig. 96.29b), the overlayer is about a half-wavelength thick and the underlayer is about a quarter-wavelength thick [18]. The MO layer is very thin (≈ 3 nm). Light reflected from the reflector is out-of-phase with the light reflected from the surface of the MO layer, and is in-phase with the light reflected from the inside of the MO layer. As a result, the effective Kerr rotation is increased several times.

Compared with magnetic recording, optical recording has the intrinsic advantages of superior reliability and portability. However, its performance is inferior due to slower data access time and transfer rate. Another advantage of optical recording, higher areal density, has been disappearing or even reversing to magnetic recording. Both magnetic and optical recording will be continuously improved in the near future, probably toward different applications. Currently there are some emerging techniques that try to

combine the magnetic and optical recording techniques. Table 96.11 is a short list of representative magnetic and optical devices for digital recording.

F. Greg Shinskey

Process Control Consultant

97.1 Introduction

Process control plays an essential role in the safe manufacture of quality products at market demand, while protecting the environment. Flow rates, pressures and temperatures within pipes and vessels, inventories of liquids and solids, and product quality are all examples of measured variables that must be controlled to meet the above objectives. While there are several means available for controlling these variables, the PID family of controllers has historically carried the major share of this responsibility and, because of their simplicity and reliability, will continue to do so in the future.

The acronym PID stands for the three principal modes of the controller, each of which bears a mathematical relationship between the controlled variable c and the **manipulated variable** m driven by the controller output. The *Proportional* mode relates changes in m to changes in c through a proportional gain. The *Integral* mode moves the output at a rate related to the deviation of c from its desired value, known as the set point or reference r . Finally, the *Derivative* mode moves the output in response to the time derivative or rate of change of c . Interestingly, the mathematical relationships were actually determined *after* controllers had already been created to solve process-control problems. The integral mode was initially called *automatic reset*, and the derivative mode *hyper-reset* or *pre-act* [1].

97.2 Open and Closed Loops

[Figure 97.1](#) describes the process and controller in functional blocks connected in a loop. Inputs to the process are manipulated m and load q variables, usually rates of flow of material or energy into or out of the process. The **load** may be a single variable or an aggregate, either independent or manipulated or controlled by another controller. If independent, it is often unmeasured, with its value inferred by the level of controller output required to maintain the controlled variable at set point. **Noise** u is shown affecting the controlled variable directly, typically caused by local turbulence in flow, pressure, and liquid-level measurements, or by nonuniformity of streams whose composition is measured.

FIGURE 97.1 Process and controller connected in a loop.

Open-Loop Responses

In the absence of automatic control, the controlled variable is subject to variations in the load, and to manual adjustments to m intermittently introduced by operators. These cause variations in c following both the steady-state and dynamic functions appearing in Fig. 97.1:

$$c = K_p(mg_m - qg_q) + u \quad (97.1)$$

where K_p is the steady-state gain, g_m and g_q are the dynamic-gain vectors in the manipulated and load paths, respectively, and u is the noise level. The vectors have both magnitude and phase angle which are functions of the frequency or period of the signal passing through. In the **open loop**, variations in m are likely to be steps introduced by operators, but variations in q could take any form — steps, ramps, random variations, or cycles — depending on the source of the disturbance. Steps are easily introduced manually, and contain all the frequencies from zero to infinity; consequently, they are useful for evaluating loop response and testing the effectiveness of controllers. Noise is typified by random variations in a frequency range above the bandwidth of the control loop.

The dynamic elements typically consist of deadtime and lags. However, liquid level is the *integral* of the difference between inflow and outflow [2], in which case K_p in Fig. 97.1 is replaced by an integrator. Any difference between inflow and outflow will then be integrated, causing liquid level to continue rising or falling until the vessel limit is reached. This process has no self-regulation, and therefore cannot be left indefinitely in an open loop.

Closed-Loop Responses

In the **closed-loop**, c responds to load and set point as follows:

$$c = \frac{rg_q}{1 + 1/K_p g_m K_c g_c} - \frac{qg_q}{g_m K_c g_c + 1/K_p} + u \quad (97.2)$$

where K_c is the proportional gain of the controller, g_c is the **dynamic gain** of its integral and derivative modes, and g_r that of its set-point filter. For the typical **self-regulating** process in the open loop, c will take an exponential path following a step change in load as shown by the dashed curve in Fig. 97.2. If the loop is closed, the controller can move m to return c to r along the solid curve in Fig. 97.2, an optimum trajectory having a minimum integrated absolute error (IAE) between c and r . The leading

FIGURE 97.2 Closed-loop control minimizes error.

FIGURE 97.3 A lead-lag filter reduces overshoot.

edge of the curve depends on g_q and the trailing edge depends on g_m and the PID settings. If the PID settings are optimized for load response, they will usually cause c to overshoot a change in set point r , as shown by the dashed curve in Fig. 97.3. If the PID settings are then readjusted to reduce set-point overshoot, load response is extended. A preferred solution is to insert a lead-lag filter in the set-point path, which produced the solid curve in Fig. 97.3.

97.3 Mode Selection

The family of PID controllers includes P, I, PI, PD, and two PID controllers. Each has its own advantages and limitations, and therefore its preferred range of applications. Each is outlined along with an application.

Proportional Control

In a **proportional** controller, the deviation between c and r must change for the output to change:

$$m = b \pm K_c(r - c) \quad (97.3)$$

where b is an adjustable bias, also known as “manual reset,” and the sign of the deviation is selected to provide negative feedback. Some controllers have proportional gain adjustable as percent **proportional band** P , where $K_c = 100/P$. If m must move to a different steady-state value because of a change in load or set point, the deviation will also change. Therefore the proportional controller allows a steady-state **offset** between c and r whenever m does not equal b which can only be eliminated by manually resetting b . Proportional control is recommended for liquid level, where K_c can be set quite high without loss of stability and there is no economic penalty for offset.

Proportional control of liquid level is actually preferred when manipulating the flow leaving a tank as the feed to a critical downstream process. Setting K_c slightly above 1.0 will keep the level in the tank for all rates of inflow, while minimizing the rate of change of outflow. This application is called **averaging level control** [2].

Integral Control

The **integral** mode eliminates offset by driving the output at a rate proportional to the deviation:

$$\frac{dm}{dt} = C \pm \frac{r - c}{I} \quad (97.4)$$

where t is time, d is the differential operator, and I is the integral time setting; C is the constant of integration, i.e., the initial value of the controller output when placed on automatic. Some controllers have integral time adjusted as integral gain or “reset rate” $1/I$ in inverse time as “repeats per minute.” Integration produces a phase lag of 90° between input and output, which increases the response time and period of oscillation of the loop. The integral controller *cannot* be used for liquid level, because two integrators in series form an unstable closed loop [2]. Its use is limited to optimizing the set points of other closed loops which are already stable [2].

PI Control

The PI controller combines the proportional and integral modes:

$$m = C \pm K_c \left[r - c + \frac{1}{I} \int (r - c) dt \right] \quad (97.5)$$

The deviation and its integral are added vectorially, producing a phase lag falling between 0 and 90° . This combination provides stability with elimination of offset, making it the most common controller used in the fluid-processing industries. It is used almost universally, even in those applications where other controllers are better suited.

PD Control

The addition of **derivative action** to a proportional controller adds response for the rate of change of the controlled variable:

$$m = b \pm K_c \left(r - c - D \frac{dc}{dt} \right) \quad (97.6)$$

where D is the derivative time setting. Derivative action is preferably applied only to c as indicated and not to the set point, which would only increase set-point overshoot. A pure derivative function has a dynamic gain increasing indefinitely with frequency — to avoid instability within the controller, it is usually limited to about 10 by filtering. This provides an optimum combination of responsiveness and

FIGURE 97.4 Commercial interacting PID controller.

noise rejection. Still, the high-frequency gain amplifies noise in flow and liquid-level measurements enough to prevent the use of the derivative mode on those loops; temperature measurements are usually noise-free, allowing it to be used to advantage there. The phase lead provided by the derivative mode reduces the period of oscillation and settling time of a loop, and improves stability.

PD controllers are recommended for batch processes, where operation begins with c away from r , and ends ideally with $c = r$ and flows at zero. The PD controller must be biased for this final output state, with D adjusted to eliminate overshoot, which for a zero-load process is permanent [2].

PID Controllers

The phase lead of derivative action more than offsets the phase lag of integral in a properly adjusted PID controller, resulting in a net phase lead and typically half the IAE of a PI controller applied to the same process. There are two types of PID controllers in common use, which differ in the way the modes are combined [3]. Early controllers combined PD and PI action in series, multiplying those functions rather than adding them. These interacting PID controllers remain in common use, even implemented digitally. Noninteracting controllers combine the integral and derivative modes in parallel, producing a more mathematically pure PID expression:

$$m = C \pm K_c \left[r - c - \frac{1}{I} \int (r - c) dt - D \frac{dc}{dt} \right] \quad (97.7)$$

The interacting controller can be described in the same form, but the coefficients of the individual terms are different [3]. The effective integral time of the interacting controller is $I + D$, its effective derivative time is $1/(1/I + 1/D)$, and its proportional gain is augmented by $1 + D/I$. Thus, the principal result of mode interaction is to require different PID settings for the two controllers applied to the same process.

A block diagram of a commercial interacting PID controller appears in Fig. 97.4, with transfer functions described in Laplace transforms whose operator s is equivalent to the differential operator d/dt . Integration is achieved by positive feedback of the output through a first-order lag set at the integral time. The feedback signal f is taken downstream of the high and low limits, and may be replaced with a constant or other variable to stop integration, in which case, the controller behaves as PD with remote bias. This feature is extremely valuable in preventing reset **windup**, which occurs whenever a controller with integral action remains in automatic while the loop is open, and results in a large overshoot when the loop is then closed [3]. Most noninteracting controllers lack this feature.

Derivative action combines a differentiator Ds with a lag (filter) of time constant αD , where α represents the inverse of the high-frequency gain limit of typically 10. Figure 97.4 also shows a lead-lag set-point filter having a lag time constant of integral time I and lead time of $G_r I$, which produces a gain of G_r to a step in set point. This gain is adjustable from 0 to 1, with 1 eliminating the filter and zero imposing a first-order lag. The effect of this lag is equivalent to eliminating proportional action from r in Eqs. 97.5 and 97.7, an optional feature in some PID controllers. The gain adjustment offers more flexibility in

optimizing set-point response as in Fig. 97.3; G_r is set around 0.3 for lag-dominant processes such as that described in Figs. 97.2 and 97.3, and closer to 1 for deadtime-dominant processes [3].

97.4 Controller Hardware

Pneumatic proportional controllers were first used early in this century, with integral and then derivative functions added around 1930. Pneumatic controllers are still in use in hazardous areas, in remote gas fields where they are operated by gas, and for simple tasks such as regulating temperatures in buildings. Electronic analog controllers began to replace pneumatic controllers in the late 1950s, but their functions were implemented using digital microprocessors beginning around 1980. Digital control began in mainframes in the 1960s, but now is available in programmable logic controllers (PLC), personal computers (PC), and in distributed control systems (DCS).

Pneumatic Controllers

The simplest pneumatic controllers are proportional units used to control heating, ventilating, and air-conditioning (HVAC) in buildings. However, complete PID controllers with functionality similar to that shown in Fig. 97.4 are also available, used for such demanding tasks as temperature control of batch exothermic reactors and regulation of flows and pressures on offshore oil platforms. There are panel-mounted units available as well as weatherproof models used for field installation. Most have auto–manual transfer stations with bumpless transfer between the two modes of operation. Their principal limitations are a speed of response limited by transmission lines (lengths beyond 30 m are unsuitable for flow and pressure control) and lack of computing capability (required for nonlinear characterization and automatic tuning).

Electronic Controllers

The first electronic controllers mimicked their pneumatic counterparts while eliminating transmission lags. Eventually remote auto–manual transfer and remote tuning were added, and microprocessors brought these controllers calculation and logic functions, signal conditioning and characterization, and auto- and self-tuning features as well. Multiple controllers are even available in a single station for implementing cascade and feedforward systems. The bandwidth of electronic *analog* controllers extends to 10 Hz, and in some units even further. *Digital* controllers execute their calculations intermittently rather than continuously; most are limited to 10 Hz operation, which with digital filtering results in an effective deadtime of 0.1 s, reducing bandwidth to about 1.3 Hz.

Electronic controllers are used extensively in field locations and dedicated to control of individual units such as pumps, dryers, wastewater-treatment facilities — wherever only a few loops are required. Peer-to-peer communication is available in some controllers for incorporation into networks, and most can communicate with personal computers where data can be displayed on a graphic interface. Configuration (selection of scales, control modes, alarms, and other functions) can be done either via keys on the controller faceplate or through a PC.

Digital Controllers

While the stand-alone digital controller evolved from electronic analog models, centralized digital controllers originated with digital computers. Mainframe computers were first used for direct digital control (DDC) where valves were manipulated by the computer, and for supervisory control, where the computer positioned set points of analog controllers. Gradually minicomputers and microprocessors replaced the mainframe, with functions becoming *distributed* among field input–output modules, workstations, control modules, etc., in clusters and other configurations as DCS. PCs are used for some workstations, and even for direct control in some plants.

Where many loops are controlled by a single processor, the interval between samples is likely to be 0.5 s or even longer. Users tend to keep expanding the functions demanded of the processor, thereby extending the interval between samples. This reduces the bandwidth of DCS controllers to values too low for combustion and compressor controls. Some digital PID algorithms produce an *incremental* output Δm , requiring an integrator downstream to produce m . These are not available in proportional or PD action because they have no fixed bias b , only a constant of integration C which is subject to change whenever the controller is operated manually.

The PLC was originally a replacement for relay logic. Eventually PID loops were added, which generally operate much faster (e.g., 100 Hz) than other digital controllers. However, many have nonstandard algorithms and lack the functionality of other PID controllers, such as proportional and PD control, windup protection, derivative filtering, set-point filtering, nonlinear characterization, and autotuning.

97.5 Tuning Controllers

A controller is only as effective as its **tuning**: the adjustment of the PID settings relative to the process parameters to optimize load and set-point response as described in Figs. 97.2 and 97.3. Tuning is required when the controller is first commissioned on a loop, and may have to be repeated if process parameters change appreciably with time, load, set point, etc. Tuning requires the introduction of a disturbance in either the open or closed loop, and interpretation of the resulting response. *Autotuning* essentially automates manual procedures, whereas *self-tuning* can recognize and correct an unsatisfactory response without testing.

Manual Tuning

Ziegler and Nichols [1] developed the first effective tuning methods, and these are still used today. Their open-loop method steps the controller output to produce a response like the broken curve in Fig. 97.2. The apparent deadtime (delay) in the response and the steepest slope of the curve are then converted into appropriate settings for PI and PID controllers using simple formulas. The open-loop method is most accurate for lag-dominant processes, but the closed-loop method is more broadly applicable. It is based on inducing a uniform cycle by adjusting the gain of a controller with only its proportional mode effective (D is set to 0 and I at maximum). The period of the cycle and the controller gain are then used to calculate appropriate PID settings.

The open-loop method has been extended to other processes [3], but remains limited to the accuracy of step-test results. Fine tuning must be done with the loop closed: with the deviation zero, place the controller in manual, step the output, and immediately transfer to automatic — this simulates a closed-loop load change. The resulting response should appear like the solid curve in Fig. 97.2, having a first peak which is symmetrical, followed by a slight overshoot and well-damped cycle. If the overshoot is excessive, I and/or D time should be increased; in the case of undershoot, they should be decreased. (To simplify tuning of PID controllers, I and D can be moved together, keeping the I/D ratio at about 4 for noninteracting controllers and 3 for interacting controllers.) If damping is light, lower the proportional gain; if recovery is slow (producing an unsymmetrical first peak), raise the proportional gain. The set point should *not* be stepped for test purposes unless set-point response is important, as for flow controllers.

Autotuning

Some autotuning controllers use a step test in the open loop, implementing Ziegler–Nichols rules. A single pulse produces more accurate identification, and a doublet pulse is better still [3]. A closed-loop method replaces proportional cycling with relay cycling, where the output switches between high and low limits as c crosses r [3]. The period of the resulting cycle is used to set I and D , and its amplitude relative to the distance between output limits to set K_c . The principal limitation of the step and relay

autotuning methods is that only two response features are used to identify a complex process. The estimated PID settings may not fit the specific process particularly well, resulting in instability in some loops and sluggishness in others. The autotuning function cannot monitor the effectiveness of its work, as self-tuning does.

Self-Tuning

A self-tuning controller need not test the process, but simply observe its closed-loop response to set-point and load changes with its current PID settings. It then performs fine-tuning as described above to bring the overshoot or damping or symmetry of the response curve closer to optimum. This may require several iterations if the PID settings are far from optimum, but can eventually converge on optimum response, and readjust as necessary whenever process parameters change. Without a test disturbance, mischaracterization is possible, especially for a sinusoidal disturbance, where detuning may result when tightening would give better control.

Defining Terms

Averaging level control: Allowing the liquid level in a tank to vary in an effort to minimize changes in its outflow.

Closed-loop response: The response of a controlled variable to changes in set point or load with the controller in the automatic mode.

Derivative action: The change in controller output responding to a rate of change in the controlled variable.

