Preface

Introduction

The purpose of *Measurement, Instrumentation, and Sensors Handbook CRCnetBase 1999* is to provide a reference that is both concise and useful for engineers in industry, scientists, designers, managers, research personnel and students, as well as many others who have measurement problems. The *CD-ROM* covers an extensive range of topics that comprise the subject of measurement, instrumentation, and sensors.

The *CD-ROM* describes the use of instruments and techniques for practical measurements required in engineering, physics, chemistry, and the life sciences. It includes sensors, techniques, hardware, and software. It also includes information processing systems, automatic data acquisition, reduction and analysis and their incorporation for control purposes.

Articles include descriptive information for professionals, students, and workers interested in measurement. Articles include equations to assist engineers and scientists who seek to discover applications and solve problems that arise in fields not in their specialty. They include specialized information needed by informed specialists who seek to learn advanced applications of the subject, evaluative opinions, and possible areas for future study. Thus, the *CD-ROM* serves the reference needs of the broadest group of users — from the advanced high school science student to industrial and university professionals.

Organization

The *CD-ROM* is organized according to the *measurement problem*. Section I includes general instrumentation topics, such as accuracy and standards. Section II covers spatial variables, such as displacement and position. Section III includes time and frequency. Section IV covers solid mechanical variables such as mass and strain. Section V comprises fluid mechanical variables such as pressure, flow, and velocity. Section VI covers thermal mechanical variables such as temperature and heat flux. Section VII includes electromagnetic variables such as voltage and capacitance. Section VIII covers optical variables such as photometry and image sensors. Section IX includes radiation such as x rays and dosimetry. Section X covers chemical variables in composition and environmental measurements. Section XI includes biomedical variables such as blood flow and medical imaging. Section XII comprises signal processing such as amplifiers and computers. Section XIII covers display such as cathode ray tube and recorder. Section XIV includes control such as optimal control and motion control. The Appendix contains conversion factors to SI units.

Locating Your Topic

To find out how to measure a given variable, do a word or phrase search, select the section and the chapters that describe different methods of making the measurement. Consider the alternative methods of making the measurement and each of their advantages and disadvantages. Select a method, sensor,

and signal processing method. Many articles list a number of vendors to contact for more information. You can also visit the <http://www.sensorsmag.com> site under Buyer's Guide to obtain a list of vendors.

Acknowledgments

I appreciate the help of the many people who worked on this handbook. David Beams assisted me by searching books, journals, and the Web for all types of measurements, then helped me to organize the outline. The Advisory Board made suggestions for revision and suggested many of the authors. Searching the INSPEC database yielded other authors who had published on a measurement method. At CRC Press, Felicia Shapiro, Associate Production Manager; Kristen Maus, Developmental Editor; Suzanne Lassandro, Book Group Production Director; and Susan Fox, Project Editor, produced the book.

John G. Webster
Editor-in-Chief

Editor-in-Chief

John G. Webster received the B.E.E. degree from Cornell University, Ithaca, NY, in 1953, and the M.S.E.E. and Ph.D. degrees from the University of Rochester, Rochester, NY, in 1965 and 1967, respectively.

He is Professor of Electrical and Computer Engineering at the University of Wisconsin-Madison. In the field of medical instrumentation he teaches undergraduate and graduate courses, and does research on RF cardiac ablation and measurement of vigilance.

He is author of *Transducers and Sensors*, An IEEE/EAB Individual Learning Program (Piscataway, NJ: IEEE, 1989). He is co-author, with B. Jacobson, of *Medicine and Clinical Engineering* (Englewood Cliffs, NJ: Prentice-Hall, 1977), with R. Pallás-Areny, of *Sensors and Signal Conditioning* (New York: Wiley, 1991), and with R. Pallas-Areny, of *Analog Signal Conditioning* (New York: Wiley, 1999). He is editor of *Encyclopedia of Medical Devices and Instrumentation* (New York: Wiley, 1988), *Tactile Sensors for Robotics and Medicine* (New York: Wiley, 1988), *Electrical Impedance Tomography* (Bristol, UK: Adam Hilger, 1990), *Teaching Design in Electrical Engineering* (Piscataway, NJ: Educational Activities Board, IEEE, 1990), *Prevention of Pressure Sores: Engineering and Clinical Aspects* (Bristol, UK: Adam Hilger, 1991), *Design of Cardiac Pacemakers* (Piscataway, NJ: IEEE Press, 1995), *Design of Pulse Oximeters* (Bristol, UK: IOP Publishing, 1997), *Medical Instrumentation: Application and Design, Third Edition* (New York: Wiley, 1998), and *Encyclopedia of Electrical and Electronics Engineering* (New York, Wiley, 1999). He is co-editor, with A. M. Cook, of *Clinical Engineering: Principles and Practices* (Englewood Cliffs, NJ: Prentice-Hall, 1979) and *Therapeutic Medical Devices: Application and Design* (Englewood Cliffs, NJ: Prentice-Hall, 1982), with W. J. Tompkins, of *Design of Microcomputer-Based Medical Instrumentation* (Englewood Cliffs, NJ: Prentice-Hall, 1981) and *Interfacing Sensors to the IBM PC* (Englewood Cliffs, NJ: Prentice Hall, 1988), and with A. M. Cook, W. J. Tompkins, and G. C. Vanderheiden, *Electronic Devices for Rehabilitation* (London: Chapman & Hall, 1985).

Dr. Webster has been a member of the IEEE-EMBS Administrative Committee and the NIH Surgery and Bioengineering Study Section. He is a fellow of the Institute of Electrical and Electronics Engineers, the Instrument Society of America, and the American Institute of Medical and Biological Engineering. He is the recipient of the AAMI Foundation Laufman-Greatbatch Prize and the ASEE/Biomedical Engineering Division, Theo C. Pilkington Outstanding Educator Award.

Contents

Section I Measurement Characteristics

- 1 Characteristics of Instrumentation *R. John Hansman, Jr.*
- 2 Operational Modes of Instrumentation *Richard S. Figliola*
- 3 Static and Dynamic Characteristics of Instrumentation
Peter H. Sydenham
- 4 Measurement Accuracy *Ronald H. Dieck*
- 5 Measurement Standards *DeWayne B. Sharp*

Section II Spatial Variables Measurement

- 6 Displacement Measurement, Linear and Angular
 - 6.1 Resistive Displacement Sensors *Keith Antonelli, James Ko, and Shyan Ku*
 - 6.2 Inductive Displacement Sensors *Halit Eren*
 - 6.3 Capacitive Sensors—Displacement *Halit Eren and Wei Ling Kong*
 - 6.4 Piezoelectric Transducers and Sensors *Ahmad Safari, Victor F. Janas, Amit Bandyopadhyay, and Andrei Kholkin*
 - 6.5 Laser Interferometer Displacement Sensors *Bernhard Günther Zagar*
 - 6.6 Bore Gaging Displacement Sensors *Viktor P. Astakhov*
 - 6.7 Time-of-Flight Ultrasonic Displacement Sensors
Teklic Ole Pedersen and Nils Karlsson
 - 6.8 Optical Encoder Displacement Sensors *J. R. René Mayer*
 - 6.9 Magnetic Displacement Sensors *David S. Nyce*
 - 6.10 Synchro/Resolver Displacement Sensors
Robert M. Hyatt, Jr. and David Dayton
 - 6.11 Optical Fiber Displacement Sensors
Richard O. Claus, Vikram Bhatia, and Anbo Wang
 - 6.12 Optical Beam Deflection Sensing *Grover C. Wetsel*

- 7 Thickness Measurement *John C. Brasunas, G. Mark Cushman, and Brook Lakew*
- 8 Proximity Sensing for Robotics *R.E. Saad, A. Bonen, K.C. Smith, and B. Benhabib*
- 9 Distance *W. John Ballantyne*
- 10 Position, Location, Altitude Measurement
- 10.1 Altitude Measurement *Dimitris E. Manolakis*
 - 10.2 Attitude Measurement *Mark A. Stedham, Partha B. Banerjee, Seiji Nishfuji, and Shogo Tanaka*

Estimation

In addressing measurement problems, it is often useful to have a conceptual model of the measurement process. This chapter presents some of the fundamental concepts of measurement in the context of a simple generalized instrument model.

In abstract terms, an *instrument* is a device that transforms a *physical variable* of interest (the *measurand*) into a form that is suitable for recording (the *measurement*). In order for the measurement to have broad and consistent meaning, it is common to employ a standard system of *units* by which the measurement from one instrument can be compared with the measurement of another.

An example of a basic instrument is a ruler. In this case the measurand is the length of some object and the measurement is the number of units (meters, inches, etc.) that represent the length.

1.1 Simple Instrument Model

Figure 1.1 presents a generalized model of a simple instrument. The physical process to be measured is in the left of the figure and the measurand is represented by an observable physical variable X . Note that the observable variable X need not necessarily be the measurand but simply related to the measurand in some known way. For example, the mass of an object is often measured by the process of *weighing*, where the measurand is the mass but the physical measurement variable is the downward force the mass exerts in the Earth's gravitational field. There are many possible physical measurement variables. A few are shown in Table 1.1.