Dynamic gain: The ratio of the change in output from a function to a change in its input which varies with time or with the frequency of the input.

Integral action: The rate of change of controller output responding to a deviation between the controlled variable and set point.

Load: A variable or aggregate of variables which affects the controlled variable.

Manipulated variable: A variable changed by the controller to move the controlled variable.

Noise: A disturbance having a frequency range too high for the controller to affect.

Offset: Steady-state deviation between the controlled variable and set point.

Open-loop response: The response of a controlled variable to process inputs in the absence of control action.

Proportional action: The change in controller output responding directly to a change in the controlled variable.

Proportional band: The percentage change in the controlled variable required to drive the controller output full scale.

Self-regulation: The property of a process through which a change in the controlled variable affects either the flow into or out of a process in such a way as to reduce further changes in the controlled variable.

Tuning: Adjusting the settings of a controller to affect its performance.

Windup: Saturation of the integral model of a controller which results in the controlled variable subsequently overshooting the set point.

98.1 Introduction

Optimal control maximizes (or minimizes) the value of a function chosen as the **performance index** or *cost function* of an operational control system. Optimal control theory, on the other hand, is the mathematics of finding parameters that cause the performance index to take an extreme value subject to system constraints.

Optimal control is applied in many disciplines, such as satellites and aerospace, aircraft and spacecraft, chemical engineering, communications engineering, robots and robotics, power systems, electric drives, computers and computer systems, etc. In many applications simple interconnections of control devices and controllers do not provide the most economic operation for which optimal control offers the solution. Hence, **optimization** is useful in obtaining the best results from a known process. If the process is operating under a steady-state condition, optimization considers the process stationary, and it is concerned only with the operating points. When the process is stationary, the resulting optimum operating point can easily be maintained by setting the predetermined set points and precalculated control parameters. Nevertheless, if the process changes from time to time, new optimum set points for the system need to be determined for each change.

The performance of a system is optimized for many reasons, such as improving the quality, increasing production, decreasing waste, obtaining greater efficiency, maximizing the safety, saving time and energy, and so on. In many optimization problems, boundary conditions are imposed by the system for safety in operations, availability of minimum and maximum power, limitations in storage capacity, capability of the operating machinery, temperature, speed, force, acceleration, indeed, for any other hard physical reason.

For the solution of optimal control problems many different methods may be used depending on the nature of the problem. For example, if the performance index and constraints can be formulated as linear algebraic functions of the controlled variables, then selection of the linear programming may be the best way to go. Simplex methods may provide a good way of solving the linear programming problem. If the equations describing the system are nonlinear, then the solution may involve nonlinear techniques or linearization of the problem in some subregions. If the problem involves determination of the largest value of a function with two or more variables, then the steepest ascent (or descent) method, sometimes termed *hill climbing* or the *gradient method* may be used.

Hill-climbing methods are still popularly used and easy to understand. They are briefly discussed here, first, to lay a good background in the sound understanding of optimal control theory.

FIGURE 98.1 Hill-climbing technique illustrated in the region of absolute maxima. The sign of the first derivative of the function changes as the derivative passes through the maximum point. This figure also demonstrates the local maxima and minima that should be taken care optimal control design.

FIGURE 98.2 Examples of hill climbing method, (a) gradient, (b) random walk. All these methods use an initial estimated point where the first derivative is guessed to be zero. This point is then used, in the direction of steepest ascent or descent as the case may be, for the next point until the absolute maximum or minimum is found.

An illustration of the hill-climbing technique in the region of absolute minima is given in Fig. 98.1. This figure also illustrates a common pitfall in control theory, the local maxima and minima. As can be seen in this figure, the sign of the first derivative of the function changes as the derivative passes through the maximum point. This method commonly uses an initial estimated point where the first derivative is considered (guessed) to be zero. This point is then used, in the direction of steepest ascent or descent as the case may be, for the next point until the absolute maxima or minima is found without being trapped in local extreme points. There are many different methods to find maxima or minima by hill-climbing methods and Fig. 98.2 illustrates some examples of implementation.

Apart from hill-climbing techniques, there are many new methods available for the solution of modern optimal control problems involving hyperspaces (many variables) complex in nature and having stringent constraints. If a good mathematical model of the system is available, optimization methods may be used for finding the optimum conditions on the model, instead of seeking optimization on the actual process. This indicates that availability of the model determines the type of optimization method to be employed.

98.2 Cost Function

In designing optimal control systems, rules may be set for determining the control decisions, subject to certain constraints, such that some measure of deviations from an ideal case is minimized. That measure is usually provided by a selected performance index or cost function. Performance index is a function whose value indicates how well the actual performance of the system matches the desired performance. Appropriate selection of the performance index is important since it determines the nature and complexity of the problem. That is, if the optimal control is linear or nonlinear, stationary or time-varying will be dependent on the selected performance index. The choice of the performance index depends on system specifications, physical realizability, and the restrictions on the controls to be used. In general, the choice of an appropriate performance index involves a compromise between a meaningful evaluation of system performance and availability of feasible mathematical descriptions.

The performance index is selected by the engineer to make the system behave in a desired fashion. By definition, a system whose design minimizes the selected performance index is optimal. It is important to point out that a system optimal for one performance index may not be optimal under another performance index. In practical systems, due to possible complexities and cost of implementation, it may be better to employ approximate optimal control laws which are not rigidly tied to a single performance index.

Before starting optimization of any system, it is necessary to formulate the system by having information on system parameters and describing equations, constraints, class of allowable control vectors, and the selected performance indexes. Then the solution can proceed by determining the optimal control vector $\mathbf{u}(k)$ within the class of allowable vectors. The control vector $\mathbf{u}(k)$ will be dependent on such factors as the nature of the performance index, constraints, initial values of state, initial outputs, and the desired state as well as the desired outputs. If analytical solutions are impossible or too complicated, then alternative computational solutions may be employed.

In simple cases, errors between the desired and actual responses can be chosen as the performance index to be minimized. As an example, different descriptions of error between actual and desired responses are depicted in Fig. 98.3. The aim is to keep the errors as small as possible. The time integral of error gives the severity of the error. However, since the positive and negative errors mathematically cancel each other, absolute values must be used:

$$\text{Integral Absolute Error} = \text{IAE} = \int_0^T |e(\tau)| d\tau \quad (98.1)$$

FIGURE 98.3 Description of errors between actual and desired responses. In simple optimal control applications, errors between the desired and actual responses can be chosen as the performance indexes. The aim is to keep the errors as small as possible.

In many cases it is better to use integral squared errors which take into account large errors rather than regular ones:

$$\text{Integral Squared Error} = \text{ISE} = \int_0^T e^2(\tau) d\tau \quad (98.2)$$

Time-dependent functions can be implemented to capture errors occurring late in time rather than normal transients:

$$\text{Integral Time Absolute Error} = \text{ITAE} = \int_0^T |e(\tau)| \tau d\tau \quad (98.3)$$

and

$$\text{Integral Time Squared Error} = \text{ITSE} = \int_0^T e^2(\tau) \tau d\tau \quad (98.4)$$

Mean square error, MSE, is also commonly used since slight modification leads to inclusion of statistical techniques and analysis of random noise:

$$\text{Mean Square Error} = \text{MSE} = \lim_{T \rightarrow \infty} \int_0^T 1/T e^2 \tau d\tau \quad (98.5)$$

Modern optimal control theory is developed within **state-space** framework and performance indexes are more complex and comprehensive as explained below.

Suppose that the control command of a system is expressed in vectorial form as \mathbf{u} and the state of the system is described by \mathbf{x} (*Oxford English Dictionary* defines *state* as condition with respect to circumstances, attributes, structure, form phase or the like). Further, suppose that the rate of change of state $\dot{\mathbf{X}}$ is a function of state \mathbf{x} , control command \mathbf{u} , and time t

$$\dot{\mathbf{X}} = f(\mathbf{x}, \mathbf{u}, t) \quad \mathbf{x}(0) = \mathbf{x}_0 \text{ known} \quad (98.6)$$

Then a control law $\mathbf{u}(\mathbf{x}, t)$ or a control history $\mathbf{u}(t)$ is determined such that a performance index or a scalar functional

$$J(\mathbf{u}) = \int_0^T g(\mathbf{x}(\tau), \mathbf{u}, \tau) d\tau \quad (98.7)$$

takes a minimum value out of all other possibilities and still holds Eq. 98.6. A boundary relationship $\mathbf{x}(T) = \mathbf{x}_f$ must also be met as a constraint.

A most common form of $J(\mathbf{u})$ is the minimum time control in which

$$J(\mathbf{u}) = \int_0^T d\tau = T \quad (98.8)$$

Many different criteria are also used, such as minimum fuel, minimum energy, and other quadratic forms

$$J(u) = \int_0^T |u(\tau)| d\tau \quad (98.9)$$

$$J(u) = \int_0^T u^2(\tau) d\tau \quad (98.10)$$

$$J(u) = \int_0^T (qx^2(\tau) + ru^2(\tau)) d\tau \quad (98.11)$$

A general term for continuous time performance index leading to optimal control is expressed as:

$$J(u(t)) = \int_0^T g(x(\tau), u(\tau)) d\tau \quad (98.12)$$

This performance index is minimized for the constraints

$$\dot{\mathbf{X}}(t) = f(\mathbf{x}(t), \mathbf{u}(t), t) \quad \text{for } t \in (t_0, t_f)$$

and $\mathbf{x}(t)$ is an admissible state, $\mathbf{x}(t) \in \mathbf{X}(t)$, $\forall t \in (t_0, t_f)$ are satisfied.

Slight variations of Eqs. 98.9 to 98.12 lead to mathematics of the discrete time or digital versions of optimal control.

98.3 Calculus of Variations

Calculus variations are suitable for solving linear or nonlinear optimization problems with linear or nonlinear boundary conditions. Basically, it is a collection of many different analytical methods and they are discussed differently from book to book. Here, a typical approach which leads to more general and widely used modern theories is introduced.

Consider a dynamic system operating in a time interval $t_0 < t < t_f$

$$\dot{\mathbf{X}} = f[\mathbf{x}, \mathbf{u}, t] \quad (98.13)$$

where the initial state \mathbf{x}_0 is given.

The system has n state and m control variables. The scalar function to be optimized is

$$J = k[\mathbf{x}_f, t_f] + \int \mathbf{L}[\mathbf{x}, \mathbf{u}, t] dt \quad (98.14)$$

Define a scalar, such as Hamiltonian

$$H = H[\mathbf{x}, \mathbf{u}, \lambda, t] = L[\mathbf{x}, \mathbf{u}, t] + \sum \lambda_i f_i \quad (98.15)$$

λ is known as the **Lagrange multiplier**. Also, define a modified objective function:

$$J = k[\mathbf{x}_1, t_1] + \int H dt \quad (98.16)$$

the resulting solution is optimal when

$$\lambda = -\delta H \setminus \delta x = -\delta L \setminus \delta x - \sum \lambda_i \delta f_i \setminus \delta x \quad (98.17)$$

$$\lambda_f = \delta k \setminus \delta x \quad (98.18)$$

$$\delta H \setminus \delta u = \delta L \setminus \delta u + \sum \lambda_i \delta f_i \setminus \delta u = 0 \quad t_0 < t < t_f \quad (98.19)$$

The solutions of Eqs. 98.17 and 98.19 in the above form are difficult to obtain. Nevertheless, based on the above ideas more general theories can be developed such as Pontryagin's maximum principle.

An advancement over the calculus of variations is the Pontryagin's maximum principle, which offers easier solutions and expands the range of applicability to bounded control problems. In its simplest form, this principle may be explained as follows.

Given the system

$$\dot{\mathbf{x}}_i = f_i[\mathbf{x}, \mathbf{u}, t] \quad (98.20)$$

and an objective function,

$$J = \sum k_i x_i(t_f) \quad (98.21)$$

The maximum principle states that if the control vector \mathbf{u} is optimum, then the Hamiltonian

$$H = \sum p_i f_i \quad (98.21a)$$

is also maximized with respect to the control vector \mathbf{u} over the set intervals.

$$p_i = \sum p_j \delta f_j \setminus \delta x_j \quad (98.21b)$$

$$p_i(t_f) = k_i \quad (98.21c)$$

where p is the adjoint or co-state vector, and

$$\delta H \setminus \delta p_i = f_i[\mathbf{x}, \mathbf{u}, t] = x_i \quad (98.21d)$$

$$\delta H \setminus \delta p_i = \sum p_j \delta f_j \setminus \delta x_j = -p_i \quad (98.21e)$$

The initial values of state vector x provide the remaining constants necessary to solve these equations for determining an optimum control vector. This method is also applicable to systems with complex performance indexes.

Another expansion of calculus of variations is the Kalman filter. Kalman is essentially a general filtering technique that can be applied to solutions of problems such as optimal estimation, prediction, noise

filtering, stochastic optimal control, and design of optimal controllers. The method has the advantage of providing estimates of variables in the presence of noise for both stationary and nonstationary processes. Most other types of noise can be treated by this method if they can be translated to Gaussian form. The technique can also be employed in systems with forcing disturbances and containing more than one noise source. Generally, systems that have either quadratic objective functions or uncorrelated Gaussian noise as the input are suitable for this technique.

A means of applying the Kalman filter to a nonlinear system is to find a good estimate of the system and then use it to define a new set of linear **state equations** which approximates the system to linear form at a normal operating point. Then the filter can be applied to the new set of linear equations. Applications of Kalman filter is endless in instrumentation and measurement systems, and other optimal control problems. It can easily be programmed on digital computers.

98.4 Riccati Equation

Some of the models in optimization problems resemble the models of traditional control theory and practice. In these models, the process and control variables are vector-valued and constrained by linear plant equations. The cost functions are in the form of quadratic costs. These type of systems are termed as **linear quadratic equations** systems or LQ systems. The theory and models of LQ systems are well developed in both deterministic and stochastic cases.

Express a quadratic optimal control problem as

$$\mathbf{x}(k+1) = \mathbf{A}\mathbf{x}(k) + \mathbf{B}\mathbf{u}(k) \quad \mathbf{x}(0) = \mathbf{x}_0 \quad (98.22)$$

where $\mathbf{x}(k)$ = state vector (n -vector)

$\mathbf{u}(k)$ = control vector (r -vector)

\mathbf{A} = $n \times n$ nonsingular vector

\mathbf{B} = $n \times r$ matrix

The aim is to find the optimal control sequence $\mathbf{u}(0), \mathbf{u}(1), \dots, \mathbf{u}(N-1)$ that minimizes a quadratic performance index

$$J = \frac{1}{2} \mathbf{x}^*(N) \mathbf{S} \mathbf{x}(N) + \frac{1}{2} \sum_{k=0}^{N-1} \mathbf{x}^*(k) \mathbf{Q} \mathbf{x}(k) + \mathbf{u}^*(k) \mathbf{R} \mathbf{u}(k) \quad (98.23)$$

where \mathbf{x}^* and \mathbf{u}^* are transposes of \mathbf{x} and \mathbf{u} matrixes, respectively,

\mathbf{Q} = $n \times n$ positive definite or positive semidefinite symmetric matrix

\mathbf{R} = $r \times r$ positive definite or positive semidefinite symmetric matrix

\mathbf{S} = $n \times n$ positive definite or positive semidefinite symmetric matrix

Matrixes \mathbf{Q} , \mathbf{S} , and \mathbf{R} are selected to weight the relative importance of the performance measures caused by the state vectors $\mathbf{x}(k)$, the final state $\mathbf{x}(N)$, and control vectors $\mathbf{u}(k)$, respectively, for $k = 0, 1, 2, \dots, N-1$.

The initial state of the system is arbitrary but the final state $\mathbf{x}(N)$ may be fixed. If the final state is fixed, then the term $\frac{1}{2} \mathbf{x}^*(N) \mathbf{S} \mathbf{x}(N)$ may be removed from the performance index and the terminal state \mathbf{x}_f may be imposed. If the final state is not fixed, then the term $\frac{1}{2} \mathbf{x}^*(N) \mathbf{S} \mathbf{x}(N)$ represents the weight of the performance measure to the final state.

There are many different ways of solving the above equations, one of which makes use of the concept of Lagrange multipliers. With the aid of Lagrange multipliers, the performance index may be modified as

$$\begin{aligned} \mathbf{L} = & \frac{1}{2} \mathbf{x}^*(N) \mathbf{S} \mathbf{x}(N) + \frac{1}{2} \sum_{k=0}^{N-1} \mathbf{x}^*(k) \mathbf{Q} \mathbf{x}(k) + \mathbf{u}^*(k) \mathbf{R} \mathbf{u}(k) + \lambda^*(k+1) \\ & \left[\mathbf{A} \mathbf{x}(k) + \mathbf{B} \mathbf{u}(k) - \mathbf{x}(k+1) \right] + \left[\mathbf{A} \mathbf{x}(k) + \mathbf{B} \mathbf{u}(k) - \mathbf{x}(k+1) \right]^* \lambda^*(k+1) \end{aligned} \quad (98.24)$$

It is known that minimization of the function \mathbf{L} is equivalent to minimization of performance index \mathbf{J} under the same constraints.