The key functional element of the instrument model shown in Figure 1.1 is the *sensor*, which has the function of converting the *physical variable input* into a *signal variable output*. Signal variables have the property that they can be manipulated in a transmission system, such as an electrical or mechanical circuit. Because of this property, the signal variable can be transmitted to an output or recording device that can be remote from the sensor. In electrical circuits, voltage is a common signal variable. In mechanical systems, displacement or force are commonly used as signal variables. Other examples of signal variable are shown in Table 1.1. The signal output from the sensor can be displayed, recorded, or used as an input signal to some secondary device or system. In a basic instrument, the signal is transmitted to a *display* or recording device where the measurement can be read by a human observer. The observed output is the measurement M . There are many types of display devices, ranging from simple scales and dial gages to sophisticated computer display systems. The signal can also be used directly by some larger

FIGURE 1.2 Instrument model with amplifier, analog to digital converter, and computer output.

system of which the instrument is a part. For example, the output signal of the sensor may be used as the input signal of a closed loop control system.

If the signal output from the sensor is small, it is sometimes necessary to amplify the output shown in Figure 1.2. The amplified output can then be transmitted to the display device or recorded, depending on the particular measurement application. In many cases it is necessary for the instrument to provide a digital signal output so that it can interface with a computer-based data acquisition or communications system. If the sensor does not inherently provide a digital output, then the analog output of the sensor is converted by an analog to digital converter (ADC) as shown in Figure 1.2. The digital signal is typically sent to a computer processor that can display, store, or transmit the data as output to some other system, which will use the measurement.

Passive and Active Sensors

As discussed above, sensors convert physical variables to signal variables. Sensors are often transducers in that they are devices that convert input energy of one form into output energy of another form. Sensors

FIGURE 1.3 Calibration curve example.

can be categorized into two broad classes depending on how they interact with the environment they are measuring. *Passive sensors* do not add energy as part of the measurement process but may remove energy in their operation. One example of a passive sensor is a thermocouple, which converts a physical temperature into a voltage signal. In this case, the temperature gradient in the environment generates a thermoelectric voltage that becomes the signal variable. Another passive transducer is a pressure gage where the pressure being measured exerts a force on a mechanical system (diaphragm, aneroid or Borden pressure gage) that converts the pressure force into a displacement, which can be used as a signal variable. For example, the displacement of the diaphragm can be transmitted through a mechanical gearing system to the displacement of an indicating needle on the display of the gage.

Active sensors add energy to the measurement environment as part of the measurement process. An example of an active sensor is a radar or sonar system, where the distance to some object is measured by actively sending out a radio (radar) or acoustic (sonar) wave to reflect off of some object and measure its range from the sensor.

Calibration

The relationship between the physical measurement variable input and the signal variable (output) for a specific sensor is known as the *calibration* of the sensor. Typically, a sensor (or an entire instrument system) is calibrated by providing a known physical input to the system and recording the output. The data are plotted on a calibration curve such as the example shown in Figure 1.3. In this example, the sensor has a linear response for values of the physical input less than X_0 . The *sensitivity* of the device is determined by the slope of the calibration curve. In this example, for values of the physical input greater than X_0 , the calibration curve becomes less sensitive until it reaches a limiting value of the output signal. This behavior is referred to as *saturation*, and the sensor cannot be used for measurements greater than its saturation value. In some cases, the sensor will not respond to very small values of the physical input variable. The difference between the smallest and largest physical inputs that can reliably be measured by an instrument determines the *dynamic range* of the device.

Modifying and Interfering Inputs

In some cases, the sensor output will be influenced by physical variables other than the intended measurand. In Figure 1.4, X is the intended measurand, Y is an *interfering input*, and Z is a *modifying input*. The interfering input Y causes the sensor to respond in the same manner as the linear superposition of Y and the intended measurand X . The measured signal output is therefore a combination of X and Y ,

FIGURE 1.4 Interfering inputs.

FIGURE 1.5 Illustration of the effect of a modifying input on a calibration curve.

with Y interfering with the intended measurand X . An example of an interfering input would be a structural vibration within a force measurement system.

Modifying inputs changes the behavior of the sensor or measurement system, thereby modifying the input/output relationship and calibration of the device. This is shown schematically in Figure 1.5. For various values of Z in Figure 1.5, the slope of the calibration curve changes. Consequently, changing Z will result in a change of the apparent measurement even if the physical input variable X remains constant. A common example of a modifying input is temperature; it is for this reason that many devices are calibrated at specified temperatures.

Accuracy and Error

The *accuracy* of an instrument is defined as the difference between the *true value* of the measurand and the *measured value* indicated by the instrument. Typically, the true value is defined in reference to some absolute or agreed upon standard. For any particular measurement there will be some error due to

FIGURE 1.6 Target analogy of measurement accuracy.

systematic (bias) and *random (noise)* error sources. The combination of systematic and random error can be visualized by considering the analogy of the target shown in Figure 1.6. The total error in each shot results from both systematic and random errors. The systematic (bias) error results in the grouping of shots being offset from the bulls eye (presumably a misalignment of the gunsight or wind). The size of the grouping is determined by random error sources and is a measure of the *precision* of the shooting.

Systematic Error Sources (Bias)

There are a variety of factors that can result in systematic measurement errors. One class of cause factors are those that change the input–output response of a sensor resulting in miscalibration. The modifying inputs and interfering inputs discussed above can result in sensor miscalibration. For example, if temperature is a modifying input, using the sensor at a temperature other than the calibrated temperature will result in a systematic error. In many cases, if the systematic error source is known, it can be corrected for by the use of *compensation methods*.

There are other factors that can also cause a change in sensor calibration resulting in systematic errors. In some sensors, aging of the components will change the sensor response and hence the calibration. Damage or abuse of the sensor can also change the calibration. In order to prevent these systematic errors, sensors should be periodically recalibrated.

Systematic errors can also be introduced if the measurement process itself changes the intended measurand. This issue, defined as *invasiveness*, is a key concern in many measurement problems. Interaction between measurement and measurement device is always present; however, in many cases, it can be reduced to an insignificant level. For example, in electronic systems, the energy drain of a measuring device can be made negligible by making the input impedance very high. An extreme example of invasiveness would be to use a large warm thermometer to measure the temperature of a small volume of cold fluid. Heat would be transferred from the thermometer and would warm the fluid, resulting in an inaccurate measurement.

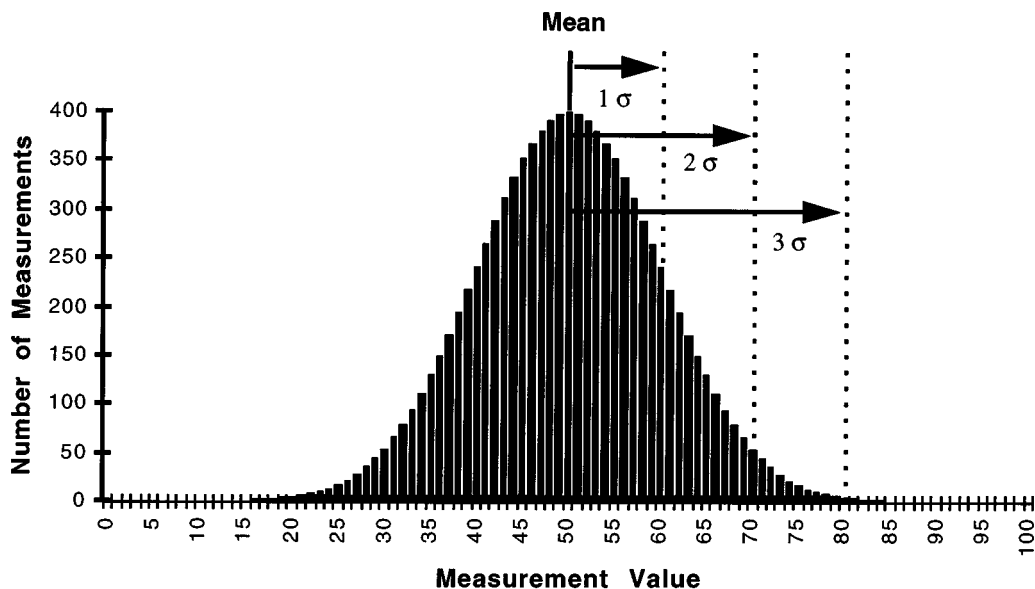

FIGURE 1.7 Example of a Gaussian distribution.

Systematic errors can also be introduced in the signal path of the measurement process shown in Figure 1.3. If the signal is modified in some way, the indicated measurement will be different from the sensed value. In physical signal paths such as mechanical systems that transmit force or displacement, friction can modify the propagation of the signal. In electrical circuits, resistance or attenuation can also modify the signal, resulting in a systematic error.

Finally, systematic errors or bias can be introduced by human observers when reading the measurement. A common example of observer bias error is *parallax error*. This is the error that results when an observer reads a dial from a non-normal angle. Because the indicating needle is above the dial face, the apparent reading will be shifted from the correct value.

Random Error Sources (Noise)

If systematic errors can be removed from a measurement, some error will remain due to the random error sources that define the precision of the measurement. Random error is sometimes referred to as *noise*, which is defined as a signal that carries no useful information. If a measurement with true random error is repeated a large number of times, it will exhibit a *Gaussian distribution*, as demonstrated in the example in Figure 1.7 by plotting the number of times values within specific ranges are measured. The Gaussian distribution is centered on the true value (presuming no systematic errors), so the mean or average of all the measurements will yield a good estimate of the true value.

The precision of the measurement is normally quantified by the standard deviation (σ) that indicates the width of the Gaussian distribution. Given a large number of measurements, a total of 68% of the measurements will fall within $\pm 1\sigma$ of the mean; 95% will fall within $\pm 2\sigma$; and 99.7% will fall within $\pm 3\sigma$. The smaller the standard deviation, the more precise the measurement. For many applications, it is common to refer to the 2σ value when reporting the precision of a measurement. However, for some applications such as navigation, it is common to report the 3σ value, which defines the limit of likely uncertainty in the measurement.

There are a variety of sources of randomness that can degrade the precision of the measurement — starting with the repeatability of the measurand itself. For example, if the height of a rough surface is to be measured, the measured value will depend on the exact location at which the measurement is taken. Repeated measurements will reflect the randomness of the surface roughness.

FIGURE 1.8 Instrument model with noise sources.

FIGURE 1.9 Example of sensor fusion.

Random error generating noise can also be introduced at each stage in the measurement process, as shown schematically in Figure 1.8. Random interfering inputs will result in noise from the measurement environment N_1 that are introduced before the sensor, as shown in the figure. An example would be background noise received by a microphone. Sensor noise N_2 can also be introduced within the sensor. An example of this would be thermal noise within a sensitive transducer, such as an infrared sensor. Random motion of electrons, due to temperature, appear as voltage signals, which are apparently due to the high sensitivity of the device. For very sensitive measurements with transducers of this type (e.g., infrared detectors), it is common to cool the detector to minimize this noise source.

Noise N_3 can also be introduced in the transmission path between the transducer and the amplifier. A common example of transmission noise in the U.S. is 60 Hz interference from the electric power grid that is introduced if the transmission path is not well grounded, or if an inadvertent electric grand loop causes the wiring to act as an antenna.

It is important to note that the noise will be amplified along with the signal as it passes through the amplifier in Figure 1.8. As a consequence, the figure of merit when analyzing noise is not the level of the combined noise sources, but the *signal to noise ratio* (SNR), defined as the ratio of the signal power to the power in the combined noise sources. It is common to report SNR in decibel units.

The SNR is ideally much greater than 1 (0 dB). However, it is sometimes possible to interpret a signal that is lower than the noise level if some identifying characteristics of that signal are known and sufficient signal processing power is available. The human ability to hear a voice in a loud noise environment is an example of this signal processing capability.

Sensor Fusion

The process of *sensor fusion* is modeled in Figure 1.9. In this case, two or more sensors are used to observe the environment and their output signals are combined in some manner (typically in a processor) to

provide a single enhanced measurement. This process frequently allows measurement of phenomena that would otherwise be unobservable. One simple example is thermal compensation of a transducer where a measurement of temperature is made and used to correct the transducer output for modifying effects of temperature on the transducer calibration. Other more sophisticated sensor fusion applications range to image synthesis where radar, optical, and infrared images can be combined into a single enhanced image.

Estimation

With the use of computational power, it is often possible to improve the accuracy of a poor quality measurement through the use of *estimation techniques*. These methods range from simple averaging or low-pass filtering to cancel out random fluctuating errors to more sophisticated techniques such as Wiener or Kalman filtering and model-based estimation techniques. The increasing capability and lowering cost of computation makes it increasingly attractive to use lower performance sensors with more sophisticated estimation techniques in many applications.

Operational Modes of Instrumentation

Richard S. Figliola
Clemson University

- 2.1 Null Instrument
- 2.2 Deflection Instrument
- 2.3 Analog and Digital Sensors
- 2.4 Analog and Digital Readout Instruments
- 2.5 Input Impedance

2.1 Null Instrument

The null method is one possible mode of operation for a measuring instrument. A **null instrument** uses the null method for measurement. In this method, the instrument exerts an influence on the measured system so as to oppose the effect of the **measurand**. The influence and the measurand are balanced until they are equal but opposite in value, yielding a null measurement. Typically, this is accomplished by some type of feedback operation that allows the comparison of the measurand against a known standard value. Key features of a null instrument include: an iterative balancing operation using some type of comparator, either a manual or automatic feedback used to achieve balance, and a null deflection at parity.

A null instrument offers certain intrinsic advantages over other modes of operation (e.g., see deflection instruments). By balancing the unknown input against a known standard input, the null method minimizes interaction between the measuring system and the measurand. As each input comes from a separate source, the significance of any measuring influence on the measurand by the measurement process is reduced. In effect, the measured system sees a very high input impedance, thereby minimizing loading errors. This is particularly effective when the measurand is a very small value. Hence, the null operation can achieve a high accuracy for small input values and a low loading error. In practice, the null instrument will not achieve perfect parity due to the usable **resolution** of the balance and detection methods, but this is limited only by the state of the art of the circuit or scheme being employed.

A disadvantage of null instruments is that an iterative balancing operation requires more time to execute than simply measuring **sensor** input. Thus, this method might not offer the fastest measurement possible when high-speed measurements are required. However, the user should weigh achievable accuracy against needed speed of measurement when considering operational modes. Further, the design of the comparator and balance loop can become involved such that highly accurate devices are generally not the lowest cost measuring alternative.

An equal arm balance scale is a good mechanical example of a manual balance-feedback null instrument, as shown in **Figure 2.1**. This scale compares the unknown weight of an object on one side against a set of standard or known weights. Known values of weight are iteratively added to one side to exert an influence to oppose the effect of the unknown weight on the opposite side. Until parity, a high or low value is noted by the indicator providing the feedback logic to the operator for adding or removing

FIGURE 2.1 The measurand and the known quantities balance one another in a null instrument.

weights in a balancing iteration. At true parity, the scale indicator is null; that is, it indicates a zero deflection. Then, the unknown input or measurand is deduced to have a value equal to the balance input, the amount of known weights used to balance the scale. Factors influencing the overall measurement accuracy include the accuracy of the standard weights used and resolution of the output indicator, and the friction at the fulcrum. Null instruments exist for measurement of most variables. Other common examples include bridge circuits, often employed for highly accurate resistance measurements and found in load cells, temperature-compensated transducers, and voltage balancing potentiometers used for highly accurate low-voltage measurements.

Within the null instrument, the iteration and feedback mechanism is a loop that can be controlled either manually or automatically. Essential to the null instrument are two inputs: the measurand and the balance input. The null instrument includes a differential comparator, which compares and computes the difference between these two inputs. This is illustrated in Figure 2.2. A nonzero output from the comparator provides the error signal and drives the logic for the feedback correction. Repeated corrections provide for an iteration toward eventual parity between the inputs and results in the null condition where the measurand is exactly opposed by the balance input. At parity, the error signal is driven to zero by the opposed influence of the balance input and the indicated deflection is at null, thus lending the name to the method. It is the magnitude of the balance input that drives the output reading in terms of the measurand.

2.2 Deflection Instrument

The deflection method is one possible mode of operation for a measuring instrument. A **deflection instrument** uses the deflection method for measurement. A deflection instrument is influenced by the measurand so as to bring about a proportional response within the instrument. This response is an output reading that is a deflection or a deviation from the initial condition of the instrument. In a typical form, the measurand acts directly on a prime element or primary circuit so as to convert its information into a detectable form. The name is derived from a common form of instrument where there is a physical deflection of a prime element that is linked to an output scale, such as a pointer or other type of readout, which deflects to indicate the measured value. The magnitude of the deflection of the prime element brings about a deflection in the output scale that is designed to be proportional in magnitude to the value of the measurand.

FIGURE 2.2 A null instrument requires input from two sources for comparison.

Deflection instruments are the most common of measuring instruments. The relationship between the measurand and the prime element or measuring circuit can be a direct one, with no balancing mechanism or comparator circuits used. The proportional response can be manipulated through signal conditioning methods between the prime element and the output scale so that the output reading is a direct indication of the measurand. Effective designs can achieve a high accuracy, yet sufficient accuracy for less demanding uses can be achieved at moderate costs.

An attractive feature of the deflection instrument is that it can be designed for either static or dynamic measurements or both. An advantage to deflection design for dynamic measurements is in the high dynamic response that can be achieved. A disadvantage of deflection instruments is that by deriving its energy from the measurand, the act of measurement will influence the measurand and change the value of the variable being measured. This change is called a loading error. Hence, the user must ensure that the resulting error is acceptable. This usually involves a careful look at the instrument input impedance for the intended measurement.

A spring scale is a good, simple example of a deflection instrument. As shown in Figure 2.3, the input weight or measurand acts on a plate-spring. The plate-spring serves as a prime element. The original position of the spring is influenced by the applied weight and responds with a translational displacement, a deflection x . The final value of this deflection is a position that is at equilibrium between the downward force of the weight, W , and the upward restoring force of the spring, kx . That is, the input force is balanced against the restoring force. A mechanical coupler is connected directly or by linkage to a pointer. The pointer position is mapped out on a corresponding scale that serves as the readout scale. For example, at equilibrium $W = kx$ or by measuring the deflection of the pointer the weight is deduced by $x = W/k$.