In order to minimize, \mathbf{L} needs to be differentiated with respect to vectors $\mathbf{x}(k)$, $\mathbf{u}(k)$, and $\lambda(k)$ and the results set to zero. The partial differentiation of the function \mathbf{L} with respect to variables gives the following

$$\delta\mathbf{L}/\delta\mathbf{x}(k) = 0 \quad \mathbf{Q}\mathbf{x}(k) + \mathbf{A} * \lambda(k+1) - \lambda(k) = 0 \quad (98.25)$$

$$\delta\mathbf{L}/\delta\mathbf{x}(N) = 0 \quad \mathbf{S}\mathbf{x}(N) - \lambda(N) = 0 \quad (98.26)$$

$$\delta\mathbf{L}/\delta\mathbf{u}(k) = 0 \quad \mathbf{R}\mathbf{u}(k) - \mathbf{B} * \lambda(k+1) = 0 \quad (98.27)$$

and

$$\delta\mathbf{L}/\delta\lambda(k) = 0 \quad \mathbf{A}\mathbf{x}(k-1) + \mathbf{B}\mathbf{u}(k-1) - \mathbf{x}(k) = 0 \quad (98.28)$$

A close inspection of the above formulae indicates that the last equation is simply the state equation for $k = 1, 2, 3, \dots, N$. And also, the value of Lagrange multiplier can be determined by Eq. 98.26. The Lagrange multiplier is often termed the **covector** or the adjoint vector.

Rewriting Eqs. 98.25 and 98.27

$$\lambda(k) = \mathbf{Q}\mathbf{x}(k) + \mathbf{A} * \lambda(k+1) \quad (98.29)$$

$$\mathbf{u}(k) = -\mathbf{R}^{-1}\mathbf{B} * \lambda(k+1) \quad (98.30)$$

the state Eq. 98.22 can be expressed as

$$\mathbf{u}(k+1) = \mathbf{A}\mathbf{x}(k) - \mathbf{B}\mathbf{R}^{-1}\mathbf{B} * \lambda(k+1) \quad (98.31)$$

In order to obtain the solution to the minimization problem we need to solve Eqs. 98.29 and 98.31 simultaneously as a two-point boundary-value problem. The solutions of these two equations in this form, and the optimal values of the state vector and the Lagrange multiplier vector will lead to the values of control vector $\mathbf{u}(k)$ which will optimize the open-loop control system. However, for closed-loop control systems the Riccati transformations must be applied.

$$\mathbf{u}(k) = -\mathbf{K}(k) \mathbf{x}(k) \quad (98.32)$$

where $\mathbf{K}(k)$ is the r^*n feedback matrix. Now the Riccati equation in feedback form can be obtained by assuming that $\lambda(k)$ is written as

$$\lambda(k) = \mathbf{P}(k) \mathbf{x}(k) \quad (98.33)$$

where $\mathbf{P}(k)$ is an $n \times n$ matrix. Substituting Eq. 98.33 into 98.29 and 98.31 gives

$$\mathbf{P}(k) \mathbf{x}(k) = \mathbf{Q}\mathbf{x}(k) + \mathbf{A} * \mathbf{P}(k+1) \mathbf{x}(k+1) \quad (98.34)$$

$$\mathbf{x}(k+1) = \mathbf{A}\mathbf{x}(k) - \mathbf{B}\mathbf{R}^{-1}\mathbf{B} * \mathbf{P}(k+1) \mathbf{x}(k+1) \quad (98.35)$$

In writing Eqs. 98.34 and 98.35 the Lagrange multiplier $\lambda(k)$ has been eliminated. This is an important step in solving two-point boundary-value problems. By further manipulations it is possible to show that

$$\mathbf{P}(k) = \mathbf{Q} + \mathbf{A} * \mathbf{P}(k+1) \mathbf{A} - \mathbf{A} * \mathbf{P}(k+1) \mathbf{B} [\mathbf{R} + \mathbf{B} * \mathbf{P}(k+1) \mathbf{B}]^{-1} \mathbf{B} * \mathbf{P}(k+1) \mathbf{A} \quad (98.36)$$

Equation 98.36 is known as the **Riccati equation**.

From Eqs. 98.26 and 98.33 writing $\hat{\lambda}(N) = \mathbf{S} \mathbf{x}(N) = \mathbf{P}(N) \mathbf{x}(N)$ gives

$$\mathbf{P}(N) = \mathbf{S} \quad (98.37)$$

Hence, the Riccati equation can be solved backward from $k = N$ to $k = 0$, starting from the known values of $\mathbf{P}(N)$.

The optimal control vector $\mathbf{u}(k)$ can now be calculated from Eqs. 98.29, 98.30, and 98.35

$$\mathbf{u}(k) = -\mathbf{R}^{-1} \mathbf{B} * \lambda(k+1) = -\mathbf{R}^{-1} \mathbf{B} * (\mathbf{A} *)^{-1} [\mathbf{P}(k) - \mathbf{Q}] \mathbf{x}(k) = -\mathbf{K}(k) \mathbf{x}(k) \quad (98.38)$$

where

$$\mathbf{K}(k) = -\mathbf{R}^{-1} \mathbf{B} * (\mathbf{A} *)^{-1} [\mathbf{P}(k) - \mathbf{Q}] \quad (98.39)$$

It is worthy noting that the optimal control vector may be obtained in slightly different forms by the different manipulations of above equations, such as

$$\mathbf{u}(k) = -\mathbf{R}^{-1} \mathbf{B} * [\mathbf{P}^{-1}(k+1) + \mathbf{B} \mathbf{R}^{-1} \mathbf{B} *]^{-1} \mathbf{A} \mathbf{x}(k) \quad (98.40)$$

Equations 98.38 and 98.39 indicate that optimal control law requires feedback of the state vector with time-varying gain $\mathbf{K}(k)$. Figure 98.4 illustrates the optimal control scheme of a system based on the quadratic performance index. In practical applications, the time-varying $\mathbf{K}(k)$ is calculated before the process begins. Once the state matrix \mathbf{A} , control matrix \mathbf{B} , and weighting matrices \mathbf{Q} , \mathbf{R} , and \mathbf{S} are known, the gain $\mathbf{K}(k)$ may be precomputed off-line to be used later. The control vector $\mathbf{u}(k)$ at each stage can be determined immediately by premultiplying the state vector $\mathbf{x}(k)$ by the known gain $\mathbf{K}(k)$.

From the above equations, the minimum value of the performance index can also be calculated. By using the initial values

$$J_{\min} = \frac{1}{2} \mathbf{x}^*(0) \mathbf{P}(0) \mathbf{x}(0) \quad (98.41)$$

FIGURE 98.4 Optimal control scheme based on quadratic performance index. The control law requires feedback of the state vector with time varying gain $\mathbf{K}(k)$. The gain $\mathbf{K}(k)$ is calculated before the process begins to be used later.

The *steady-state* solutions of Riccati equations are necessary when dealing with time-invariant (steady-state) optimal controls. There are many ways of obtaining steady-state Riccati solutions; an example is given below.

$$\mathbf{P} = \mathbf{Q} + \mathbf{A} * \mathbf{P} \mathbf{A} - \mathbf{A} * \mathbf{P} \mathbf{B} (\mathbf{R} + \mathbf{B} * \mathbf{P} \mathbf{B})^{-1} \mathbf{B} * \mathbf{P} \mathbf{A} \quad (98.42)$$

The steady-state value of \mathbf{K} may be found as

$$\mathbf{K} = (\mathbf{R} + \mathbf{B} * \mathbf{P} \mathbf{B})^{-1} \mathbf{B} * \mathbf{P} \mathbf{A} \quad (98.43)$$

and the optimal control law for the steady-state operation may be expressed as

$$\mathbf{u}(k) = -(\mathbf{R} + \mathbf{B} * \mathbf{P} \mathbf{B})^{-1} \mathbf{B} * \mathbf{P} \mathbf{A} \mathbf{x}(k) \quad (98.44)$$

This section is presented for discrete-time optimal control systems rather than continuous systems, due to recent widespread use of computers and microprocessors as online and off-line control tools. Since the principles are the same, solutions can easily be extended for continuous time systems with minor modifications.

98.5 State Feedback Matrix

The state feedback method is another design technique that allows the designer to locate the poles of the system wherever they are needed. This type of approach is termed the **pole-placement method**, where the term *pole* refers to the poles of the closed-loop transfer function as in Fig. 98.5. In this method, it is assumed that **state variables** are measurable and are available for feedback. If the state is available, the system is said to be deterministic; the system is noise free and its parameters are fully known. If the state is not available, then methods such as measurement feedback laws or state estimators may be selected.

In many applications, instead of state variables, it is more convenient to use state estimates coming from an observer or **Kalman filter**. In this case there are three well-known methods available: the certainty equivalent, the separation, and the dual control. Certainty equivalence has considerable advantages over others since it leads to deterministic optimal control laws such as Pontryagin's principle or the conditional mean of the state such as Kalman filter. It leads to a practical controller, which may be built as a filter and optimal law in cascade.

State feedback controllers are relatively easy to implement. For example, in the pole-placement method the relationship of the feedback control \mathbf{u} to state \mathbf{x} for **linear systems** is

$$\mathbf{u}(k) = -\mathbf{K} \mathbf{x}(k) \quad (98.45)$$

In linear quadratic cases, the gain \mathbf{K} is time varying:

$$\mathbf{u}(k) = -\mathbf{K}(k) \mathbf{x}(k) \quad (98.46)$$

where \mathbf{K} is $(n \times r)$ feedback matrix. This is correct at least in two cases.

1. In linear systems with no noise, pole-placement controllers, and an observer as the state estimator, the control algorithms for

$$\begin{aligned} \mathbf{x}(k+1) &= \mathbf{A} \mathbf{x}(k) + \mathbf{B} \mathbf{u}(k) \\ \mathbf{y}(k) &= \mathbf{C} \mathbf{x}(k) \end{aligned}$$

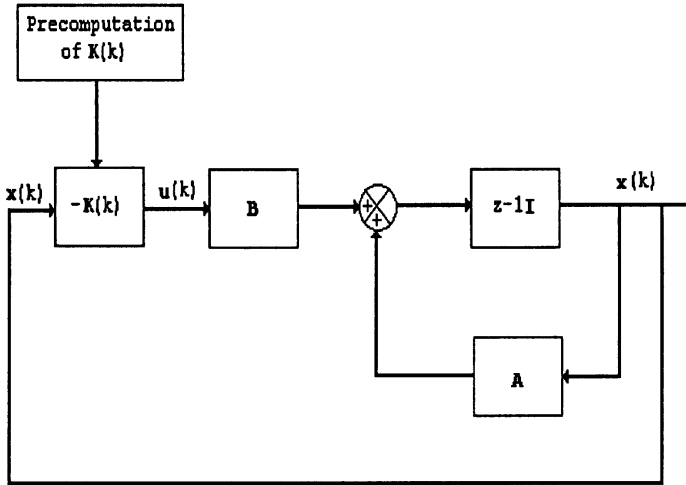

FIGURE 98.5 Pole-placement design of closed loop transfer function. This method assumes that state variables are measurable and are available for feedback.

is

$$\hat{\mathbf{x}}(k+1) = (\mathbf{A} - \mathbf{GC})\hat{\mathbf{x}}(k) + \mathbf{G}\mathbf{y}(k) + \mathbf{B}\mathbf{u}(k) \quad (98.47)$$

$$\mathbf{u}(k) = \mathbf{K}\hat{\mathbf{x}}(k) \quad (98.48)$$

where the eigenvalues of $(\mathbf{A} - \mathbf{GC})$ and $(\mathbf{A} + \mathbf{BK})$ are chosen to meet design specifications.

2. In linear systems, influenced by Gaussian white noise, in which the control is optimal according to a quadratic criterion, the system

$$\mathbf{x}(k+1) = \mathbf{A}\mathbf{x}(k) + \mathbf{B}\mathbf{u}(k) + \mathbf{G}\mathbf{v}(k) \quad (98.49)$$

$$\mathbf{y}(k) = \mathbf{C}\mathbf{x}(k) + \mathbf{w}(k) \quad (98.50)$$

has control law of the form

$$\hat{\mathbf{x}}(k+1/k) = \mathbf{A}\hat{\mathbf{x}}(k) + \mathbf{B}\hat{\mathbf{u}}(k) \quad (98.51)$$

$$\hat{\mathbf{x}}(k+1) = \mathbf{A}\hat{\mathbf{x}}(k+1/k) + \mathbf{G}(k+1)\mathbf{y}(k+1) - \mathbf{C}\hat{\mathbf{x}}(k+1/k) \quad (98.52)$$

$$\hat{\mathbf{u}}(k) = \mathbf{K}(k)\hat{\mathbf{x}}(k) \quad (98.53)$$

where $\mathbf{K}(k)$ and $\mathbf{G}(k)$ are optimal gains for the deterministic optimal controls and the Kalman filters, respectively.

In practice, not all the state variables are easily accessible, and in general only the outputs of the system are measurable. Therefore, when feedback from the state variables are required in a given design, it is necessary to observe the states from information contained in the output as well as the input variables. The subsystem that performs the observation of the state variables based on the information received from the measurements of inputs and outputs is called the state observer. [Figure 98.6](#) shows the block diagram of such a system.

Suppose a state feedback gain \mathbf{K} has been selected so that the eigenvalues of

FIGURE 98.6 Use of state observer. When feedbacks from the state variables are required, it may be possible to observe the states from information contained in the output as well as the input variables based on the information received from the measurements.

$$\mathbf{x}(k+1) = \mathbf{A}\mathbf{x}(k) + \mathbf{B}\mathbf{u}(k) \quad (98.54)$$

$$\mathbf{u}(k) = -\mathbf{K}(k)\mathbf{x}(k) + \mathbf{r}(k) \quad (98.55)$$

are located at $\lambda_1, \lambda_2, \dots, \lambda_n$. Furthermore, assume that gain \mathbf{G} in the identity observer

$$\hat{\mathbf{x}}(k+1) = (\mathbf{A} - \mathbf{G}\mathbf{C})\hat{\mathbf{x}}(k) + \mathbf{B}\mathbf{u}(k) + \mathbf{G}\mathbf{y}(k) \quad (98.56)$$

is chosen such that eigenvalues of the observers are $\mu_1, \mu_2, \dots, \mu_n$.

When the observer state estimate $\hat{\mathbf{x}}(k)$ is used instead of state $\mathbf{x}(k)$ the resulting system has a state dimension $2n$, modeled by

$$\begin{bmatrix} \mathbf{x}(k+1) \\ \hat{\mathbf{x}}(k+1) \end{bmatrix} = \begin{bmatrix} \mathbf{A} & -\mathbf{B}\mathbf{K} \\ \mathbf{G}\mathbf{C} & \mathbf{A} - \mathbf{G}\mathbf{C} - \mathbf{B}\mathbf{K} \end{bmatrix} \begin{bmatrix} \mathbf{x}(k) \\ \hat{\mathbf{x}}(k) \end{bmatrix} + \begin{bmatrix} \mathbf{B} \\ \mathbf{B} \end{bmatrix} \mathbf{r}(k) \quad (98.57)$$

A similarity transform

$$\begin{bmatrix} \mathbf{x}(k) \\ \mathbf{e}(k) \end{bmatrix} = \mathbf{P} \begin{bmatrix} \mathbf{x}(k) \\ \hat{\mathbf{x}}(k) \end{bmatrix} \quad (98.58)$$

where

$$\mathbf{P} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{I} & -\mathbf{I} \end{bmatrix} \quad (98.59)$$

corresponds to a change of variables to $\mathbf{x}(k)$ and $\mathbf{e}(k) = \mathbf{x}(k) - \hat{\mathbf{x}}(k)$ converts this to

$$\begin{bmatrix} \mathbf{x}(k+1) \\ \mathbf{e}(k+1) \end{bmatrix} = \begin{bmatrix} \mathbf{A} - \mathbf{B}\mathbf{K} & \mathbf{B}\mathbf{K} \\ \mathbf{0} & \mathbf{A} - \mathbf{G}\mathbf{C} \end{bmatrix} \begin{bmatrix} \mathbf{x}(k) \\ \mathbf{e}(k) \end{bmatrix} + \begin{bmatrix} \mathbf{B} \\ \mathbf{0} \end{bmatrix} \mathbf{r}(k) \quad (98.60)$$

This system has the same eigenvalues as the original because of the nature of the similarity transforms and the eigenvalues are the solution of

$$\det(\lambda\mathbf{I} - (\mathbf{A} - \mathbf{B}\mathbf{K}))(\lambda\mathbf{I} - (\mathbf{A} - \mathbf{G}\mathbf{C})) = 0 \quad (98.61)$$

This requires that one of

$$\det(\lambda\mathbf{I} - (\mathbf{A} - \mathbf{BK})) = 0 \quad (98.62)$$

$$\det(\lambda\mathbf{I} - (\mathbf{A} - \mathbf{GC})) = 0 \quad (98.63)$$

must hold. These are also the eigenvalues of the design for the pole-placement feedback state controller $\lambda_1, \lambda_2, \dots, \lambda_n$ and of the design of the state observer $\mu_1, \mu_2, \dots, \mu_n$, respectively. This indicates that the use of observer does not move the designed poles from the pole-placement algorithm.

The algorithms for pole placement observer are well known and they are part of many control design packages. Steady-state Kalman gains and optimal control gains are also commonly available in such programs. Codes for Kalman filters and LQ controllers are also easy to write.