The flow diagram logic for a deflection instrument is rather linear, as shown in Figure 2.4. The input signal is sensed by the prime element or primary circuit and thereby deflected from its initial setting. The deflection signal is transmitted to signal conditioners that act to condition the signal into a desired form. Examples of signal conditioning are to multiply the deflection signal by some scaler magnitude, such as in amplification or filtering, or to transform the signal by some arithmetic function. The conditioned signal is then transferred to the output scale, which provides the indicated value corresponding to the measurand value.

FIGURE 2.3 A deflection instrument requires input from only one source, but may introduce a loading error.

FIGURE 2.4 The logic flow chart for a deflection instrument is straightforward.

2.3 Analog and Digital Sensors

Analog sensors provide a signal that is continuous in both its magnitude and its temporal (time) or spatial (space) content. The defining word for analog is “continuous.” If a sensor provides a continuous output signal that is directly proportional to the input signal, then it is analog.

Most physical variables, such as current, temperature, displacement, acceleration, speed, pressure, light intensity, and strain, tend to be continuous in nature and are readily measured by an analog sensor and represented by an analog signal. For example, the temperature within a room can take on any value within its range, will vary in a continuous manner in between any two points in the room, and may vary continuously with time at any position within the room. An analog sensor, such as a bulb thermometer or a thermocouple, will continuously respond to such temperature changes. Such a continuous signal is shown in Figure 2.5, where the signal magnitude is analogous to the measured variable (temperature) and the signal is continuous in both magnitude and time.

Digital sensors provide a signal that is a direct digital representation of the measurand. Digital sensors are basically binary (“on” or “off”) devices. Essentially, a digital signal exists at only discrete values of

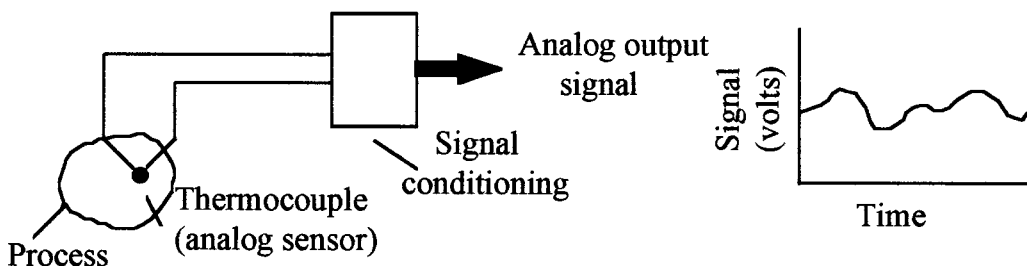

FIGURE 2.5 A thermocouple provides an analog signal for processing.

FIGURE 2.6 A rotating shaft with a revolution counter produces a digital signal.

time (or space). And within that discrete period, the signal can represent only a discrete number of magnitude values. A common variation is the **discrete sampled signal** representation, which represents a sensor output in a form that is discrete both in time or space and in magnitude.

Digital sensors use some variation of a binary numbering system to represent and transmit the signal information in digital form. A binary numbering system is a number system using the base 2. The simplest binary signal is a single bit that has only one of two possible values, a 1 or a 0. Bits are like electrical “on-off” switches and are used to convey logical and numerical information. With appropriate input, the value of the bit transmitted is reset corresponding to the behavior of the measured variable. A digital sensor that transmits information one bit at a time uses serial transmission. By combining bits or transmitting bits in groups, it is also possible to define logical commands or integer numbers beyond a 0 or 1. A digital sensor that transmits bits in groups uses parallel transmission. With any digital device, an M -bit signal can express 2^M different numbers. This also provides the limit for the different values that a digital device can discern. For example, a 2-bit device can express 2^2 or 4 different numbers, 00, 01, 10, and 11, corresponding to the values of 0, 1, 2, and 3, respectively. Thus, the resolution in a magnitude discerned by a digital sensor is inherently limited to 1 part in 2^M .

The concept of a digital sensor is illustrated by the revolution counter in [Figure 2.6](#). Such devices are widely used to sense the revolutions per minute of a rotating shaft. In this example, the sensor is a magnetic pick-up/voltage converter that outputs a pulse with each pass of a magnetic stud mounted to a hub on the rotating shaft. The output from the pick-up normally is “off” but is momentarily turned “on” by the passing stud. This pulse is a voltage spike sent to a digital register whose value is increased by a single count with each spike. The register can send the information to an output device, such as the digital display shown. The output from the sensor can be viewed in terms of voltage spikes with time. The count rate is related to the rotational speed of the shaft. As seen, the signal is discrete in time. A single stud with pick-up will increase the count by one for each full rotation of the shaft. Fractions of a rotation can be resolved by increasing the number of studs on the hub. In this example, the continuous rotation of the shaft is analog but the revolution count is digital. The amplitude of the voltage spike is set to activate the counter and is not related to the shaft rotational speed.

2.4 Analog and Digital Readout Instruments

An **analog readout instrument** provides an output indication that is continuous and directly analogous to the behavior of the measurand. Typically, this might be the deflection of a pointer or an ink trace on a graduated scale, or the intensity of a light beam or a sound wave. This indicated deflection may be driven by changes in voltage or current, or by mechanical, magnetic, or optical means, or combinations

FIGURE 2.7 A seven-segment display chip can display any digit from 0 to 9.

of these. The resolution of an analog readout is defined by the smallest usable increment on its readout scale. The span of the readout is defined by the difference between the minimum and maximum values that it can indicate. Its range specifies the minimum and maximum values that it can indicate.

A **digital readout instrument** provides an output indication that is discrete. The value of the digital output is directly related to the value of the measurand. The digital readout is typically in the form of a numerical value that is either a fixed number or a number that is updated periodically. One means of displaying a digital number is the seven-segment digital display chip, shown in Figure 2.7, whose output can be updated by altering the grounding inputs A through G. The resolution of a digital readout is given by its least count, the equivalent amount of the smallest change resolved by the least significant digit in the readout. The span and range are defined as for analog instruments.

Many digital devices combine features of an analog sensor with a digital readout or, in general, convert an analog signal to a discrete signal, which is indicated through a digital output. In such situations, an analog to digital converter (ADC) is required. This hybrid device has its analog side specified in terms of its full-scale analog range, E_{FSR} , which defines the analog voltage span over which the device will operate. The digital side is specified in terms of the bit size of its register. An M -bit device will output an M -bit binary number. The resolution of such a device is given by $E_{\text{FSR}}/2^M$.

2.5 Input Impedance

In the ideal sense, the very act of measurement should not alter the value of the measured signal. Any such alteration is a **loading error**. Loading errors can occur at any junction along the signal chain but can be minimized by impedance matching of the source with the measuring instrument. The measuring instrument input impedance controls the energy that is drawn from the source, or measured system, by a measuring instrument. The power loss through the measuring instrument is estimated by $P = E^2/Z_2$ where Z_2 is the input impedance of the measuring instrument, and E is the source voltage potential being measured. Thus, to minimize the power loss, the input impedance should be large.

This same logic holds for the two instruments in a signal chain as the subsequent instrument draws energy from the previous instrument in the chain. As a general example, consider the situation in Figure 2.8 in which the output signal from one instrument provides the input signal to a subsequent device in a signal chain. The open circuit potential, E_1 , is present at the output terminal of source device 1 having output impedance, Z_1 . Device 2 has an **input impedance** Z_2 at its input terminals. Connecting

FIGURE 2.8 An equivalent circuit is formed by applying a measuring instrument to the output terminals of an instrument.

the output terminals of device 1 to the input terminals of device 2 creates the equivalent circuit also shown in Figure 2.7. The potential actually sensed by device 2 will be

$$E_2 = E_1 \frac{1}{1 + Z_1/Z_2}$$

The difference between the actual potential E_1 at the output terminals of device 1 and the measured potential E_2 is a **loading error** brought on by the input impedance of measuring device 2. It is clear that a high input impedance Z_2 relative to Z_1 minimizes this error. A general rule is for the input impedance to be at least 100 times the source impedance to reduce the loading error to 1%.

In general, null instruments and null methods will minimize loading errors. They provide the equivalent of a very high input impedance to the measurement, minimizing energy drain from the measured system. Deflection instruments and deflection measuring techniques will derive energy from the process being measured and therefore require attention to proper selection of input impedance.

Defining Terms

Analog sensor: Sensors that output a signal that is continuous in both magnitude and time (or space).

Deflection instrument: A measuring device whose output deflects proportional to the magnitude of the measurand.

Digital sensor: Sensors that output a signal that is discrete (noncontinuous) in time and/or magnitude.

Input impedance: The impedance measured across the input terminals of a device.

Loading error: That difference between the measurand and the measuring system output attributed to the act of measuring the measurand.

Measurand: A physical quantity, property, or condition being measured. Often, it is referred to as a measured value.

Null instrument: A measuring device that balances the measurand against a known value, thus achieving a null condition. A null instrument minimizes measurement loading errors.

Readout: This is the display of a measuring system.

Resolution: This is the least count or smallest detectable change in measurand capable.

Sensor: The portion of a measurement system that responds directly to the physical variable being measured.

- 3.2 Dynamic Characteristics of Instrument Systems
Dealing with Dynamic States • Forcing Functions • Characteristic Equation Development • Response of the Different Linear Systems Types • Zero-Order Blocks • First-Order Blocks • Second-Order Blocks
- 3.3 Calibration of Measurements

Before we can begin to develop an understanding of the static and time changing characteristics of measurements, it is necessary to build a framework for understanding the process involved, setting down the main words used to describe concepts as we progress.

Measurement is the process by which relevant information about a system of interest is interpreted using the human thinking ability to define what is believed to be the new knowledge gained. This information may be obtained for purposes of controlling the behavior of the system (as in engineering applications) or for learning more about it (as in scientific investigations).

The basic entity needed to develop the knowledge is called *data*, and it is obtained with physical assemblies known as sensors that are used to observe or sense system variables. The terms *information* and *knowledge* tend to be used interchangeably to describe the entity resulting after data from one or more sensors have been processed to give more meaningful understanding. The individual variables being sensed are called *measurands*.

The most obvious way to make observations is to use the human senses of seeing, feeling, and hearing. This is often quite adequate or may be the only means possible. In many cases, however, sensors are used that have been devised by man to enhance or replace our natural sensors. The number and variety of sensors is very large indeed. Examples of man-made sensors are those used to measure temperature, pressure, or length. The process of sensing is often called *transduction*, being made with transducers. These man-made sensor assemblies, when coupled with the means to process the data into knowledge, are generally known as (measuring) instrumentation.

The degree of perfection of a measurement can only be determined if the goal of the measurement can be defined without error. Furthermore, instrumentation cannot be made to operate perfectly. Because of these two reasons alone, measuring instrumentation cannot give ideal sensing performance and it must be selected to suit the allowable error in a given situation.

FIGURE 3.1 A patient's temperature chart shows changes taking place over time.

Measurement is a process of mapping actually occurring variables into equivalent values. Deviations from perfect measurement mappings are called *errors*: what we get as the result of measurement is not exactly what is being measured. A certain amount of error is allowable provided it is below the level of uncertainty we can accept in a given situation. As an example, consider two different needs to measure the measurand, time. The uncertainty to which we must measure it for daily purposes of attending a meeting is around a 1 min in 24 h. In orbiting satellite control, the time uncertainty needed must be as small as milliseconds in years. Instrumentation used for the former case costs a few dollars and is the watch we wear; the latter instrumentation costs thousands of dollars and is the size of a suitcase.

We often record measurand values as though they are constant entities, but they usually change in value as time passes. These “dynamic” variations will occur either as changes in the measurand itself or where the measuring instrumentation takes time to follow the changes in the measurand — in which case it may introduce unacceptable error.

For example, when a fever thermometer is used to measure a person's body temperature, we are looking to see if the person is at the normally expected value and, if it is not, to then look for changes over time as an indicator of his or her health. Figure 3.1 shows a chart of a patient's temperature. Obviously, if the thermometer gives errors in its use, wrong conclusions could be drawn. It could be in error due to incorrect calibration of the thermometer or because no allowance for the dynamic response of the thermometer itself was made.

Instrumentation, therefore, will only give adequately correct information if we understand the static and dynamic characteristics of both the measurand and the instrumentation. This, in turn, allows us to then decide if the error arising is small enough to accept.

As an example, consider the electronic signal amplifier in a sound system. It will be commonly quoted as having an amplification constant after feedback if applied to the basic amplifier of, say, 10. The actual amplification value is dependent on the frequency of the input signal, usually falling off as the frequency increases. The frequency response of the basic amplifier, before it is configured with feedback that markedly alters the response and lowers the amplification to get a stable operation, is shown as a graph of amplification gain versus input frequency. An example of the open loop gain of the basic amplifier is given in Figure 3.2. This lack of uniform gain over the frequency range results in error — the sound output is not a true enough representation of the input.

FIGURE 3.2 This graph shows how the amplification of an amplifier changes with input frequency.

Before we can delve more deeply into the static and dynamic characteristics of instrumentation, it is necessary to understand the difference in meaning between several basic terms used to describe the results of a measurement activity.

The correct terms to use are set down in documents called *standards*. Several standardized metrology terminologies exist but they are not consistent. It will be found that books on instrumentation and statements of instrument performance often use terms in different ways. Users of measurement information need to be constantly diligent in making sure that the statements made are interpreted correctly.

The three companion concepts about a measurement that need to be well understood are its *discrimination*, its *precision*, and its *accuracy*. These are too often used interchangeably — which is quite wrong to do because they cover quite different concepts, as will now be explained.

When making a measurement, the smallest increment that can be discerned is called the *discrimination*. (Although now officially declared as wrong to use, the term *resolution* still finds its way into books and reports as meaning discrimination.) The discrimination of a measurement is important to know because it tells if the sensing process is able to sense fine enough changes of the measurand.

Even if the discrimination is satisfactory, the value obtained from a repeated measurement will rarely give exactly the same value each time the same measurement is made under conditions of constant value of measurand. This is because errors arise in real systems. The spread of values obtained indicates the precision of the set of the measurements. The word *precision* is not a word describing a quality of the measurement and is incorrectly used as such. Two terms that should be used here are: *repeatability*, which describes the variation for a set of measurements made in a very short period; and the *reproducibility*, which is the same concept but now used for measurements made over a long period. As these terms describe the outcome of a set of values, there is need to be able to quote a single value to describe the overall result of the set. This is done using statistical methods that provide for calculation of the “mean value” of the set and the associated spread of values, called its *variance*.

The *accuracy* of a measurement is covered in more depth elsewhere so only an introduction to it is required here. Accuracy is the closeness of a measurement to the value defined to be the true value. This

FIGURE 3.3 Two sets of arrow shots fired into a target allow understanding of the measurement concepts of discrimination, precision, and accuracy. (a) The target used for shooting arrows allows investigation of the terms used to describe the measurement result. (b) A different set of placements.

concept will become clearer when the following illustrative example is studied for it brings together the three terms into a single perspective of a typical measurement.

Consider then the situation of scoring an archer shooting arrows into a target as shown in Figure 3.3(a). The target has a central point — the bulls-eye. The objective for a perfect result is to get all arrows into the bulls-eye. The rings around the bulls-eye allow us to set up numeric measures of less-perfect shooting performance.

Discrimination is the distance at which we can just distinguish (i.e., discriminate) the placement of one arrow from another when they are very close. For an arrow, it is the thickness of the hole that decides the discrimination. Two close-by positions of the two arrows in Figure 3.3(a) cannot be separated easily. Use of thinner arrows would allow finer detail to be decided.

Repeatability is determined by measuring the spread of values of a set of arrows fired into the target over a short period. The smaller the spread, the more precise is the shooter. The shooter in Figure 3.3(a) is more precise than the shooter in Figure 3.3(b).

If the shooter returned to shoot each day over a long period, the results may not be the same each time for a shoot made over a short period. The mean and variance of the values are now called the *reproducibility* of the archer's performance.

Accuracy remains to be explained. This number describes how well the mean (the average) value of the shots sits with respect to the bulls-eye position. The set in Figure 3.3(b) is more accurate than the set in Figure 3.3(a) because the mean is nearer the bulls-eye (but less precise!).

At first sight, it might seem that the three concepts of discrimination, precision, and accuracy have a strict relationship in that a better measurement is always that with all three aspects made as high as is affordable. This is not so. They need to be set up to suit the needs of the application.

We are now in a position to explore the commonly met terms used to describe aspects of the static and the dynamic performance of measuring instrumentation.

FIGURE 3.4 Instruments are formed from a connection of blocks. Each block can be represented by a conceptual and mathematical model. This example is of one type of humidity sensor.

3.1 Static Characteristics of Instrument Systems

Output/Input Relationship

Instrument systems are usually built up from a serial linkage of distinguishable building blocks. The actual physical assembly may not appear to be so but it can be broken down into a representative diagram of connected blocks. Figure 3.4 shows the block diagram representation of a humidity sensor. The sensor is activated by an input physical parameter and provides an output signal to the next block that processes the signal into a more appropriate state.

A key generic entity is, therefore, the relationship between the input and output of the block. As was pointed out earlier, all signals have a time characteristic, so we must consider the behavior of a block in terms of both the static and dynamic states.

The behavior of the static regime alone and the combined static and dynamic regime can be found through use of an appropriate mathematical model of each block. The mathematical description of system responses is easy to set up and use if the elements all act as linear systems and where addition of signals can be carried out in a linear additive manner. If nonlinearity exists in elements, then it becomes considerably more difficult — perhaps even quite impractical — to provide an easy to follow mathematical explanation. Fortunately, general description of instrument systems responses can be usually be adequately covered using the linear treatment.

The output/input ratio of the whole cascaded chain of blocks 1, 2, 3, etc. is given as:

$$[\text{output/input}]_{\text{total}} = [\text{output/input}]_1 \times [\text{output/input}]_2 \times [\text{output/input}]_3 \dots$$

The output/input ratio of a block that includes both the static and dynamic characteristics is called the *transfer function* and is given the symbol G .

The equation for G can be written as two parts multiplied together. One expresses the static behavior of the block, that is, the value it has after all transient (time varying) effects have settled to their final state. The other part tells us how that value responds when the block is in its dynamic state. The static part is known as the *transfer characteristic* and is often all that is needed to be known for block description.