Note: For further reading on the topic refer to the sources in references.

Defining Terms

Calculus variations: A technique which can be used for solving linear or nonlinear optimization problems with boundary conditions.

Controllability: Property of a control system such that a determined input takes every state variable from a desired initial state to desired final state.

Controller: A subsystem that assists to achieve the desired output of a plant or process.

Cost function: A function whose value indicates how well the actual performance of the system matches the desired performance.

Covector: Lagrange multiplier.

Hill climbing: A method of determining absolute maxima or minima by using an initial guess point and derivatives of the function.

Kalman Filter: A procedure which provides optimal estimates of state.

Lagrange multiplier: A mathematical expression that modifies the performance index to give an optimal solution.

Linear quadratic equation: Cost functions in quadratic form.

Linear system: A system that possesses the properties of superposition.

Optimal control: A control technique that maximizes or minimizes the cost function of a system.

Optimization: Procedure of obtaining maximum or minimum performance.

Performance index: Cost function.

Pole-placement method: A design technique that makes use of the system closed-loop properties.

Riccati equation: A set of equations that transform control equations to lead to optimal solutions.

State equation: A set of simultaneous, first-order differential equations with n variables leading to solutions of state variables.

State-space model: Mathematical expression of a system that consists of simultaneous, first-order differential equations and an output equation.

State variables: A set of linearly independent system variables so that once the values are set they can determine the value of all system variables later in time.

List of Manufacturers

There are no manufacturers of optimal controllers. Most mathematical packages, such as **MATLAB Optimization Toolbox**, **CAD/CAM** algorithms, the majority of artificial intelligence and neural network software tools, and other simulation and design packages, offer solutions to optimal control problems. Optimization tools are also part of specialized design packages addressing specific applications, such as **FPGA**, a language-based design, technology-specific optimization; **OPTCON**, optimal control algorithms for linear stochastic models; **DISNEL**; **MIMO**; and so on.

Electropneumatic and Electrohydraulic Instruments: Modeling of Electrohydraulic and Electrohydrostatic Actuators

99.1 Introduction

In control systems, the output of the controller (also of the equalizer or compensator), which operates on the command (and feedback) input signals, is invariably sent to an actuator. The latter is a power element critically positioned at the plant input, and, to a large extent, determines the performance of the overall control system. Thus, the importance of the accurate modeling of the actuator element with respect to achieving and maintaining the desired control system performance over its operating range cannot be overemphasized. The impact of items such as the actuator phase lag characteristics, parameter variations and aging, sensor noise, and operating scenario (e.g., in a flight control context it is referred to as *flight conditions*) should be explicitly considered in a control system design process. To achieve a robust control system, where these items are taken into account, requires a good understanding and an accurate model of the actuation element. This chapter discusses the actuator modeling process.

99.2 Background

Power-to-weight considerations have driven actuator design to pneumatic, hydraulic, electrohydraulic, and recently, in flight control applications, electrohydrostatic configurations. In this chapter the point of view

is taken that the actuator element constitutes a feedback control system in its own right. Thus, the actuator comprises of an “amplifier” element (the servo valve), a power element (the “ram”), an actuator displacement sensor, and a controller about which more will be said in the sequel. Furthermore, it is important that the actuator subsystem be considered in the context of the complete control system, e.g., a flight control system. This point of view is promulgated throughout this chapter. First, a relatively simple hydraulic actuator is considered. The focus then shifts to the modern electrohyrostatic actuator (EHA) technology which, in the flight control application, offers a high degree of combat survivability and easier maintainability since its components are collocated with the actuator. Since the EHA does not require long hydraulic lines, required maintenance time and equipment can be reduced. This also substantially reduces the profile exposed to hostile fire. In addition, actuator failures due to various causes and/or aging need to be taken into account in designing the overall control system. The design of a robust control system, utilizing an actuator, requires an accurate actuator model in order to satisfy the system performance specifications. The EHA and its flight control application are used as the “vehicle” for presenting the actuator modeling process.

Actuator Modeling Requirements

When an actuator needs to be replaced in a control system, for reasons cited previously, by one “off the shelf,” the robustness of the overall control system must be unaffected by this replacement unit. Thus, the actuator design process entails

1. The derivation of an accurate mathematical model for the actuator.
2. Sensitivity analyses on the actuator control systems. This should include sensitivity to variations in load, component efficiencies, physical plant parameters, and actuator sensor noise.
3. The identification of a reasonable set of plant variations for the actuator, based on the sensitivity analysis, which is required for designing a robust actuator control system that will meet the specifications in the presence of predicted variations.

99.3 Hydraulic Actuator Modeling

The modeling of a purely hydraulic actuator employed in an irreversible flight control system is presented first. Based upon the notation shown in Fig. 99.1 the following relationships are obtained:

$$x_1 = \delta_{ec} a \tag{99.1a}$$

$$\frac{x_v - x_f}{b + c} = \frac{x_v - x_1}{c} \tag{99.1b}$$

FIGURE 99.1 Irreversible control system.

FIGURE 99.2 (a) Actuator block diagram; (b) block diagram of actuator feedback control system; (c) simplified block diagram.

which yield

$$x_v b + x_f c = x_1 (b + c) \quad (99.2)$$

From these equations Fig. 99.2a is obtained. Next, the relationships

$$\frac{dx_p}{dt} = \frac{Q}{A}, \quad Q = Kx_v, \quad \delta_e = \frac{x_p}{d+e}, \quad x_f = e\delta_e \quad (99.3)$$

are utilized to yield the block diagram of a typical feedback control system (shown in Fig. 99.2b) which represents the irreversible hydraulic actuator under consideration. This block diagram is simplified to the one shown in Fig. 99.2c, which yields the first-order transfer function of the actuator:

$$G(s) = \frac{\delta_e(s)}{\delta_{e_c}(s)} = \frac{K}{\tau s + 1} \quad (99.4)$$

where the gain $K = [a(b+c)]/ce$, the time constant $\tau = [Ab(d+e)]/cKe$ of the actuator, and $0.025 < \tau < 0.1$ s. For a step input command, a typical actuator time response is shown in Fig. 99.3.

More-detailed dynamic modeling of the valve leads to higher-order hydraulic actuator models. For example, the transfer function of the currently used actuator of the F-16 aircraft is of fourth order [1] and its frequency response is compared with its first-order approximation in Fig. 99.4. It is indeed important to use the full-blown high-order actuator dynamic model in robust control system design. As Fig. 99.4 shows, the simplified first-order model fits well the high-order model in the low-frequency range. Unfortunately, a significant phase angle difference exists at the higher frequencies where the actuator will be operating, for the higher frequencies are within the bandwidth of modern robust (“high gain”) control system compensators.

FIGURE 99.3 Time response of an actuator.

FIGURE 99.4 Comparison of first- and fourth-order actuator models.

FIGURE 99.5 Electrohydraulic actuator.

The next step in the actuator state of development is then an electronic “fly-by-wire” mechanization of the feedback loop. This is shown in Fig. 99.5 where an actuator is shown that employs an electric (solenoid-controlled) valve, a potentiometer to measure the control surface deflection (actuator displacement), and where the power element of the actuator, the RAM, is an hydraulic cylinder.

99.4 EHA Actuator Modeling

The novel EHA actuator (see, e.g., Reference 2) offers a high degree of maintainability and survivability because all the actuator elements are collocated and a central hydraulic pump with the attendant high-pressure hydraulic plumbing is not needed. The modeling of the modules of the EHA is outlined first.

FIGURE 99.6 Motor model.

Motor

Electric motors with the rotor moment of inertia J_m and electromechanical damping B_m (see Fig. 99.6), are subject to variations in output torque and subsequent fluctuations in rotor speed ω_m . Since the torque due to the load counteracts the torque generated by the motor, perturbation may also be caused by variations of the load torque. This relationship is expressed as

$$\tau_e(s) = \tau_{cmd}(s) - \tau_{load}(s) \quad (99.5)$$

where τ_{load} is the load torque due to the differential pressure of the fluid in the pump. This results in a first-order transfer function

$$\frac{\Omega_m(s)}{\tau_e(s)} = \frac{1}{J_m s + b_m} \quad (99.6)$$

Pump and Fluid

Electric motors have a limited torque-to-mass ratio, due to the finite and limited magnetic flux density that can be generated [3]. High-pressure hydraulic systems, with the system pressure of 2000 to 5000 psi, can generate high forces resulting in more compact and higher torque-to-mass ratios than electric motors. Generally, high-pressure hydraulic systems are stiffer against the load than electric motors. Hence, the EHA utilizes a dc motor to pump high-pressure fluid into the piston chamber. The dc motor internal to the EHA converts the electric power into mechanical power. It is the pump that converts this mechanical power into hydraulic power. The hydraulic power, acting against the piston, is converted to mechanical power capable of moving the load, e.g., large flight control surfaces.

The flow rate Q_m generated by the pump is proportional to the motor speed, i.e.,

$$Q_m(s) = \frac{D_m}{2\pi} \Omega_m(s) \quad (99.7)$$

where D_m represents the pump displacement constant. The flow rate of the hydraulic fluid is primarily dependent on two factors: change in chamber volume and change in pressure due to the compressibility of the fluid effect [4]. The chamber volume changes as the piston moves through the chamber at speed dx_p/dt . The flow rate due to the changes in chamber volume is then expressed as $\pm A dx_p/dt$. Secondary fluid dynamic effects include fluid compressibility, internal leakage flow, and external leakage flow. These secondary effects are modeled by a first-order equation as follows:

FIGURE 99.7 Simplified actuator control (not drawn to scale).

$$\delta Q(s) = Q_m(s) - AsX_p = [K_s s + C_1]P(s) \quad (99.8)$$

which results in the transfer function

$$\frac{P(s)}{\delta Q(s)} = \frac{1}{K_s s + C_1} \quad (99.9)$$

Piston and Flight Control Surface

Piston and Flight Control Surface Fundamentals

The pressure developed by the pump and fluid acts on the piston surface (see Fig. 99.7), causing the RAM to extend or retract. This force then generates a torque through a hinge to deflect the control surface. This torque has to overcome two load components: control surface inertia and aerodynamic loads. The control surface inertia is primarily due to the fact that the control surface has certain size and mass. The aerodynamic load only occurs in flight, when the air pressure over the control surface applies aerodynamic forces to it. The aerodynamic load is determined by three factors: the surface area of the flight control surface, aerodynamic loading which varies with altitude and airspeed, and the relative angle of the surface to the wind. The surface angle to the wind depends on the angle of surface deflection and on the angle of attack of the aircraft.

Piston and Flight Control Surface Dynamics

Flexible Hinge Joint Model

The magnitude of F_A acting on the piston is equal to $\wp A$, where \wp is the differential pressure developed by the pump and fluid and A is the surface area of the piston. Thus, the force created by the pump and fluid can be expressed as

$$F_A = \wp A \quad (99.10)$$

The piston dynamics, with the piston mass M_p and piston damping B_p , can be described by the second-order model:

$$F_A - F_p = [M_p s^2 + B_p s]X_p \quad (99.11)$$

The resulting torque acting on the flight control surface due to this force imbalance can be described by

$$\tau_R = \frac{K_h}{R_h} (X_p - X_L) \quad (99.12)$$

where K_h is the hinge stiffness constant and R_h is the hinge length. The stabilator inertia acts against the torque generated by the actuator, such that

$$\tau_R - \tau_L = [J_L s^2 + B_L s] \theta_L \quad (99.13)$$

where τ_L is the torque created by the aerodynamic load and stabilator inertia. The variables J_L and B_L represent the mass properties of the flight control surface.

Stiff Hinge Joint Model

Equations 99.11 through 99.13 represent a rather complex model of load dynamics. The complexity of the model can be reduced if the linkage between the actuator and flight control surface is considered rigid. This is a valid assumption, since the natural frequency of the hinge for a well-designed actuation system is much greater than the actuator bandwidth of concern. Hence, the piston and load dynamics are still expressed as

$$F_A - F_p = [M_p s^2 + B_p s] X_p \quad (99.14)$$

and

$$\tau_R - \tau_L = [J_L s^2 + B_L s] \theta_L \quad (99.15)$$

Dividing Eq. 99.15 by R_h yields

$$F_R - \frac{\tau_L}{R_h} = \left[\frac{J_L s^2 + B_L s}{R_h} \right] \theta_L \quad (99.16)$$

Assuming rigidity of the hinge assembly, $F_R \approx F_p$. Hence, adding Eqs. 99.14 and 99.16 results in

$$F_A - \frac{\tau_L}{R_h} = [M_p s^2 + B_p s] X_p + \left[\frac{J_L s^2 + B_L s}{R_h} \right] \theta_L \quad (99.17)$$

where τ_L is defined as

$$\tau_L = (\text{Load}_{\text{aero}}) \theta_L \quad (99.18)$$

Since rigidity implies that $X_p = X_L$ and $\theta_L = X_p/R_h$, Eq. 99.17 is further reduced to

$$F_e = F_A - \frac{\tau_L}{R_h} = \left[\left(M_p + \frac{J_L}{R_h^2} \right) s^2 + \left(B_p + \frac{B_L}{R_h} \right) s \right] X_p \quad (99.19)$$

or expressed in a transfer function form:

$$\frac{X_p(s)}{F_e(s)} = \frac{1}{s \left[\left(M_p + \frac{J_L}{R_h^2} \right) s + \left(B_p + \frac{B_L}{R_h} \right) \right]} \quad (99.20)$$

FIGURE 99.8 Bare EHA block diagram.

Equation 99.20 represents a simplified model of the load dynamics. A complete simplified design model of the bare EHA, without the controller, is shown in Fig. 99.8 using the individual component models.

Hinge Moments

The aerodynamic loads mentioned previously describe the torque opposing the piston motion. Thus, load generated by the flow of air above and below the flight control surface applies a torque to the hinge assembly, which in turn adds backpressure to the piston. The hinge moment is modeled as follows:

$$\tau_L = \bar{q} S_t R_h \left(Ch_\alpha \frac{\alpha(s)}{\theta_L(s)} + Ch_\delta \right) \theta_L \quad (99.21)$$

where S_t denotes the surface area of the control surface, \bar{q} denotes the dynamic pressure, Ch_α and Ch_δ denote the hinge moment coefficients of the control surface with respect to angle of attack and surface deflection δ . The aerodynamic load dynamic pressure \bar{q} is a function of airspeed U_0 and air density [2] ρ , as expressed by

$$\bar{q} = \frac{1}{2} \rho U_0^2 \quad (99.22)$$

The air density in a standard atmosphere drops exponentially with increasing altitude. The dynamic pressure \bar{q} increases as the Mach number gets higher and altitude decreases. The hinge moment for modern fighters with all movable tails, where $Ch_\alpha \approx Ch_\delta$, is modeled by

$$\tau_L = \bar{q} S_t R_h Ch_\delta \left(\frac{\alpha(s)}{\theta_L(s)} + 1 \right) \theta_L \quad (99.23)$$

Aircraft Short Period Approximation

If the aircraft forward speed is assumed constant (i.e., the speed perturbations $u \approx 0$), the X force equation can be neglected since it does not significantly contribute to the short-period oscillation [5]. Thereby, the short-period approximation of the longitudinal channel of the aircraft which is relevant to the actuator dynamics is extracted and is written as

$$\begin{bmatrix} \dot{\alpha} \\ \dot{q} \end{bmatrix} = \begin{bmatrix} z_\alpha & z_q \\ m_\alpha & m_q \end{bmatrix} \begin{bmatrix} \alpha \\ q \end{bmatrix} + \begin{bmatrix} z_\delta \\ M_\delta \end{bmatrix} [\delta_e] \quad (99.24)$$

This yields a second-order minimum-phase transfer function of the form:

$$\frac{\alpha(s)}{\delta(s)} = \frac{-K(s+a)}{(s+b)(s+c)} \quad (99.25)$$

FIGURE 99.9 Comparison of full and short period approximation for longitudinal equations of motions.

For the frequency of interest, the short-period approximation closely resembles the full state model. As seen in Fig. 99.9, where the solid lines represent the full state model frequency response of the vehicle and + lines represent the short-period model frequency response of the vehicle, phase and attenuation characteristics are closely matched at high frequency. The approximation, as seen in the figure, is not valid for frequencies below 0.5 rad/s due to the effects from the slow longitudinal mode, which is referred to as the phugoid.

Quantitative Feedback Theory (QFT)

Robust QFT [3,6] compensators are ideal for obtaining the desired response from an actuator. The term *robust* in control theory implies that a system under control, in this case the actuator, remains stable throughout its operating envelope, rejects disturbances, and results in minimum degradation in the performance specifications. A QFT designed feedback system, which uses output feedback, assures that the output tracks the input values despite parametric uncertainties or disturbances. The output of a unity-gain feedback system with uncertain plant models can vary depending on the plant conditions; however, the output of a robust QFT feedback control system with uncertain plant models will not vary much. The unity-gain system, however, cannot control the tracking response, which necessitates the inclusion of a prefilter.