The static and dynamic response of the cascade of blocks is simply the multiplication of all individual blocks. As each block has its own part for the static and dynamic behavior, the cascade equations can be rearranged to separate the static from the dynamic parts and then by multiplying the static set and the dynamic set we get the overall response in the static and dynamic states. This is shown by the sequence of Equations 3.1 to 3.4.

$$G_{\text{total}} = G_1 \times G_2 \times G_3 \dots \quad (3.1)$$

$$= [\text{static} \times \text{dynamic}]_1 \times [\text{static} \times \text{dynamic}]_2 \times [\text{static} \times \text{dynamic}]_3 \dots \quad (3.2)$$

$$= [\text{static}]_1 \times [\text{static}]_2 \times [\text{static}]_3 \dots \times [\text{dynamic}]_1 \times [\text{dynamic}]_2 \times [\text{dynamic}]_3 \dots \quad (3.3)$$

$$= [\text{static}]_{\text{total}} \times [\text{dynamic}]_{\text{total}} \quad (3.4)$$

An example will clarify this. A mercury-in-glass fever thermometer is placed in a patient's mouth. The indication slowly rises along the glass tube to reach the final value, the body temperature of the person. The slow rise seen in the indication is due to the time it takes for the mercury to heat up and expand up the tube. The static *sensitivity* will be expressed as so many scale divisions per degree and is all that is of interest in this application. The dynamic characteristic will be a time varying function that settles to unity after the transient effects have settled. This is merely an annoyance in this application but has to be allowed by waiting long enough before taking a reading. The wrong value will be viewed if taken before the transient has settled.

At this stage, we will now consider only the nature of the static characteristics of a chain; dynamic response is examined later.

If a sensor is the first stage of the chain, the static value of the gain for that stage is called the *sensitivity*. Where a sensor is not at the input, it is called the *amplification factor* or *gain*. It can take a value less than unity where it is then called the *attenuation*.

Sometimes, the instantaneous value of the signal is rapidly changing, yet the measurement aspect part is static. This arises when using ac signals in some forms of instrumentation where the amplitude of the waveform, not its frequency, is of interest. Here, the static value is referred to as its *steady state* transfer characteristic.

Sensitivity may be found from a plot of the input and output signals, wherein it is the slope of the graph. Such a graph, see Figure 3.5, tells much about the static behavior of the block.

The intercept value on the *y*-axis is the *offset* value being the output when the input is set to zero. Offset is not usually a desired situation and is seen as an error quantity. Where it is deliberately set up, it is called the *bias*.

The range on the *x*-axis, from zero to a safe maximum for use, is called the *range* or *span* and is often expressed as the zone between the 0% and 100% points. The ratio of the span that the output will cover

FIGURE 3.5 The graph relating input to output variables for an instrument block shows several distinctive static performance characteristics.

FIGURE 3.6 Drift in the performance of an instrument takes many forms: (a) drift over time for a spring balance; (b) how an electronic amplifier might settle over time to a final value after power is supplied; (c) drift, due to temperature, of an electronic amplifier varies with the actual temperature of operation.

for the related input range is known as the *dynamic range*. This can be a confusing term because it does not describe dynamic time behavior. It is particularly useful when describing the capability of such instruments as flow rate sensors — a simple orifice plate type may only be able to handle dynamic ranges of 3 to 4, whereas the laser Doppler method covers as much as 10^7 variation.

Drift

It is now necessary to consider a major problem of instrument performance called *instrument drift*. This is caused by variations taking place in the parts of the instrumentation over time. Prime sources occur as chemical structural changes and changing mechanical stresses. Drift is a complex phenomenon for which the observed effects are that the sensitivity and offset values vary. It also can alter the accuracy of the instrument differently at the various amplitudes of the signal present.

Detailed description of drift is not at all easy but it is possible to work satisfactorily with simplified values that give the average of a set of observations, this usually being quoted in a conservative manner. The first graph (a) in Figure 3.6 shows typical steady drift of a measuring spring component of a weighing balance. Figure 3.6(b) shows how an electronic amplifier might settle down after being turned on.

Drift is also caused by variations in environmental parameters such as temperature, pressure, and humidity that operate on the components. These are known as *influence parameters*. An example is the change of the resistance of an electrical resistor, this resistor forming the critical part of an electronic amplifier that sets its gain as its operating temperature changes.

Unfortunately, the observed effects of influence parameter induced drift often are the same as for time varying drift. Appropriate testing of blocks such as electronic amplifiers does allow the two to be separated to some extent. For example, altering only the temperature of the amplifier over a short period will quickly show its temperature dependence.

Drift due to influence parameters is graphed in much the same way as for time drift. Figure 3.6(c) shows the drift of an amplifier as temperature varies. Note that it depends significantly on the temperature

of operation, implying that the best designs are built to operate at temperatures where the effect is minimum.

Careful consideration of the time and influence parameter causes of drift shows they are interrelated and often impossible to separate. Instrument designers are usually able to allow for these effects, but the cost of doing this rises sharply as the error level that can be tolerated is reduced.

Hysteresis and Backlash

Careful observation of the output/input relationship of a block will sometimes reveal different results as the signals vary in direction of the movement. Mechanical systems will often show a small difference in length as the direction of the applied force is reversed. The same effect arises as a magnetic field is reversed in a magnetic material. This characteristic is called *hysteresis*. Figure 3.7 is a generalized plot of the output/input relationship showing that a closed loop occurs. The effect usually gets smaller as the amplitude of successive excursions is reduced, this being one way to tolerate the effect. It is present in most materials. Special materials have been developed that exhibit low hysteresis for their application — transformer iron laminations and clock spring wire being examples.

Where this is caused by a mechanism that gives a sharp change, such as caused by the looseness of a joint in a mechanical joint, it is easy to detect and is known as *backlash*.

Saturation

So far, the discussion has been limited to signal levels that lie within acceptable ranges of amplitude. Real system blocks will sometimes have input signal levels that are larger than allowed. Here, the dominant errors that arise — *saturation* and *crossover distortion* — are investigated.

As mentioned above, the information bearing property of the signal can be carried as the instantaneous value of the signal or be carried as some characteristic of a rapidly varying ac signal. If the signal form is not amplified faithfully, the output will not have the same linearity and characteristics.

The gain of a block will usually fall off with increasing size of signal amplitude. A varying amplitude input signal, such as the steadily rising linear signal shown in Figure 3.8, will be amplified differently according to the gain/amplitude curve of the block. In uncompensated electronic amplifiers, the larger amplitudes are usually less amplified than at the median points.

At very low levels of input signal, two unwanted effects may arise. The first is that small signals are often amplified more than at the median levels. The second error characteristic arises in electronic amplifiers because the semiconductor elements possess a dead-zone in which no output occurs until a small threshold is exceeded. This effect causes crossover distortion in amplifiers.

If the signal is an ac waveform, see Figure 3.9, then the different levels of a cycle of the signal may not all be amplified equally. Figure 3.9(a) shows what occurs because the basic electronic amplifying elements are only able to amplify one polarity of signal. The signal is said to be *rectified*. Figure 3.9(b) shows the effect when the signal is too large and the top is not amplified. This is called *saturation* or *clipping*. (As with many physical effects, this effect is sometimes deliberately invoked in circuitry, an example being where it is used as a simple means to convert sine-waveform signals into a square waveform.) Crossover distortion is evident in Figure 3.9(c) as the signal passes from negative to positive polarity.

Where input signals are small, such as in sensitive sensor use, the form of analysis called *small signal* behavior is needed to reveal distortions. If the signals are comparatively large, as for digital signal considerations, a *large signal* analysis is used. Design difficulties arise when signals cover a wide dynamic range because it is not easy to allow for all of the various effects in a single design.

Bias

Sometimes, the electronic signal processing situation calls for the input signal to be processed at a higher average voltage or current than arises normally. Here a dc value is added to the input signal to raise the level to a higher state as shown in Figure 3.10. A need for this is met where only one polarity of signal

FIGURE 3.7 Generalized graph of output/input relationship where hysteresis is present. (From P. H. Sydenham, *Handbook of Measurement Science*, Vol. 2, Chichester, U.K., John Wiley & Sons, 1983. With permission.)

can be amplified by a single semiconductor element. Raising the level of all of the waveform equally takes all parts into the reasonably linear zone of an amplifier, allowing more faithful replication. If bias were not used here, then the lower half cycle would not be amplified, resulting in only the top half appearing in the output.

Error of Nonlinearity

Ideally, it is often desired that a strictly linear relationship exists between input and output signals in amplifiers. Practical units, however, will always have some degree of nonconformity, which is called the *nonlinearity*. If an instrument block has constant gain for all input signal levels, then the relationship graphing the input against the output will be a straight line; the relationship is then said to be linear.

FIGURE 3.8 Nonlinear amplification can give rise to unwanted output distortion.

FIGURE 3.9 Blocks can incorrectly alter the shape of waveforms if saturation and crossover effects are not controlled: (a) rectification; (b) saturation; and (c) crossover distortion.

Linearity is the general term used to describe how close the actual response is compared with that ideal line. The correct way to describe the error here is as the *error of nonlinearity*. Note, however, that not all responses are required to be linear; another common one follows a logarithmic relationship.

Detailed description of this error is not easy for that would need a statement of the error values at all points of the plot. Practice has found that a shorthand statement can be made by quoting the maximum departure from the ideal as a ratio formed with the 100% value.

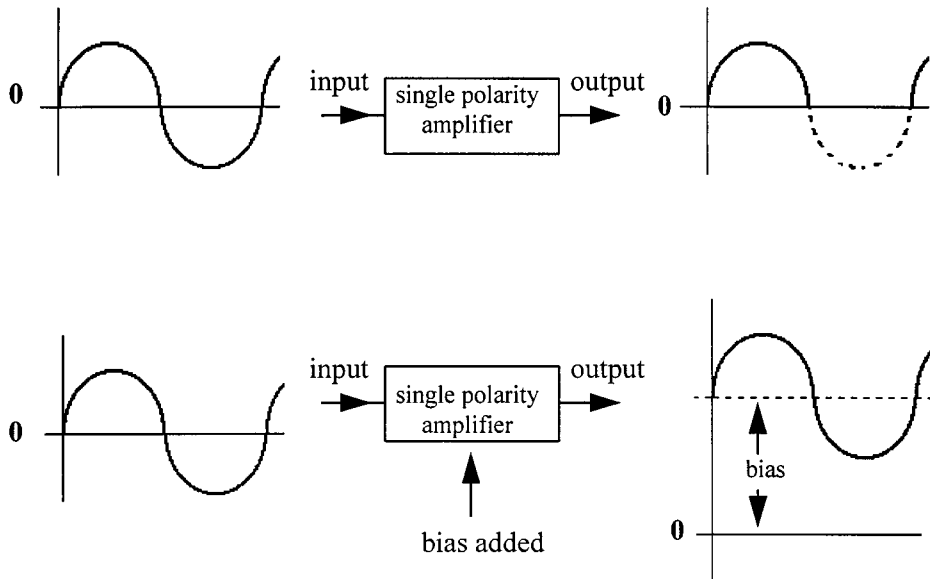

FIGURE 3.10 Bias is where a signal has all of its value raised by an equal amount. Shown here is an ac input waveform biased to be all of positive polarity.

Difficulties arise in expressing error of nonlinearity for there exist many ways to express this error. Figure 3.11 shows the four cases that usually arise. The difference arises in the way in which the ideal (called the “best fit”) straight line can be set up. Figure 3.11(a) shows the line positioned by the usually calculated statistical averaging method of least squares fit; other forms of line fitting calculation are also used. This will yield the smallest magnitude of error calculation for the various kinds of line fitting but may not be appropriate for how the stage under assessment is used. Other, possibly more reasonable, options exist. Figure 3.11(b) constrains the best fit line to pass through the zero point. Figure 3.11(c) places the line between the expected 0% and the 100% points. There is still one more option, that where the theoretical line is not necessarily one of the above, yet is the ideal placement, Figure 3.11(d).

In practice then, instrument systems linearity can be expressed in several ways. Good certification practice requires that the method used to ascertain the error is stated along with the numerical result, but this is often not done. Note also that the error is the worst case and that part of the response may be much more linear.

The description of instrument performance is not a simple task. To accomplish this fully would require very detailed statements recording the performance at each and every point. That is often too cumbersome, so the instrument industry has developed many short-form statements that provide an adequate guide to the performance. This guide will be seen to be generally a conservative statement.

Many other descriptors exist for the static regime of an instrument. The reader is referred to the many standards documents that exist on instrument terminology; for example, see Reference [3].

3.2 Dynamic Characteristics of Instrument Systems

Dealing with Dynamic States

Measurement outcomes are rarely static over time. They will possess a dynamic component that must be understood for correct interpretation of the results. For example, a trace made on an ink pen chart recorder will be subject to the speed at which the pen can follow the input signal changes.

FIGURE 3.11 Error of nonlinearity can be expressed in four different ways: (a) best fit line (based on selected method used to decide this); (b) best fit line through zero; (c) line joining 0% and 100% points; and (d) theoretical line. (From P. H. Sydenham, *Handbook of Measurement Science*, Vol. 2, Chichester, U.K., John Wiley & Sons, 1983. With permission.)

To properly appreciate instrumentation design and its use, it is now necessary to develop insight into the most commonly encountered types of dynamic response and to develop the mathematical modeling basis that allows us to make concise statements about responses.

If the transfer relationship for a block follows linear laws of performance, then a generic mathematical method of dynamic description can be used. Unfortunately, simple mathematical methods have not been found that can describe all types of instrument responses in a simplistic and uniform manner. If the behavior is nonlinear, then description with mathematical models becomes very difficult and might be impracticable. The behavior of nonlinear systems can, however, be studied as segments of linear behavior joined end to end. Here, digital computers are effectively used to model systems of any kind provided the user is prepared to spend time setting up an adequate model.

Now the mathematics used to describe linear dynamic systems can be introduced. This gives valuable insight into the expected behavior of instrumentation, and it is usually found that the response can be approximated as linear.

The modeled response at the output of a block G_{result} is obtained by multiplying the mathematical expression for the input signal G_{input} by the transfer function of the block under investigation G_{response} , as shown in Equation 3.5.

$$G_{\text{result}} = G_{\text{input}} \times G_{\text{response}} \quad (3.5)$$

To proceed, one needs to understand commonly encountered input functions and the various types of block characteristics. We begin with the former set: the so-called *forcing functions*.

Forcing Functions

Let us first develop an understanding of the various types of input signal used to perform tests. The most commonly used signals are shown in Figure 3.12. These each possess different valuable test features. For example, the sine-wave is the basis of analysis of all complex wave-shapes because they can be formed as a combination of various sine-waves, each having individual responses that add to give all other wave-shapes. The step function has intuitively obvious uses because input transients of this kind are commonly encountered. The ramp test function is used to present a more realistic input for those systems where it is not possible to obtain instantaneous step input changes, such as attempting to move a large mass by a limited size of force. Forcing functions are also chosen because they can be easily described by a simple mathematical expression, thus making mathematical analysis relatively straightforward.

Characteristic Equation Development

The behavior of a block that exhibits linear behavior is mathematically represented in the general form of expression given as Equation 3.6.

$$\dots\dots\dots a_2 d^2 y / dt^2 + a_1 dy / dt + a_0 y = x(t) \quad (3.6)$$

Here, the coefficients a_2 , a_1 , and a_0 are constants dependent on the particular block of interest. The left-hand side of the equation is known as the *characteristic equation*. It is specific to the internal properties of the block and is not altered by the way the block is used.

The specific combination of forcing function input and block characteristic equation collectively decides the combined output response. Connections around the block, such as feedback from the output to the input, can alter the overall behavior significantly: such systems, however, are not dealt with in this section being in the domain of feedback control systems.

Solution of the combined behavior is obtained using Laplace transform methods to obtain the output responses in the time or the complex frequency domain. These mathematical methods might not be familiar to the reader, but this is not a serious difficulty for the cases most encountered in practice are

FIGURE 3.12 The dynamic response of a block can be investigated using a range of simple input forcing functions. (From P. H. Sydenham, *Handbook of Measurement Science*, Vol. 2, Chichester, U.K., John Wiley & Sons, 1983. With permission.)

well documented in terms that are easily comprehended, the mathematical process having been performed to yield results that can be used without the same level of mathematical ability. More depth of explanation can be obtained from [1] or any one of the many texts on energy systems analysis. Space here only allows an introduction; this account is linked to [1], Chapter 17, to allow the reader to access a fuller description where needed.

The next step in understanding block behavior is to investigate the nature of Equation 3.6 as the number of derivative terms in the expression increases, Equations 3.7 to 3.10.

$$\text{Zero order} \quad a_0 y = x(t) \quad (3.7)$$

$$\text{First order} \quad a_1 dy/dt + a_0 y = x(t) \quad (3.8)$$

$$\text{Second order} \quad a_2 d^2 y/dt^2 + a_1 dy/dt + a_0 y = x(t) \quad (3.9)$$

$$n\text{th order} \quad a_n d^n y/dt^n + a_{n-1} d^{n-1} y/dt^{n-1} + \dots + a_0 y = x(t) \quad (3.10)$$

Note that specific names have been given to each order. The zero-order situation is not usually dealt with in texts because it has no time-dependent term and is thus seen to be trivial. It is an amplifier (or attenuator) of the forcing function with gain of a_0 . It has infinite bandwidth without change in the amplification constant.

The highest order usually necessary to consider in first-cut instrument analysis is the second-order class. Higher-order systems do occur in practice and need analysis that is not easily summarized here. They also need deep expertise in their study. Computer-aided tools for systems analysis can be used to study the responses of systems.

Another step is now to rewrite the equations after Laplace transformation into the frequency domain. We then get the set of output/input Equations 3.11 to 3.14.

$$\text{Zero order} \quad Y(s)/X(s) = 1 \quad (3.11)$$

$$\text{First order} \quad Y(s)/X(s) = 1/(\tau s + 1) \quad (3.12)$$

$$\text{Second order} \quad Y(s)/X(s) = 1/(\tau_1 s + 1)(\tau_2 s + 1) \quad (3.13)$$

$$n\text{th order} \quad Y(s)/X(s) = 1/(\tau_1 s + 1)(\tau_2 s + 1) \dots (\tau_n s + 1) \quad (3.14)$$

The terms τ_1, \dots, τ_n are called *time constants*. They are key system performance parameters.

Response of the Different Linear Systems Types

Space restrictions do not allow a detailed study of all of the various options. A selection is presented to show how they are analyzed and reported, that leading to how the instrumentation person can use certain standard charts in the study of the characteristics of blocks.