Plant (specifically, actuator) uncertainties may be caused by manufacturing tolerances. For example, a component *A* is specified to be 10 ± 0.1 mm long. In a large production run, the length of component *A* may be anywhere between 9.9 and 10.1 mm. This tolerance range may be substantial enough to produce noticeable variations in the plant model. Plant uncertainties may also be caused by the environment, specifically the system (actuator) operating conditions. For example, the parameters of an aircraft model display large variations depending on altitude and airspeed. Finally, the performance of various components decay over time, introducing an additional element of uncertainty.

The QFT design paradigm accounts for the plant variations in the design procedure. It is a linear design technique for designing a linear robust controller for linear or nonlinear control systems [3,6] — in this case the actuator control system. As long as all the QFT design requirements are met, the output responses are guaranteed to conform to the specification boundaries. The initial step in the design process is to establish the upper and lower performance tracking boundaries. The maximum allowable disturbance is used to determine the disturbance boundary. The phase margin angle, gain margin, or maximum peak value is used to establish the stability boundary. These combined boundaries establish the limitation of the system performance. The next step is to analyze the system to determine the parameters that will

FIGURE 99.10 Two feedback loops in QFT two degrees of freedom structure.

cause noticeable variations to the plant. The system, often modeled only as a single plant transfer function in other design methods, is now modeled more completely as a *set* of plant transfer functions. The variations now form a closed region in the Nichols magnitude and phase chart, called the template; larger template sizes indicate a higher degree of plant uncertainty. Templates at different frequencies differ in size and shape.

A most important aspect of modeling is the thorough analysis of the bare actuator plant, in order to find the sources of plant variation. For an aircraft application the three largest sources of variations are the fluctuations in aerodynamic load on the flight control surfaces, motor torque, and hydraulic pump fluid pressure.

99.5 Actuator Compensator Design

QFT compensators, which are designed in the frequency domain, are ideally suited for the actuator control system. The QFT compensator processes its inputs, which are the commanded actuator displacement and the measured current actuator position, and generates a commanded signal to, e.g., the solenoid valve in a hydraulic actuator, or a current for the electric dc motor in the EHA actuator. In order to proceed with the actuator QFT compensator design, the block diagram as shown in Fig. 99.7 is transformed to the standard inner and outer QFT loop structures shown in Fig. 99.10 [2,3,6]. For this design problem the external disturbance $d_2(t)$ can be ignored, i.e., $d_2(t) = 0$, whereas the $d_1(t)$ disturbance models a possible measurement bias. The inner loop controls the angular rate of the motor while the outer loop controls the surface deflection. Since tracking in the inner loop is less important, for its function is to reduce the uncertainty level of the outer loop, the inner loop prefilter can be set to unity and the tracking performance enforcement is relegated to the prefilter F_{θ} of the outer loop.

99.6 Conclusion

The modeling of a hierarchy of hydraulic actuators has been presented. The modeling of modern EHAs is emphasized and dynamic models of its subcomponents are carefully developed. A systems approach to actuator modeling and design is taken and the feedback structure is highlighted. In this chapter it is stressed that, because of the complex feedback interactions at work, proper actuator modeling requires consideration of the latter in the full context of the control system in which it is to be employed. Thus, in this presentation the aerospace application is considered. At the same time the actuator is being viewed not as a component of a control system, but as a control system in its own right. Hence, it is shown that simple mechanical feedback linkages which fulfilled the role of a controlling element for the actuator can be replaced by a more flexible, high-performance, robust, full-blown electronic actuator compensator. Concerning electropneumatic instruments and sensors, these are critical elements in systems where the flow of liquids and/or gases is being controlled, e.g., in the chemical industries. In aerospace, electropneumatic sensors are used to measure airspeed, altitude, and the angle of attack and sideslip angles of the aircraft; these functions are collocated in the air data computer (ADC). Currently, modern sensors use feedback action for accuracy enhancement, and, as such, the design of modern electropneumatic

instruments and sensors is conceptually similar to the design of EHAs. Detailed information on actuators and sensors may be found in References 4 and 7.

Nomenclature

A	ram cross section area
a, b, c, d, e, R_h	length of linkages
x, X	displacement
J	moment of inertia; o, ovin
K	gain
Q	flow rate
s	Laplace variable
D_m	pump displacement constant
F	force
M_p	mass of piston
B_p	piston damping
K_h	hinge stiffness constant
\bar{q}	dynamic pressure
S_t	aerodynamic surface area
C_h	hinge moment coefficient
U, u	airspeed
q	pitch rate
M, z, m	aerodynamic stability derivatives
P	pressure
δ	deflection angle
τ	torque
Ω, ω	rotor speed
P	differential pressure developed by the pump
θ	deflection angle
α	angle of attack of aircraft
ρ	air density

100.1 Introduction

Where hazardous atmospheres can exist, electricity should be a primary concern of every engineer and system designer. Hazardous atmospheres can exist not only in the more common surroundings of industrial, chemical, and environmental facilities, but also in many less obvious environs where dust is present, where gas can accumulate, and where combustible gas-forming reactions occur. To minimize risks in such areas, it is necessary to design specific hazard-reducing electric systems. Most electric equipment is built to specific standards aimed to reduce the incidence of fires and human casualties. The majority of such incidents can be attributed to poor or defective installations, improper use of approved equipment, deteriorated equipment, and accidental applications. In combination with an explosive atmosphere, these factors can result in extremely dangerous conditions. Designing an electric system for a hazardous location requires careful planning, research, engineering, and ingenuity in using proper protection techniques to develop better applications and classifications that reduce hazards.

100.2 Fundamentals of Explosion Protection

Safety of personnel and equipment present in hazardous area should never be taken for granted. In 1913 a massive methane gas explosion in a coal mine in Glamorganshire, South Wales claimed the lives of 439 mine workers. After months of research and studies, a group of experts and scientists concluded that the explosion was caused by a small amount of electric energy stored in the circuit. This small amount of energy combined with the presence of an explosive gas and air mixture and the absence of proper protection proved to be fatal for the mine workers.

To understand the dangers associated with electric equipment in hazardous areas, one must first understand the basics. Chemically speaking, **oxidation**, combustion, and explosions are all exothermic reactions where heat is given off at different reaction speeds. For these reactions to occur, three components must be present simultaneously in certain concentrations. These components are (1) fuel (liquid, gas, or solids), (2) a sufficient amount of oxygen (air), and (3) an ignition source (electric or thermal).

Some of the ignition sources that can be potentially hazardous include (1) hot surfaces (motor windings, heat trace cable, light fixtures), (2) electric sparks and arcs (when circuits are opened and closed, short circuits), (3) mechanic sparks (friction, grinding), (4) electrostatic discharge (separation process in which at least one chargeable substance is present), and (5) radiation, compression, and shock waves.

When dealing with electric equipment in hazardous locations, it is important to understand and to be familiar with the following terms:

1. *Flash Point* — the minimum temperature at normal air pressure at which a combustible or flammable material releases sufficient vapors ignitable by an energy source. Depending on the flash point (FP), flammable liquids are divided into four classes of hazard:
 - a. AI (FP < 21°C),
 - b. AII (21 < FP < 55°C),
 - c. AIII (55°C < FP < 100°C), and
 - d. B (FP < 21°C at 15°C dissolving in water).
2. *Ignition temperature* — the minimum temperature under normal operating pressure at which a dangerous mixture ignites independently of the heating or heated element.
3. *Flammable limits* — the upper explosive limit (UEL) or the maximum concentration ratio of vapor to air mixture above which the propagation of flame does not occur when exposed to an ignition source. Here, the mixture is said to be “too rich” to burn. The lower explosive limit (LEL) is the minimum concentration ratio of vapor to air mixture below which the propagation of flame does not occur when exposed to an ignition source. Also, here, the mixture is said to be “too lean” to explode. Significant attention must be given to LEL, since it provides the minimum quantity of gas necessary to create a hazardous mixture. Generally, the flammable limits are indicated in percent by volume, which is abbreviated % vol. Note that the explosion of a mixture in the middle the UEL and the LEL is much more violent than if the mixture were closer to either limit.
4. *Maximum surface temperature* — the maximum temperature generated by a piece of electric equipment under normal or fault conditions. This temperature must be below the minimum ignition temperature of the potentially explosive surrounding atmosphere. Equipment used in hazardous locations must be clearly marked to indicate class, group, and maximum surface temperature or range referenced to 40°C (104°F) ambient temperature. Table 100.1 shows that an apparatus with a specific T class can be used in the presence of all gases having an ignition temperature higher than the T temperature class of the device. For added safety, it is recommended that the maximum surface temperature be not more than 80% of the minimum ignition temperature of the surrounding gas. The reader is cautioned not to confuse maximum working (operating) temperature with maximum surface temperature, which is measured under worst-case conditions of the electric apparatus. An electric apparatus designed to operate with a maximum ambient temperature of 70°C — even in the worst conditions of the expected temperature range — must not have a temperature rise greater than a safety margin of 10°C to be classified as T6 or 5°C for classes T3, T4, and T5 (Table 100.1).
5. *Vapor density* — the weight of a volume of pure vapor gas compared with the weight of an equal volume of dry air under the same normal atmospheric pressure and temperature. It is calculated as the ratio of molecular weight of the gas to the average molecular weight of air (28.96). Methane gas (CH₄) with molecular weight of 16 and vapor density of 0.6 tends to rise, while acetone (C₃H₆O) with molecular weight of 58 and vapor density of 2 tends to settle closer to ground levels.

In the U.S., the National Electrical Code (NEC) defines a hazardous area as “an area where a potential hazard may exist under normal or abnormal conditions because of the presence of flammable, combustible, or ignitable materials” [1]. This general description is divided into different classes, divisions, and groups to assess the extent of the hazard properly and to design and specify safe operating electric systems.

TABLE 100.1 Maximum Surface Temperature Under All Operating Conditions

Maximum Temperature		Identification Number
°C	°F	
450	842	T1
300	572	T2
280	536	T2A
260	500	T2B
230	446	T2C
215	419	T2D
200	392	T3
180	356	T3A
165	329	T2B
160	320	T3C
135	275	T4
120	248	T4A
100	212	T5
85	185	T6

Note: Surface temperature of electric apparatus during operation must not exceed limitations of the hazard present. The need for classification is important not only for safety, but for economic reasons as well. Proper application, good engineering, and experience can reduce the extent of the most volatile areas (Class I, Division 1) within reasonably safe distances of potential leaks and ignition sources. Under Class I, Division 1, equipment and installation costs can become an economic burden because the equipment is considerably more expensive and must pass stringent tests to ensure proper and safe operation under normal or abnormal conditions. The National Fire Protection Association (NFPA 497 A & B) [2], and the American Petroleum Institute *Recommended Practice for Classification of Locations for Electrical Installations at Petroleum Facilities* (ANSI/API RP 500) [3] are excellent resources for defining hazardous area boundaries.

100.3 Classification of Hazardous Areas

Classification of a hazardous area within a facility is usually determined by highly qualified personnel including chemical engineers, process engineers, and safety officers. Their primary objective is to determine where a potentially hazardous atmosphere exists, under what conditions it exists, and how long it exists. Careful study and design of electric installations, especially in hazardous areas, are crucial for the safe operation of electric equipment and prevention of an accidental ignition of flammable materials. The NEC, which has been adopted by many states, agencies, and companies as the basis for inspections, describes the requirements and procedures for electric installations in hazardous areas. Articles 500–504 contain the requirements of electric equipment and wiring for all voltages in locations where fire or explosion hazards may exist due to flammable gases or vapors, flammable liquids, combustible dust, or ignitable fibers or flyings.

Table 100.2 describes hazardous locations by Class, Division, and Group. The Class defines the physical form of combustible material mixed with oxygen molecules. The Division defines the probability of an

TABLE 100.2 Area Classification Based on NEC

Division 1 — Hazard Is Present under Normal Operating Conditions	
Class I	Gases and Vapor
Group A	Acetylene
Group B	Hydrogen
Group C	E.g., ethylene
Group D	E.g., methane
Class II	Combustible Dusts
Group E	Metal dust
Group F	Coal dust
Group G	Grain dust
Class III	Fibers

Division 2 — Hazard Is Present Only under Abnormal Operating Conditions

explosive fuel to air mixture being present. The Group indicates the type of vapor or dust present. The NEC gives the following definitions [1]:*

Class I, Division 1 Locations

1. Where ignitable concentrations of flammable gases or vapors can exist under normal operation conditions; may exist frequently because of repair or maintenance operations or because of leakage; and where breakdown or faulty operation of equipment or processes might release ignitable concentrations of flammable gases or vapors, and cause simultaneous failure of electric equipment.

Class I, Division 2 Locations

1. Where volatile flammable liquids or flammable gases are handled, processed, or used but where the liquids, vapors, or gases will normally be confined within closed containers or closed systems from which they can escape only in case of accidental rupture or breakdown of such containers or systems, or in case of abnormal operation of equipment;
2. Where ignitable concentrations of gases or vapors are normally prevented by positive mechanical ventilation, and where they might become hazardous through failure or abnormal operation of the ventilating equipment;
3. Adjacent to Class I, Division 1 locations, and where ignitable concentrations of gases or vapors might occasionally be communicated; unless such communication is prevented by positive-pressure ventilation from a source of clean air, and effective safeguards against ventilation failure are provided.

Class II, Division 1 Locations

1. Where combustible dust is in the air under normal operation conditions in quantities sufficient to produce explosive or ignitable mixtures;

*Reprinted with permission from NFPA 70-1996, the *National Electrical Code*®, © 1995, National Fire Protection Association, Quincy, MA 02269. 2. Where mechanical failure or abnormal operation of machinery or equipment might cause such explosive or ignitable mixtures to be produced, and also might provide a source of ignition through simultaneous failure of electric equipment, operation of protective devices, or from other causes;
3. Where combustible dusts of an electrically conductive nature may be present in hazardous quantities.

Class II, Division 2 Locations

Where combustible dust normally is not in the air in quantities sufficient to produce explosive or ignitable mixtures, and dust accumulations normally are insufficient to interfere with the safe dissipation of heat from electric equipment, or may be ignitable by abnormal operation or failure of electric equipment.

Class III, Division 1 Locations

Where easily ignitable fibers or materials producing combustible flyings are handled, manufactured, or used.

Class III, Division 2 Locations

Where easily ignitable fibers are stored or handled. Quantities and properties of hazardous materials are the basis upon which the NEC classifies hazardous locations. Each hazardous location must be evaluated carefully to determine the appropriate classification to facilitate the design process and to help specify the correct equipment.

100.4 Enclosure Types and Requirements

Choosing the proper type of enclosure for electric equipment is important for two reasons:

1. Personnel protection against accidental contact with enclosed electric equipment.
2. Protection of internal equipment against outside harm.

Enclosures are designated by a type number indicating the degree of protection and the condition for which they are suitable. In some applications, enclosures have a dual purpose and therefore are designated by a two-part type number shown with the smaller number first (i.e., 7/9). The following enclosure types, with their enclosed equipment, have been evaluated in accordance with Underwriters Laboratories, Inc. UL 698, *Industrial Control Equipment for Use in Hazardous Locations*, and are marked to show the class and group letter designations.

Type 7 Enclosures — Type 7 enclosures are nonventilated, intended for indoor applications, and classified for Class I, Group A, B, C, D as defined in Table 100.2. The letters A to D sometimes appear as a suffix to the designation Type 7 to give the complete designation. According to UL 698, Type 7 enclosures must be designed to withstand an internal explosion pressure of specific gases and to prevent such an explosion from igniting a hazardous mixture outside the enclosure (explosion test). In addition, Type 7 enclosures fabricated from sheet steel are designed to withstand two times the internal explosion pressure for 1 min without permanent deformation and three times the explosion pressure without rupture. If constructed of cast iron, the enclosure must be capable of withstanding four times the explosion pressure without rupture or deformation. This test may be waived if calculations show a safety factor of five to one for cast metal or four to one for fabricated steel. The enclosed heat-generating devices are specifically designed to prevent external surfaces from reaching temperatures capable of igniting explosive vapor-air mixture outside the enclosure (temperature test).

Type 8 Enclosures — Type 8 enclosures are nonventilated, intended for indoor applications, and intended for Class I, Group A, B, C, D as outlined in Table 100.2. The letters A to D appear as a suffix to the designation Type 8 to give the complete designation. According to UL 698, the oil-immersed equipment must be able to operate at rated voltage and most severe current conditions in the presence of flammable gas–air mixtures without igniting these mixtures.

Type 9 Enclosures — Type 9 enclosures are nonventilated, intended for indoor applications, and classified for Class II, Group E, F, G as outlined in Table 100.2. The letters E, F, or G appear as a suffix to the designation Type 9 to give the complete designation. According to UL 698, the enclosure with its enclosed equipment is evaluated in accordance with UL 698 in effect at the time of manufacture. This evaluation includes a review of dimensional requirements for shaft opening and joints, gaskets material, and temperature rise under a blanket of dust. The device is operated at full rated load until equilibrium temperatures are reached, then allowed to cool to ambient temperature over a period of at least 30 h while continuously subjected to circulating dust of specified properties. No dust shall enter the enclosure (dust penetration test). Furthermore, Type 9 enclosures must also pass the “temperature test with dust blanket,” which is similar to the temperature rise test except the circulating dust is not aimed directly at the device during testing. The dust in contact with the enclosure shall not ignite or discolor from heat, and the exterior surface temperature based on 40°C (104°F) shall not exceed specific temperatures under normal or abnormal conditions. Where gasketed enclosures are used, gaskets shall be of a noncombustible, nondeteriorating, vermin-proof material and shall be mechanically attached. Type 9 ventilated enclosures are the same as nonventilated enclosures, except that ventilation is provided by forced air from a source outside the hazardous area to produce positive pressure within the enclosure. The enclosure must also meet temperature design test.

Type 10 Enclosures — Type 10 enclosures are nonventilated and designed to meet the requirements of the U.S. Bureau of Mines which relate to atmospheres containing mixtures of methane and air, with or without coal dust present.

It is important to note that enclosures for hazardous applications are designed for specific applications and must be installed and maintained as recommended by the enclosure manufacturer, since any misapplication or alteration to the enclosure may jeopardize its integrity and may eventually cause catastrophic failure of the system. All enclosures should be solidly grounded and properly labeled with a warning sign reminding the operator of the importance of deenergizing the incoming power to the enclosure prior to its servicing.

100.5 Protection Methodologies

Choosing a protection technique that suits each application can appear complicated because safety, reliability, cost, and maintenance factors must all be considered. Over the years, few hazardous area safety protection methodologies have been used. Although methodologies differ in application and principles of operation, they all have one thing in common: to eliminate one or more components necessary for combustion. Three of the most widely used methodologies are

1. Intrinsic safety
2. Explosion-proof
3. Purging and pressurization

Intrinsic Safety

Simply stated, intrinsic safety (IS) is all about preventing explosions. IS is based on the principle of limiting the thermal and electrical energy levels in the hazardous area to levels that cannot cause an ignition of a specific hazardous mixture in its most ignitable concentration. IS pertains to the minimum ignition temperature and the minimum ignition electric energy required to cause a specific group to ignite. The energy level provided by an IS circuit is low (≈ 1 W) and is used only to power up instruments with a low energy demand. An IS circuit incorporates an intrinsically safe apparatus (field device), an

associated apparatus, and an interconnecting wiring system. Designing intrinsically safe systems begins with studying the field device. This will help determine the type of associated apparatus which can be used so that the circuit functions properly under normal operating conditions, but still safe under fault conditions. Field devices can be simple, such as **resistance temperature devices (RTDs)**, thermocouples, mechanical switches, proximity switches, light emitting diodes (LEDs), or they can be nonsimple, such as transmitters, solenoid valves, and relays. A field device is considered and recognized as a “simple device” if its energy storing or generating values do not exceed 1.2 V, 0.1 A, 25 mW (or 20 μJ) in an intrinsically safe system under normal or abnormal conditions.

The simple device may be connected to an intrinsically safe circuit without further certification or approval. The fact that these devices do not have the ability to store or generate high levels of energy does not mean they can be installed in a hazardous area without modification. They must always be used with an associated apparatus to limit the amount of energy in the hazardous area, since a fault outside the hazardous area can cause sufficient high levels of energy to leak into the hazardous area. A nonsimple device (i.e., relay, transmitter) is capable of generating and storing energy levels exceeding the aforementioned values. Such devices require evaluation and approval under the entity concept (described later) to be used in conjunction with an intrinsically safe circuit. Under the entity concept, these devices have the following entity parameters: V_{\max} (maximum voltage allowed), I_{\max} (maximum current allowed), C_i (internal capacitance), and L_i (internal inductance). Under fault conditions, voltage and current must be kept below the V_{\max} and I_{\max} of the apparatus to prevent any excess heat or spark, which can be disastrous in hazardous areas. C_i and L_i indicate the ability of a device to store energy in the form of internal capacitance and internal inductance, and their value must be less than C_a and L_a of the associated apparatus (Table 100.3).

TABLE 100.3 Comparison of Entity Values of a Field Device and a Safety Barrier

Field Device		Safety Barrier
V_{\max}	\geq	V_{oc}
I_{\max}	\geq	I_{sc}
C_i	\leq	C_a (maximum allowed capacitance)
L_i	\leq	L_a (maximum allowed inductance)

An associated apparatus (Fig. 100.1), also known as a safety barrier, is an energy-limiting device needed to protect a field device located in a hazardous area from receiving excessive voltage or current. An associated apparatus is normally installed in a dust- and moisture-free enclosure (NEMA 4) located in a nonhazardous area, as close as possible to the hazardous area to minimize the capacitance effect of the cable. If installed in a hazardous area, the associated apparatus must be installed in an explosion-proof enclosure (i.e., NEMA 7D).

Figure 100.1 shows the three major components of a Zener safety barrier. (Note that there are other types of barriers such as isolation and repeater types.) The components are

1. The resistor, which limits the current to a specific value known as short circuit current (I_{sc}).
2. The fuse, which acts as an interrupter or protective device in case of a diode failure (fuse will blow if diode conducts).
3. The **Zener diode**, which limits the voltage to a specific value known as open circuit voltage (V_{oc}). Zener diodes are unique in their ability to conduct current under reverse bias conditions. When voltage is applied to the Zener diode in the reverse direction, a small amount of current known as leakage current is passed through. This current remains small until the bias voltage exceeds the Zener breakdown voltage. Exceeding the breakdown voltage causes the inherently high resistance of the Zener diode to drop to a very low value, thus allowing the current to increase abruptly. This sudden current increase forces the Zener diode to become a conductor, thereby diverting the excess voltage to ground. If the current continues to flow above and beyond the fuse rating, the

FIGURE 100.1 Major components of barrier circuit.

fuse will open and the circuit will be completely interrupted. Most safety barriers incorporate at least two diodes in parallel to provide maximum protection in case one diode fails (redundant safety).

In 1988, ANSI/UL 913 [5] allowed the use of intrinsic safety barriers with replaceable fuses as follows: “if it is accessible for replacement, and the fuse on a fuse protected shunt diode barrier shall not be replaceable by one of higher rating.” The fuses are housed in tamper-proof assemblies to prevent confusion or misapplication. The diodes have specific power ratings which must not be exceeded. The Zener diodes and fuses are governed by a very specific set of parameters which allow the fuse to operate at one-third the power rating of the Zener diode and to avoid irreversible damage to the Zener diode. The power rating for the Zener diode can be determined as follows:

$$Z_w = 1.5 \times V_{oc} \times 2 \times I_f$$

where

Z_w = minimum power rating of the Zener diode

V_{oc} = maximum Zener diode open-circuit voltage

I_f = fuse current rating

Selecting the best barrier for the application depends on the field device and requires analysis to ensure proper operation of the intrinsically safe circuit under normal or abnormal conditions. Three of the more important characteristics requiring examination are (1) internal resistance, (2) rated voltage, and (3) circuit polarity. Regardless of the selected barrier, each has an internal resistance (R_i) which limits the short circuit current under fault conditions. As current passes through R_i , it creates a voltage drop across the barrier that must be accounted for ($V = IR$). The rated voltage of the safety barrier must be equal to or reasonably greater than the supply voltage. The word *reasonably* is significant because excessive supply voltage can cause the diode to conduct, rushing high current through the fuse and blowing it. The use of a regulated power supply can significantly reduce problems associated with excessive supply voltage. To complete an analysis, the circuit polarity must be established. While ac barriers can be connected with either positive or negative power supply, dc barriers can be rated to either positive or negative.

Making Field Devices Intrinsically Safe

RTDs and thermocouples can be made intrinsically safe by using isolated temperature converters (ITCs) that convert a low dc signal from the field device into a proportional 4 to 20 mA signal. These ITCs require no ground connection for the safe and proper operation of the IS circuit. Because of their ability to store energy, transmitters are considered nonsimple devices and must be approved as intrinsically safe. If they are third-party approved, their entity parameter must be carefully considered. Transmitters (4 to

20 mA) convert physical measurements in hazardous areas, such as pressure and flow, into electric signals which can be transmitted to a controller in a safe area. Depending upon the conditions, 4 to 20 mA signals can be made intrinsically safe by using a repeater barrier which duplicates the output signal to match the input signal. Repeaters can be grounded or ungrounded. Ungrounded repeater barriers are known as “transformer-isolated barriers,” since the incoming voltage or signal is completely isolated from the outgoing voltage or signal via a transformer. Digital inputs, such as mechanical and proximity switches, which are simple devices, can be made intrinsically safe by using a switch amplifier. A switch amplifier is simply a relay or an optocoupler (a high-speed relay that uses optical isolation between the input and the output) that transfers a discrete signal (i.e., on/off) from the hazardous area to a safe area. Grounded safety barriers are passive devices designed specifically to prevent excessive energy in a non-hazardous area from reaching a hazardous area. These barriers can be used with most field devices. In order for such barriers to function properly, there is emphatic need for a solid, low-impedance ($<1 \Omega$) connection to ground to prevent ground loops and induced voltages which can hinder operation of the system.

Ignition Curves

All electric circuits possess certain electric characteristics that can be classified under three categories: resistance, **inductance**, and capacitance. To some extent, all circuits possess these three characteristics. However, some of these characteristics may be so small that their effects are negligible compared with that of the others, thus the terms, resistive, inductive, and capacitive circuit. Since the concept of IS is based on the principle that a large electric current can cause an explosion in a hazardous area and the lack of it cannot, it is necessary to identify the ranges of currents that are safe and those that are dangerous.

What is a dangerous amount of electric energy? The answer lies in the ignition curves. Ignition curves are published in most IS standards, such as ANSI/UL 913 [5]. Three of the most referenced curves are shown in Fig. 100.2. The curves show the amount of energy required to ignite various hazardous atmospheric mixtures in their most easily ignitable concentration. The most easily ignitable concentration is determined by calculating the percentage of volume-to-air between the upper and lower explosive limits of a specific hazardous atmospheric mixture. In the three referenced curves, the energy levels (voltage and current) below the group curve are not sufficient to cause an ignition of the referenced group.

Since specific ignition temperature is directly related to the amount of voltage and current consumed, both V_{oc} and I_{sc} of the safety barrier must be less than V_{max} and I_{max} . When designing an intrinsically safe system, the cable resistance R (Ω/m), the inductance L ($\mu H/m$), and the capacitance C (pF/m), which are inherently distributed over the length of the cable, must be considered. The capacitance and inductance can be readily obtained from the cable manufacturer’s literature. If these parameters are not available, certain default values can be used based on NFPA 493/78 (A-4-2). They are $C_c = 200$ pF/m (60 pF/ft), $L_c = 0.66$ $\mu H/m$, and (0.2 $\mu H/ft$). To determine the maximum wiring distance required to ensure proper operation, the capacitance and inductance must be calculated. One common approach uses “lumped parameters,” in which the voltage and current of both the intrinsically safe apparatus and the associated intrinsically safe apparatus are compared and matched according to Eqs. 100.1 and 100.2. Any deviation from either Eqs. 100.1 and 100.2 can compromise the integrity of the system and introduce hazardous conditions. The reactive parts of the system must also be considered and verified to demonstrate that C_a and L_a values of the associated apparatus are not exceeded by the field device and the field wiring values as shown in Eqs. 100.3 and 100.4. This method, although simple and effective, tends to exaggerate the wiring capacitance and inductance effect, which can be limiting in some applications. Another method takes advantage of the relation between the cable resistance and inductance. This method can be used if the L/R ratio of the associated apparatus is higher than the calculated L/R ratio of the cable. Under these conditions, the lesser D_a (maximum allowed distance) value can be ignored and the cable length can be extended to the higher D_a value. This method is more flexible where cable length is an issue. Figure 100.3 and the following example illustrate these methods.

(a)

(c)

$$L_c \leq L_a - L_i \quad 3.5 \text{ mH} - 2.0 \text{ mH} = 1.5 \text{ mH} \quad (100.4)$$

The maximum length of the field wiring, referred to its capacitance and inductance, is the lesser value of D_a .

$$D_a = 0.15 \mu\text{F}/150 \text{ pF/m} = 1000 \text{ m}$$

$$D_a = 1.5 \text{ mH}/2.0 \mu\text{H/m} = 750 \text{ m (maximum distance of field wiring)}$$

L/R ratio method:

Since the cable L/R ratio of $41.6 \mu\text{H}/\Omega$ ($2 \mu\text{H/m}/48 \Omega/\text{km}$) is less than the given associated apparatus L/R ratio, the inductive effect can be ignored and the maximum distance can be increased to 1000 m.

Certification and Approval

Although approval and certification processes help to provide safety, careful planning, designing, and engineering are still necessary. IS standards, procedures, and tests are recognized worldwide. Testing authorities include Underwriters Laboratories, Inc. (UL) and Factory Mutual Research Corp. (FM) in the U.S., Canadian Standards Association (CSA) in Canada, and Physikalisch-Technische Bundesanstalt (PTB) in Europe. Intrinsically safe products are suitable for all Classes, Divisions, and Groups outlined in Table 100.2. It is necessary to emphasize that the intrinsically safe product must be rated and classified for each specific application (Class, Division, and Group). In the U.S., FM adopted two methods for testing and approving equipment to be used in hazardous areas:

1. *Loop (System) Approval:* Where an intrinsically safe apparatus is evaluated in combination with a specific associated apparatus and is approved to be installed in this manner. Any changes to the circuit require reevaluation and certification (Fig. 100.4).
2. *Entity Approval:* Where an intrinsically safe apparatus and the associated apparatus are separately evaluated and given their own electrical entity parameters (Fig. 100.5). The correct application matches the entity parameters shown in Table 100.3. When examining the safety of a circuit, it is crucial to compare the entity values of an intrinsically safe apparatus with an associated apparatus.

Most safety barriers are entity approved for all hazardous locations. Since most field devices have the ability to store energy, they must have loop approval or entity approval for the proper construction and operation of an intrinsically safe system.

IS engineers often advocate the use of intrinsically safe equipment for the following reasons:

1. *Safety.* No explosion can occur in an intrinsically safe system under any operating condition. IS equipment operates on lower power levels and prevents shocks, excess thermal energy, and arcing. In different systems and under various scenarios, shocks, thermal energy, and arcing may cause a hazard.

FIGURE 100.5 Entity approval. Intrinsically safe apparatus and associated apparatus are evaluated separately.

2. *Reliability.* The components and assemblies of intrinsically safe circuits are tested for reliability before they are labeled and certified. Most intrinsically safe equipment is designed with special circuitry to provide surge suppression and to prevent spikes and transients.
3. *Ease of handling and installation.* Intrinsically safe systems tend to be small and do not require expensive, bulky accessories such as enclosures, seals, and rigid metallic conduits which increase the initial investment.
4. *Economy.* In some geographic locations, facilities containing hazardous conditions must carry special liability insurance. With the proper installation of intrinsically safe circuits and equipment, the probability of an explosion is 10^{-18} [8], or nearly nonexistent. As a result, insurance rates tend to be lower.
5. *Maintenance.* Equipment may be calibrated and maintained without disconnecting power, thereby resulting in less downtime.

The wiring of intrinsically safe systems is similar to any other application, but to ensure a proper operating system, certain guidelines regarding identification and separation must be strictly followed. All intrinsically safe components including terminal blocks, conductors, and intrinsically safe apparatus must be explicitly marked and labeled. The conventional color used to identify intrinsically safe equipment is blue. In an open wiring installation, intrinsically safe conductors must be physically separated from nonintrinsically safe conductors by at least 50 mm (2 in.) so an induced voltage does not defeat the purpose of IS. Where intrinsically safe conductors occupy a raceway, the raceway should be labeled, "Intrinsically Safe Circuits." Intrinsically safe conductors should not be placed with nonintrinsically safe conductors. Where a cable tray is used, a grounded sheet metal partition may be used as an acceptable means of separation. Where intrinsically safe and nonintrinsically safe conductors occupy the same enclosure, a 50-mm (2-in.) separation must be maintained. In addition, a grounded metal partition shall be in place to prevent contact of any conductors that may come loose. Insulation deterioration of intrinsically safe conductors of different circuits occupying the same raceway or enclosure can be detrimental to the operation of the system. Intrinsically safe conductors must have an insulation grade capable of withstanding an ac test voltage of 550 V root-mean-square (rms) or twice the operating voltage of the intrinsically safe circuit. Nonintrinsically safe conductors in the same enclosure with intrinsically safe conductors must have an insulation grade capable of withstanding an ac test voltage of $2U + 1000$ V, with a minimum of 1500 V rms, where U is the sum of rms values of the voltages of the intrinsically safe conductors. A commonly used and highly recommended practice utilizes separate compartments for intrinsically safe and nonintrinsically safe conductors. In addition to physical separation of intrinsically safe conductors and nonintrinsically safe conductors, sealing of conduits and raceways housing intrinsically safe conductors is essential to prevent the passage of gases, vapors, and dusts from hazardous to nonhazardous areas. According to the NEC, seal-offs are not required to be explosion-proof. Where an associated apparatus is installed in an explosion-proof enclosure in a hazardous area, seal-offs must be explosion-proof. Although it is not required by Code, it is a good engineering practice to install explosion-proof seal-offs on conduits housing intrinsically safe conductors, as shown in Fig. 100.6.

FIGURE 100.6 Explosion-proof seal-off fitting. (Courtesy of Crouse-Hinds Division of Cooper Industries, Inc.)

Explosion-Proof Fundamentals

Explosion-proof design is a mechanical concept that relies heavily on the mechanical construction of an enclosure and the narrow tolerances between its joints, threads, and flanges to safely contain, cool, and vent any internal explosion that may occur. By definition, explosion-proof enclosures must prevent the ignition of explosive gases or vapors that may surround it (Type 7 and Type 10 enclosures only). In hazardous areas, Class I, Divisions 1 and 2, arcing devices, such as switches, contactors, and motor starters must be enclosed in an explosion-proof enclosure specifically rated for that area. Contrary to popular belief, explosion-proof enclosures are not and should not be vapor-tight. Succinctly stated, an explosion inside an enclosure must be prevented from starting a larger explosion outside the enclosure. Unlike IS, explosion-proof enclosures address the maximum internal pressure (see NEMA Type 7 enclosures). [Figure 100.7](#) illustrates the rugged construction of a standard explosion-proof panel board.

In addition to its durability and strength, explosion-proof enclosures must also be “flame-tight.” The joints or flanges must be held within narrow tolerances to allow cooling of hot gases resulting from internal explosions. In this way, if any gases are released into the outside hazardous atmosphere, they are cool enough not to cause ignition.

Explosion-proof enclosures tend to be bulky (making them easy to identify) and heavy, requiring conduit seals and careful handling. Unlike intrinsically safe equipment, explosion-proof equipment operates on normal power levels which are necessary due to the high power requirements of some circuits and equipment. With the proper equipment, installation, and maintenance, explosion-proof enclosures can safely and effectively distribute high levels of voltage and power into hazardous areas.

Where ignitable amounts of dust are present, enclosures housing electric equipment must be dust-ignition-proof. These enclosures must exclude combustible dusts from entering, while preventing arcs, sparks, or heat generated internally from igniting dust surrounding the exterior of the enclosure. These enclosures must also efficiently dissipate the heat generated internally, since many types of dust will ignite at relatively low temperatures. Unlike Class I, Division 1 explosion-proof enclosures (Type 7), Class II, Division 1 dust-ignition-proof enclosures (Type 9) are designed to prevent an explosion. Subsequently, dust-ignition-proof enclosures need not be as strong or have walls as thick as explosion-proof enclosures since there will be no internal explosion.

Purging and Pressurization

This methodology allows the safe operation of electric equipment where hazardous conditions exist and where no other methodology is applicable because of the imperative high-energy demands and actual

FIGURE 100.7 Explosion-proof lighting panelboard. (Courtesy of Crouse-Hinds Division of Cooper Industries, Inc.)

physical dimensions. This is true for large-sized motors and switchgear units where they are not commercially available for Class I, Group A and B. In addition, this methodology is used where control panels that house the instruments and electric equipment must be located in hazardous areas. Purging and pressurization is a protection method that relies on clean air or inert gas (i.e., nitrogen) to be continuously supplied to the enclosure at sufficient flow to keep the equipment adequately cooled and to provide adequate internal pressure to prevent the influx of combustible atmospheres into the enclosure. Although the enclosures are not explosion-proof, they must be relatively vapor-tight and must have adequate strength to perform safely and satisfactorily. The system consists of

1. *Clean Air (or Inert Gas) Supply:* Careful study and analysis is of crucial importance to this process since the air supplied must be reasonably free of contaminants. Finding a safe location for an air intake requires skill and ingenuity. Consulting with an HVAC specialist is recommended. Other factors such as vapor density, location, wind pattern, and surrounding environment should also be considered. Where compressors and blowers are used to supply compressed air, caution must be exercised when selecting the proper compressor or blower size and location in order to meet airflow requirements without compromising the main objective of safety and reliability.
2. *Purging:* A pressurized enclosure that has been out of service for some time tends to collect a combustible mixture. Before energizing, inert gas and positive pressure must provide a sufficient initial clean air volume to minimize the concentration of any combustible mixture that may be present. For typical applications, a flow of four times the internal volume of the enclosure is usually sufficient to minimize the concentration of combustible mixture that may exist. For unusual applications, the flow volume must be carefully calculated to ensure the success of the purging process.

3. *Pressurization*: This process uses the concept of pressure differential between the outside and the inside of the enclosure to keep flammable materials from entering. This is accomplished by maintaining a higher pressure on the inside of the enclosure. For safe operation, the protected enclosure must be constantly maintained at a positive pressure of at least 25 Pa (0.1 in. water) [2] above the surrounding atmosphere during the operation of the protected equipment.
4. *Signals and Alarms*: When positive pressure is lost, warnings and alarms are essential. Three types of pressurization and alarms can be used, depending on the nature of the controls of the enclosure and the degree of hazard outside. In addition, door interlocks are required to prevent opening of the protected enclosure while the circuit is energized.

According to NFPA 496, there are three types of pressurization. They are

Type X — Reduces the classification within the protected enclosure from Division 1 to nonclassified. This usually involves a source of ignition housed in a tight enclosure located in a potentially hazardous atmosphere. Type X requires a disconnecting means (flow or pressure switch) to deenergize power to the protected enclosure completely and automatically immediately upon failure of the protective gas supply (loss of either pressure or flow). The disconnecting means must be explosion-proof or intrinsically safe, as it is usually located in the hazardous area.

Type Y — Reduces the classification within the protected enclosure from Division 1 to Division 2. The protected enclosure houses equipment rated for Division 2 and does not provide a source of ignition. Therefore, no immediate hazard is created. Type Y requires a visual or audible alarm in case of system failure. *Word of caution*: Safeguards must be established to ensure that any malfunction in the system does not raise the external surface temperature of the enclosure to over 80% of the ignition temperature of the combustible mixture present.

Type Z — Reduces the classification within the protected enclosure from Division 2 to nonclassified. Type Z requires a visual or audible alarm to be activated if failure to maintain positive pressure or flow within the protected enclosure has been detected.

Recognizing and understanding the potential dangers associated with the use of electricity in hazardous areas is a crucial part of selecting the best protection. Techniques for most applications, where the need for different energy demands is required, will likely involve a combination of various methodologies and specialized technologies. Properly performed analysis and investigation may appear to be time-consuming and expensive, but for those who are willing to adhere to the established guidelines and solid engineering practices, the process will help ensure the highest level of compliance while yielding tremendous savings and preventing property damage and injuries.

Defining Terms

Inductance: The ability of an electric apparatus to store an electric charge (energy). An inductor will release this energy when the circuit is opened (broken).

Oxidation: The process where negatively charged ions (anions) lose electrons at the anode during electrochemical process. For anions to become neutral, they must lose electrons.

Resistance temperature device (RTD): A device that measures temperature based on change of resistance.

Zener diode: A nonlinear solid state device that does not conduct current in reverse bias mode until a critical voltage is reached. It is then able to conduct current in reverse bias without damage to the diode. Zener diodes have almost constant voltage characteristics in the reverse bias region (usual operation).

Pulse Width–Modulated Power Amplifier • Measuring the System Dynamics

101.1 Introduction

There are many systems, such as robots, whose ability to move themselves or other objects is their primary purpose. There is a myriad of other systems, such as xerographic printers, where the motion is not the desired outcome but is required in the performance of the mainline objective. All of these systems require one or more “prime movers,” which directly or indirectly create all motion in the system.

All of these applications have differing requirements for both the type and precision of the motion produced. There are applications, such as children’s toys, that can perform well with imprecise motion requirements. Conversely, there are applications, such as printing, that require very precise motion control.

Depending on the type of motion required, a prime mover can be chosen from one of several candidates. The most ubiquitous motor types are dc brush type motors, dc brushless motors, and hybrid stepping motors. The system, which includes the prime mover, can be controlled simply as a function of time (i.e., open loop) or as a function of both time and system state (i.e., closed loop).

A closed-loop system requires some mechanism of measuring the “state” of the system. For motion systems, this is typically one or more sensors that measure position and/or velocity. In addition, for many of the control techniques, specifically, linear controllers, it is also advantageous to have a model of the system being controlled. The model can be used in conjunction with a plethora of design techniques to improve the dynamic response of the system significantly.

This chapter will describe the major modes of operations for the prime movers listed and will detail a method for measuring the open-loop response of a candidate motion system.

FIGURE 101.1 Typical torque–speed curve.

101.2 Hybrid Stepping Motors

Hybrid stepping motors are useful devices that provide fairly accurate positioning in the open loop: their most common mode of operation. They are successful in open-loop operation because they will remain within a commanded position increment or step as long as the motor has sufficient torque to resist any external torque applied by the system.

Since the motor operates in the open loop, it is chosen *a priori* to ensure it provides the torque necessary to remain within step. The maximum torque needed to operate the system is a function of the inertia of the system, the acceleration profile of the system, the external torque on the system, etc. Once the maximum torque required at every speed is determined, a motor can be chosen from its torque–speed curve. The torque–speed curve describes the maximum torque that can be tolerated at each speed without failing to follow a commanded step (referred to as a “losing step”). A motor whose torque–speed curve exceeds the torque requirements of the system at all speeds will be sufficient for the application. Figure 101.1 shows a typical torque–speed curve.

Hybrid stepping motors have a plurality of coils (almost always two) that, when commutated in a predefined sequence, cause the motor to turn. When the motor is operated in a mode referred to as “full stepping,” the current command to each winding is constant in magnitude, but varying in polarity (positive or negative). Note that the definition of which direction of current flow is “positive” is purely arbitrary. In this mode, the motor has only four separate energizations of the winding to complete a full revolution, although clever mechanical arrangements allow the number of steps per revolution to be greatly increased: typically 200 but as large as 800.

With two distinct windings (referred to as A and B), the four possible arrangements of winding energizations are A+B+, A+B–, A–B–, A–B+. If these combinations of winding currents are commanded to the motor in the sequence listed in the previous sentence, the motor will turn.

Chopping Current Amplifiers

As previously stated, the motion of the stepper requires a current of a particular amplitude to be applied. For economic reasons, most systems have a voltage power supply available (V_{ss}) — not a current source. A “current chopper” is a lost cost closed-loop switching amplifier that regulates the current to the motor

winding. It takes advantage of the fact that the motor winding has a significant inductance. The two motor windings have dynamic equations [1]

$$\begin{aligned} dI_A/dt &= (V_A - I_A R_A + K_b \omega \sin\theta)/L_A \\ dI_B/dt &= (V_B - I_B R_B + K_b \omega \cos\theta)/L_B \end{aligned} \quad (101.1)$$

where I is the current winding (A), R is the current resistance (Ω), L is the current inductance (H), V is the applied voltage to the winding (V), K_b is the torque constant of the motor (Nm/A), ω is the motor velocity (rad/s), and θ is the motor position (electrical rad).

Every t_s s (where t_s is very small, i.e., 10 μ s) the current chopper applies either V_{ss} or $-V_{ss}$ to the motor winding, depending on whether the desired current (I_M) is greater than or less than the measured (i.e., actual) winding current:

$$\begin{aligned} \text{if } (I_A > I_M), \quad V_A &= -V_{ss} \quad \text{else} \quad V_A = V_{ss} \\ \text{if } (I_B > I_M), \quad V_B &= -V_{ss} \quad \text{else} \quad V_B = V_{ss} \end{aligned} \quad (101.2)$$

The usual requirement is that ($V_{ss} t_s/L$) is small in comparison with I_M , resulting in a the chopping range that is small when compared with the desired current. Furthermore, the mechanical system that includes the motor is typically low pass in nature, so it will have minimal response to the small-amplitude, very high frequency components present in the motor winding current.

Microstepping

Another common open-loop mode for stepper operation is microstepping. In microstepping, the commanded reference positions can be between the “full-step” positions of the motor. The commanded currents for the reference position θ_{ref} are

$$\begin{aligned} I_A &= I_M \cos(\theta_{ref}) \\ I_B &= I_M \sin(\theta_{ref}) \end{aligned} \quad (101.3)$$

where θ_{ref} is the desired electrical position of the motor (in four full steps, θ_{ref} traverses one full electrical revolution). For constant velocity applications,

$$\theta_{ref} = N\omega_d t \quad (101.4)$$

where N is the number of electrical revolutions per mechanical revolution (one quarter the number of steps per revolution) of the motor and ω_d is the desired velocity (rad/s).

Closed-Loop Control

In addition to the open-loop uses of hybrid stepping motors, several researchers have recently invented methods of operating these motors in a closed-loop fashion. The principal difficulty arises because hybrid stepping motors are nonlinear devices, so the plethora of design techniques available in linear control theory cannot be directly applied. Hamman and Balas [1] use a fourth-order model to linearize the system about each step. This is useful in altering the undamped response of the stepper motor to a

commanded change in position. Schweid [2] suggests a scheme that allows good transient behavior during constant velocity applications, but uses the complete fourth-order model. In systems that use current choppers, a second-order model is sufficient. The following control law can then be applied [3-5]:

$$\begin{aligned} I_A &= I_M \cos(\theta_{\text{ref}}) - I_C \sin \theta \\ I_B &= I_M \sin(\theta_{\text{ref}}) + I_C \sin \theta \end{aligned} \quad (101.5)$$

The currents of Equation 101.6 linearize the model of the stepper motor, allowing common control techniques such as PID control to be applied [6]. The value I_M is used as an open-loop component to microstep the motor, while I_C is a feedback term that permits an improved dynamic response.

Position Measurement

The implementation of closed-loop control requires a method of measuring the position of the motor. Furthermore, there is the added constraint that this position measurement must be aligned with the motor construction and not have a positional offset with respect to it. This is because the control scheme of Equation 101.5 requires a command current I_C be multiplied by the sine and cosine of the motor position. One way to implement this is to have an incremental encoder with an index pulse attached to the motor. A calibration can then determine the relative position of the index pulse to the motor shaft and use this relationship in all future positional measurement.

Another scheme uses the back emf of the two coil windings to estimate the position. Some motors are constructed with additional sensing coils that allow easy measurement of these values. From Equation 101.2, the back emf of both coils can be found using

$$\begin{aligned} V_{\text{emfA}} &= -K_b \omega \sin \theta = V_A - I_A R_A - L_A dI_A/dt \\ V_{\text{emfB}} &= -K_b \omega \cos \theta = V_B - I_B R_B - L_B dI_B/dt \end{aligned} \quad (101.6)$$

and the position could be found using

$$\theta = \text{atan}(-V_{\text{emfA}}/V_{\text{emfB}}) \quad (101.7)$$

In most motors, however, V_{emfA} and V_{emfB} are not directly measurable. However, it is possible to obtain an excellent estimate of position in constant-velocity system by approximating the back emf signals through low-pass-filtered measurements of the coil voltages. One method developed at Xerox that has a U.S. patent (U.S. 5378975) is described here. Taking the Laplace transform of Equation 101.6 yields

$$\begin{aligned} V_{\text{emfA}}(s) &= V_A(s) - (R_A + sL_A)I_A(s) \\ V_{\text{emfB}}(s) &= V_B(s) - (R_B + sL_B)I_B(s) \end{aligned} \quad (101.8)$$

Filtering both sides with low-pass analog filters matched to the dynamics of the coil produces:

$$\begin{aligned} V_{\text{filtA}}(s) &= V_A(s) / \left(s(L_A/R_A) + 1 \right) - R_A I_A, \\ V_{\text{filtB}}(s) &= V_B(s) / \left(s(L_B/R_B) + 1 \right) - R_B I_B \end{aligned} \quad (101.9)$$

The quantities V_{filtA} and V_{filtB} are easily obtained by low-pass filtering the coil voltage with a simple RC circuit and subtracting the IR term. The subtraction is easily implemented because the current is a known input (in fact it is commanded), and the resistance is easily measured.

Assuming that the coils are matched: $L = L_A = L_B$, $R = R_A = R_B$ and the motor is moving at constant velocity, $\theta = N\omega_d t$, the back EMF voltages are sinusoidal. The low-pass-filtered versions of these voltages are given by

$$\begin{aligned} V_{\text{filtA}}(s) &= \left| H(N\omega_d) \right| K_B \sin(\theta + \phi) \\ V_{\text{filtB}}(s) &= \left| H(N\omega_d) \right| K_B \cos(\theta + \phi) \end{aligned} \quad (101.10)$$

where $|H(N\omega_d)|$ is the magnitude response of the low-pass filter at the input frequency, $N\omega_d$, and $\phi = -\text{atan}(N\omega_d L/R)$ is the phase shift due to the filtering. Dividing the two Equations 101.10 and taking the inverse tangent yields

$$\theta = \text{atan}\left(-V_{\text{filtA}}(t)/V_{\text{filtB}}(t)\right) + \text{atan}\left(N\omega_d L/R\right) \quad (101.11)$$

The full derivation and analysis are found in Reference 7. In addition, Reference 7 includes a Kalman filtering technique to improve the velocity measurement estimate from the position estimate. This is needed because the derivative or difference of the position measurement is highly sensitive to noise.

101.3 dc Brush and Brushless Motors

The dc servomotor is the oldest and probably the most commonly used actuator for servo systems. The name arises because a constant (or dc) voltage applied to the motor will produce motor movement. Over a linear range these motors exhibit a torque that is proportional to the current flowing in the winding. The chief disadvantage of the brush dc motor is the brush, which performs the mechanical commutation. These brushes are the first part of the motor to fail, severely limiting the reliability of dc brush motors when compared with other actuators.

Another motor that operates similarly to a dc brush motor is the dc brushless motor (a dc voltage will cause it to rotate). Its method of commutation, however, is much different. Whereas the dc motor accomplishes switching mechanically with brushes, the dc brushless motor contains Hall effect sensors that electronically control the switching. As a result, dc brushless motors have much greater life and reliability.

Pulse Width–Modulated Power Amplifier

In many systems where they operate, dc motors are required to have a varying voltage at their input in order to create the position or velocity profiles desired. Many of these systems, however, have only a single power supply V_{ss} . Rather than using analog power amplifiers that are both expensive and inefficient, a pulse width–modulated (PWM) amplifier is used. A pulse width power amplifier can deliver only V_{ss} or $-V_{\text{ss}}$ (or zero in some designs) V to the motor. Different voltages are delivered to the motor by varying the relative percentage that V_{ss} and $-V_{\text{ss}}$ are applied to the motor at a high fixed frequency. The mean or average voltage to the motor is a linear function of this relative percentage or duty cycle. The motor also receives the higher harmonics of the switched input that are integer multiples of the base frequency of the square wave. Most motors, however, have at least two poles (an electric and a mechanical) which are significantly slower than the switching frequency and thus greatly attenuate any possible effect they might have on motion. [Figure 101.2](#) shows a PWM amplifier set to deliver 12 V to the motor.

FIGURE 101.2 PWM amplifier set to deliver 12 V to the motor.

Measuring the System Dynamics

In systems with moderate or stringent motion requirements, the dc brush and brushless motors are operated in a closed-loop fashion. In order to perform in closed loop, some measure of either position or velocity is needed. A tachometer is commonly used to measure rotational speed. It outputs a voltage that is proportional to the speed of a rotating member. If a position measurement is required, an incremental encoder can be used. The incremental encoder produces a digital pulse at equal points in position. For example, a 1000 line/revolution encoder would produce a digital wave with 1000 rising (and falling) edges during one revolution.

Once the full system (including feedback sensors) is determined, a feedback control algorithm can be developed. As part of the design of many compensation algorithms, especially linear compensators such as state feedback or PID, one of the most important tasks is to have a good model of the dynamics of the system.

There are several ways to generate the model. One of the most common methods is to create the state equations of the system from the physical equations. This requires knowledge of all the parameters of the system. Sometimes these parameters are hard to measure and are not provided by the manufacturer. One example of this might be the torsional constant of a hard rubber roll in the system.

Even if all of the parameters are known, it is still desirable to have a method that measures the response of the system. This provides a way to either validate the model or to inform the designer that the model is not an accurate representation of the system.

A method is presented that permits the collection of input/output data of a system. This data can then be used to fit a frequency response curve or a transfer function model of the system. Signal analyzers, such as the HP3562A, have the ability to perform such curve fitting accurately. In addition, if the data are collected in a discrete fashion, there are commercially available software tools, such as MATLAB, that can provide model estimation in either a parametric (e.g., state space/transfer function) or nonparametric (e.g., frequency response) form. Although this procedure is described for motor systems, it is easily implemented in most linear systems.

Assume a typical closed-loop system as shown in Fig. 101.3. There are several obstacles that make it difficult to obtain the open- or closed-loop transfer function of this system. These obstacles include the inability to measure some of the outputs and the inability to control/modify certain inputs.

To acquire the frequency response of a system it is useful to perturb the system with a known input and measure the elicited response. A controllable input — one that can be externally manipulated — is required to accomplish this task. The only controllable inputs of the system in Fig. 101.3 are the torque acting upon the motor shaft and the reference command.

Changing the external torque would require mechanically attaching a calibrated brake or another motor. This is not only cumbersome, but it also can alter the system dynamics, as it introduces an inertia

FIGURE 101.3 Typical closed-loop system.

FIGURE 101.4

to the true system under measurement. Within many systems, the reference signal is a digital square wave (since the feedback element is an incremental encoder and produces a similar wave), and therefore requires a voltage-to-frequency converter if the reference is to be directly manipulated. This converter may include dynamics that can corrupt the measured data.

In addition to a controllable input, a measurable output must be available. In many servo systems, the only measurable outputs are the motor armature voltage and the position/velocity. The armature voltage may be a PWM signal that needs to be filtered to create an analog voltage. In the case of an incremental encoder, the output consists of a digital square wave generated by an incremental encoder: a frequency-to-voltage converter is required to produce an analog output. This converter may include dynamics that can corrupt the measured data.

Consider the system described in Fig. 101.4. The summing junction placed in the system has the advantage that can be added at any point that is convenient for measurement purposes — it is no longer limited to unaugmented system inputs or outputs.

In the case of analog controllers, the inputs and outputs of the summing junction are analog voltages, making them easily controlled and measured. The summing node can be easily implemented using a simple op-amp adder circuit. This introduces no appreciable dynamics into the original system and will not, therefore, skew the measured data.

When the system response is to be measured, the time-varying contributions of the other system inputs: the velocity reference and external torque, T_d , acting upon the system must be eliminated. The designer must set the velocity reference as a constant value. There is usually little control of the external torque acting on the system, and this will introduce noise into the measurement technique. To ensure a large signal-to-noise ratio (SNR), the alternative reference input (signal $z(t)$) should be made as large as possible.

The alternative reference input, $z(t)$, can stimulate the system with a swept sine input, a random input, or any other desired signal. During the stimulation, a time record is collected of the other nodes of the summing junction, $y(t)$ and $x(t)$. The transfer function between Y and X is

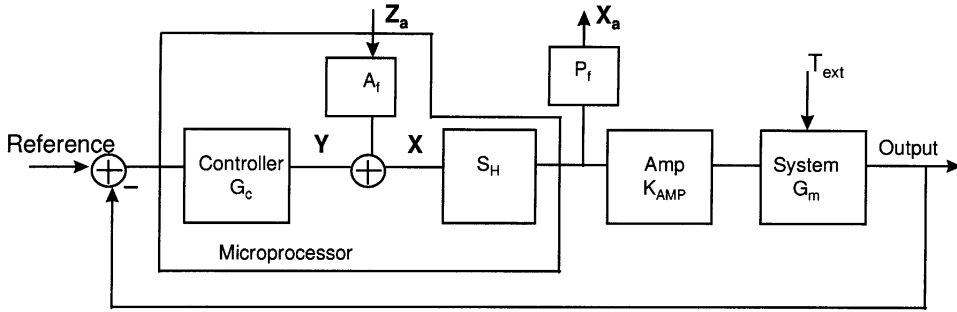

FIGURE 101.5

$$\mathbf{Y}(s)/\mathbf{X}(s) = -G_c(s)K_{amp}(s)G_m(s), \quad -\mathbf{Y}(s)/\mathbf{X}(s) = G_c(s)K_{amp}(s)G_m(s) \quad (101.12)$$

The second term is, by definition, the open-loop transfer function of the system. As before, MATLAB or a signal analyzer can provide either a parametric or nonparametric fit of this transfer function from the data record.

Note that this technique requires the system be functioning in a closed-loop mode during data collection. Typically, G_c is set as a proportional controller at a value that will ensure stability of the overall system. For a good data collection, the proportional gain should be made as large as possible.

The case of a digital or microprocessor-controlled system can be handled similarly, with some slight modification. Consider the system of Fig. 101.5, where a microprocessor acts as the system controller. In this instance, the summing junction can be implemented internal to the microprocessor by executing an add instruction. The problem here becomes getting the data into and out of the microprocessor. Getting the data into the microprocessor requires the addition of an analog-to-digital converter (ADC). In the block diagram, this ADC process is represented by the block A_f . A_f allows representation of any dynamics inherent in the ADC design (especially gain). The output of the microprocessor may be a digital PWM signal. This signal may need to be low-pass-filtered to create an analog voltage for the signal analyzer taking the data. The low-pass filter is represented by P_f in the Fig. 101.5. It is typically a simple RC circuit whose cutoff frequency is much lower than the PWM signal frequency.

Given the condition that ω_{ref} is static and external torque, T_d , is minimal, the transfer function between $\mathbf{Z}_a(s)$ and $\mathbf{X}_a(s)$ in Fig. 101.5 is

$$\mathbf{Z}_a(s)/\mathbf{X}_a(s) = \left(1 + G_c(s)S_H(s)K_{amp}(s)G_m(s)\right) / \left(A_f(s)S_H(s)P_f(s)\right) \equiv \mathbf{O}(s) \quad (101.13)$$

when $G_c = 0$, $\mathbf{Z}_a(s)/\mathbf{X}_a(s) = 1/(A_f(s)S_H(s)P_f(s)) \equiv \mathbf{C}(s)$, $(\mathbf{O}(s) - \mathbf{C}(s))/\mathbf{C}(s) = G_c(s)S_H(s)K_{amp}(s)G_m(s)$, this is the system open-loop transfer function.

A more direct approach is possible if a logic analyzer is not used but a software-based system identification package such as MATLAB is used to fit the data. The stimulus, z , can either be stored as a set of data in a lookup table in the microprocessor memory or can be generated in real time using any random number generator algorithm or other algorithm. The data Y and X at the internal summing junction can be captured via a logic analyzer or emulator if the values of $y(k)$ (the value of y at the k th sample period) and $x(k)$ are written to an external bus every sample period. Under this configuration neither a DAC nor ADC is necessary, nor is any mathematical combination of two different transfer functions required to produce the desired open-loop transfer function. The transfer function between $\mathbf{Y}(z)$ and $\mathbf{X}(z)$ is

$$\begin{aligned} \mathbf{Y}(z)/\mathbf{X}(z) &= -G_c(z)S_H(z)K_{amp}(z)G_m(z) \\ -\mathbf{Y}(z)/\mathbf{X}(z) &= G_c(z)S_H(z)K_{amp}(z)G_m(z) \end{aligned} \quad (101.14)$$

Again, this is the open-loop transfer function of the system, acquired using only minimal additional software and a logic analyzer. As before, the input/output set of data can be sent to any system identification algorithm to fit the transfer function.

Appendix

Units and Conversions

B. W. Petley

National Physical Laboratory

This appendix contains several tables that list the SI base units ([Table A.1](#)), define the SI base units ([Table A.2](#)), list their derived units ([Table A.3](#)), list their prefixes ([Table A.4](#)), and list their conversion units ([Table A.5](#)).

TABLE A.1 The SI Base Units

Base quantity	Name of Base Unit	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

TABLE A.2 The International Definitions of the SI Base Units^a

**unit of length
(meter)**

The meter is the length of the path traveled by light in vacuum during a time interval of $1/299\,792\,458$ of a second (17th CGPM,^b 1983, Resolution 1).

Note: The original international prototype, made of platinum-iridium, is kept at the BIPM^c under conditions specified by the 1st CGPM in 1889.

**unit of mass
(kilogram)**

The kilogram is the unit of mass: it is equal to the mass of the international prototype of the kilogram (3rd CGPM, (1901).

**unit of time
(second)**

The second is the duration of $9\,192\,631\,770$ periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom (13th CGPM, 1967, Resolution 1).

**unit of electric current
(ampere)**

The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible cross section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length (CIPM, 1946, Resolution 2 approved by the 9th CGPM, 1948).

Note: The expression “MKS unit of force” which occurs in the original text has been replaced here by “newton,” a name adopted for this unit by the 9th CGPM (1948), Resolution 7.

**unit of thermodynamic temperature
(kelvin)**

The kelvin, unit of thermodynamic temperature, is the fraction $1/273.16$ of the thermodynamic temperature of the triple point of water (13th CGPM, 1967, Resolution 4).

The 13th CGPM (1967, Resolution 3) also decided that the unit kelvin and its symbol K should be used to express an interval or a difference in temperature.

Note: In addition to the thermodynamic temperature (symbol T), expressed in kelvin, use is also made of Celsius temperature (symbol t) defined by the equation

$$t = T - T_0$$

where $T_0 = 273.15$ K by definition. To express Celsius temperature, the unit “degree Celsius” which is equal to the unit “kelvin” is used; in this case “degree Celsius” is a special name used in place of “kelvin.” An interval or difference of Celsius temperature can, however, be expressed in kelvins as well as degrees Celsius.

**unit of amount of substance
(mole)**

1. The mole is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12.
2. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles.

In the definition of the mole, it is understood that unbound atoms of carbon-12, at rest, and in their ground state, are referred to.

Note: This definition specifies at the same time the nature of the quantity whose unit is the mole.

**Unit of luminous intensity
(candela)**

The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of $(1/683)$ watt per steradian (16th CGPM, 1979, resolution 3).

^a The U.S. denotes the unit of length by “meter” in place of the international usage of “metre”.

^b CGPM: Conférence Général de Poids et Mesures; CIPM: Comité International des Poids et Mesures.

^c BIPM: Bureau International des Poids et Mesures.

TABLE A.3 SI Derived Units with Special Names^a

Derived quantity	Name	Symbol	Expressed in Terms of Other Units	Expressed in Terms of SI Base Units
Plane angle	radian	rad		m m ⁻¹
Solid angle	steradian	sr		m ² m ⁻²
Frequency	hertz	Hz		s ⁻¹
Force	newton	N		m kg s ⁻²
Pressure, stress	pascal	Pa	N m ⁻²	m ⁻¹ kg s ⁻²
Energy, work, quantity of heat	joule	J		m ² kg s ⁻²
Power, radiant flux	watt	W		m ² kg s ⁻³
Electric charge, quantity of electricity	coulomb	C		s A
Electric potential, potential difference, electromotive force	volt	V	W/A	m ² kg s ⁻³ A ⁻¹
Capacitance	farad	F	C/V	m ⁻² kg ⁻¹ s ⁴ A ²
Electric resistance	ohm	Ω	V/A	m ² kg s ⁻³ A ⁻²
Electric conductance	siemens	S	A/V	m ⁻² kg ⁻¹ s ³ A ²
Magnetic flux	weber	Wb	V s	m ² kg s ⁻² A ⁻¹
Magnetic flux density	tesla	T	Wb/m ²	kg s ⁻² A ⁻¹
Inductance	henry	H	Wb/A	m ² kg s ⁻² A ⁻²
Celsius temperature	degree Celsius	°C		K
Luminous flux	lumen	lm	cd sr	cd m ² m ⁻² = cd
Illuminance	lux	lx	m ⁻² cd sr	m ⁻² cd
Activity (referred to a radio nuclide)	becquerel	Bq		s ⁻¹
Absorbed dose, specific energy imparted, kerma	gray	Gy	J/kg	m ² s ⁻²
Dose equivalent, ambient dose equivalent, organ equivalent dose	sievert	Sr	J/kg	m ² s ⁻²

^a Note that when a unit is named after a person the *symbol* takes a capital letter and the *name* takes a lowercase letter.

TABLE A.4 SI Prefixes^a

Factor	Prefix	Symbol	Factor	Prefix	Symbol
10 ²⁴	yotta	Y	10 ⁻¹	deci	d
10 ²¹	zetta	Z	10 ⁻²	centi	c
10 ¹⁸	exa	E	10 ⁻³	milli	m
10 ¹⁵	peta	P	10 ⁻⁶	micro	μ
10 ¹²	tera	T	10 ⁻⁹	nano	n
10 ⁹	giga	G	10 ⁻¹²	pico	p
10 ⁶	mega	M	10 ⁻¹⁵	femto	f
10 ³	kilo	k	10 ⁻¹⁸	atto	a
10 ²	hecto	h	10 ⁻²¹	zepto	z
10	deca	da	10 ⁻²⁴	yocto	y

^a The 11th CGPM (1960, Resolution 12) adopted a first series of prefixes and symbols of prefixes to form the names and symbols of the decimal multiples and submultiples of SI units. Prefixes for 10⁻¹⁵ and 10⁻¹⁸ were added by the 12th CGPM (1964, Resolution 8), those for 10¹⁵ and 10¹⁸ by the 15th CGPM (1975, Resolution 10), and those for 10²¹, 10²⁴, 10⁻²¹, and 10⁻²⁴ were proposed by the CIPM (1990) for approval by the 19th CGPM (1991).

1 quart (U.S. dry)	$1.101\ 221 \times 10^{-3} \text{ m}^3$
1 gallon (U.S. dry)	$4.404\ 884 \times 10^{-3} \text{ m}^3$
1 peck	$8.809\ 768 \times 10^{-3} \text{ m}^3$
1 bushel (U.S.) [2150.42 in. ³]	$3.523\ 907 \times 10^{-2} \text{ m}^3$

^aThe conversion factor for a compound unit is usually not given here if it may easily be derived from simpler conversions; e.g., the conversion factors for "ft/s" to "m/s" or "ft/s²" to "m/s²" are not given, since they may be obtained from the conversion factor for "ft." Values are given to five or six significant digits except for exact values, which are usually indicated in bold type. A few former cgs measures are also included.

^bThe International Steam Table calorie of 1956.

^cIn practice the prefix kilo is usually omitted. The kilogram calorie or large calorie is an obsolete term for the kilocalorie which is used to express the energy content of foods.

^dTypographer's definition, 1886.

^eOriginally, in 1929, the International nautical mile.

^fBased on 1 day = 86,400 s and 1 Julian century = 36,525 days.

^gPost 1964 value, SI symbol l or L. Between 1901 and 1964 the liter was defined as 1.000th 028 dm³.

^hAlthough often given, it is doubtful whether normal usage justifies this accuracy. In Europe and elsewhere the teaspoon and tablespoon are usually exactly 5 mL and 15 mL, respectively.