Zero-Order Blocks

To investigate the response of a block, multiply its frequency domain forms of equation for the characteristic equation with that of the chosen forcing function equation.

This is an interesting case because Equation 3.7 shows that the zero-order block has no frequency-dependent term (it has no time derivative term), so the output for all given inputs can only be of the same time form as the input. What can be changed is the amplitude given as the coefficient a_0 . A shift in time (phase shift) of the output waveform with the input also does not occur as it can for the higher-order blocks.

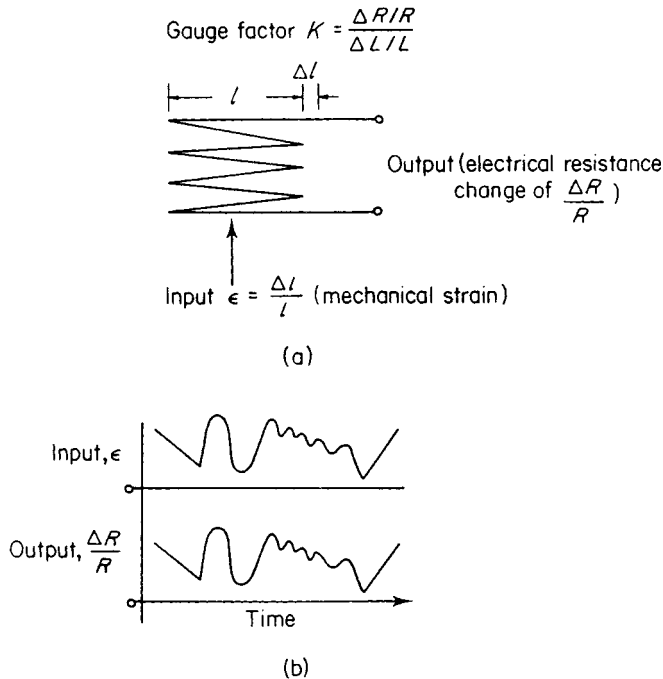

FIGURE 3.13 Input and output responses for a zero-order block: (a) strain gage physical and mathematical model; and (b) responses. (From P. H. Sydenham, *Handbook of Measurement Science*, Vol. 2, Chichester, U.K., John Wiley & Sons, 1983. With permission.)

This is the response often desired in instruments because it means that the block does not alter the time response. However, this is not always so because, in systems, design blocks are often chosen for their ability to change the time shape of signals in a known manner.

Although somewhat obvious, [Figure 3.13](#), a resistive strain gage, is given to illustrate zero-order behavior.

First-Order Blocks

Here, Equation 3.8 is the relevant characteristic equation. There is a time-dependent term, so analysis is needed to see how this type of block behaves under dynamic conditions. The output response is different for each type of forcing function applied. Space limitations only allow the most commonly encountered cases — the step and the sine-wave input — to be introduced here. It is also only possible here to outline the method of analysis and to give the standardized charts that plot generalized behavior.

The step response of the first-order system is obtained by multiplying Equation 3.12 by the frequency domain equation for a step of amplitude A . The result is then transformed back into the time domain using Laplace transforms to yield the expression for the output, $y(t)$

$$y(t) = AK(1 - e^{-t/\tau}) \quad (3.15)$$

where A is the amplitude of the step, K the static gain of the first-order block, t the time in consistent units, and τ the time constant associated with the block itself.

This is a tidy outcome because Equation 3.15 covers the step response for all first-order blocks, thus allowing it to be graphed in normalized manner, as given in [Figure 3.14](#). The shape of the response is always of the same form. This means that the step response of a first-order system can be described as having “a step of AK amplitude with the time constant τ .”

FIGURE 3.14 The step response for all first-order systems is covered by these two normalized graphs. (From P. H. Sydenham, *Handbook of Measurement Science*, Vol. 2, Chichester, U.K., John Wiley & Sons, 1983. With permission.)

If the input is a sine-wave, the output response is quite different; but again, it will be found that there is a general solution for all situations of this kind. As before, the input forcing equation is multiplied by the characteristic equation for the first-order block and Laplace transformation is used to get back to the time domain response. After rearrangement into two parts, this yields:

$$y(t) = \left[AK\tau\omega e^{-t/\tau} / (\tau^2\omega^2 + 1) \right] + \left[AK / (\tau^2\omega^2 + 1)^{1/2} \cdot \sin(\omega t + \phi) \right] \quad (3.16)$$

where ω is the signal frequency in angular radians, $\phi = \tan^{-1}(-\omega\tau)$, A the amplitude of the sine-wave input, K the gain of the first-order block, t the time in consistent units, and τ the time constant associated with the block.

The left side of the right-hand bracketed part is a short-lived, normally ignored, time transient that rapidly decays to zero, leaving a steady-state output that is the parameter of usual interest. Study of the steady-state part is best done by plotting it in a normalized way, as has been done in [Figure 3.15](#).

These plots show that the amplitude of the output is always reduced as the frequency of the input signal rises and that there is always a phase lag action between the input and the output that can range from 0 to 90° but never be more than 90°. The extent of these effects depends on the particular coefficients of the block and input signal. These effects must be well understood when interpreting measurement results because substantial errors can arise with using first-order systems in an instrument chain.

Second-Order Blocks

If the second-order differential term is present, the response of a block is quite different, again responding in quite a spectacular manner with features that can either be wanted or unwanted.

As before, to obtain the output response, the block's characteristic function is multiplied by the chosen forcing function. However, to make the results more meaningful, we first carry out some simple substitution transformations.

The steps begin by transforming the second-order differential Equation 3.6 into its Laplace form to obtain:

$$X(s) = a_2 s^2 Y(s) + a_1 s Y(s) + a_0 Y(s) \quad (3.17)$$

This is then rearranged to yield:

$$G(s) = Y(s) / X(s) = 1 / a_0 \cdot 1 / \left\{ (a_2 / a_0) s^2 + (a_1 / a_0) s + 1 \right\} \quad (3.18)$$

FIGURE 3.15 The amplitude and phase shift of the output of all first-order systems to a sine-wave input is shown by these two normalized curves; (a) amplitude and (b) phase. (From P. H. Sydenham, *Handbook of Measurement Science*, Vol. 2, Chichester, U.K., John Wiley & Sons, 1983. With permission.)

The coefficients can then be expressed in system performance terms as follows.

Angular natural frequency $\omega_n = (a_0/a_2)^{1/2}$ (3.19)

Damping ratio $\zeta = a_1/2(a_0 \cdot a_2)^{1/2}$ (3.20)

Static gain $K = 1/a_0$ (3.21)

These three variables have practical relevance, as will be seen when the various responses are plotted.

Using these transformed variables, the characteristic equation can be rewritten in two forms ready for investigation of output behavior to step and sine-wave inputs, as:

$$G(s) = K / \left\{ (1/\omega_n^2)s^2 + (2\zeta/\omega_n)s + 1 \right\} \quad (3.22)$$

and then as:

$$G(s) = K / (\tau^2 s^2 + 2\zeta\tau s + 1) \quad (3.23)$$

We are now ready to consider the behavior of the second-order system to the various forcing inputs.

First consider the step input. After forming the product of the forcing and characteristic functions, the time domain form can be plotted as shown in [Figure 3.16](#).

FIGURE 3.16 The response of second-order systems to a step input is seen from this normalized plot. (From P. H. Sydenham, *Handbook of Measurement Science*, Vol. 2, Chichester, U.K., John Wiley & Sons, 1983. With permission.)

This clearly shows that the response is strongly dependent on the damping ratio ζ value. If it is less than unity, it exhibits an oscillatory movement settling down to the final value. If the damping value is greater than unity, the response moves to the final value without oscillation. The often preferred state is to use a damping factor of unity, *critical damping*. The choice of response depends strongly on the applications, for all levels of damping ratio have use in practice, ranging from needing an oscillation that never ceases (zero damping) to the other extreme where a very gradual rate of change is desired.

A similar analysis is used to see how the second-order system responds to the sine-wave input. The two response plots obtained are shown in [Figure 3.17](#): one for the amplitude response, and the other showing how the phase shifts as the frequency changes.

The most unexpected result is seen at the point where the gain rises to infinity for the zero damping state. This is called *resonance* and it occurs at the block's *natural frequency* for the zero damping state. Resonance can be a desirable feature, as in detecting a particular frequency in a radio frequency detection circuit, or it may be most undesirable, as when a mechanical system resonates, possibly to destruction. It can be seen that it is mostly controlled by the damping ratio. Note also that the phase shift for the second-order system ranges from 0 to 180°. This has important implications if the block is part of a feedback loop because as the frequency rises, the phase shift from the block will pass from stable negative feedback (less than 90°) to positive feedback (greater than 90°), causing unwanted oscillation.

More detail of the various other situations, including how to deal with higher orders, cascaded blocks of similar kind, and ramp inputs are covered elsewhere [1].

3.3 Calibration of Measurements

We have already introduced the concept of accuracy in making a measurement and how the uncertainty inherent in all measurements must be kept sufficiently small. The process and apparatus used to find out if a measurement is accurate enough is called *calibration*. It is achieved by comparing the result of a measurement with a method possessing a measurement performance that is generally agreed to have less uncertainty than that in the result obtained. The error arising within the calibration apparatus and process

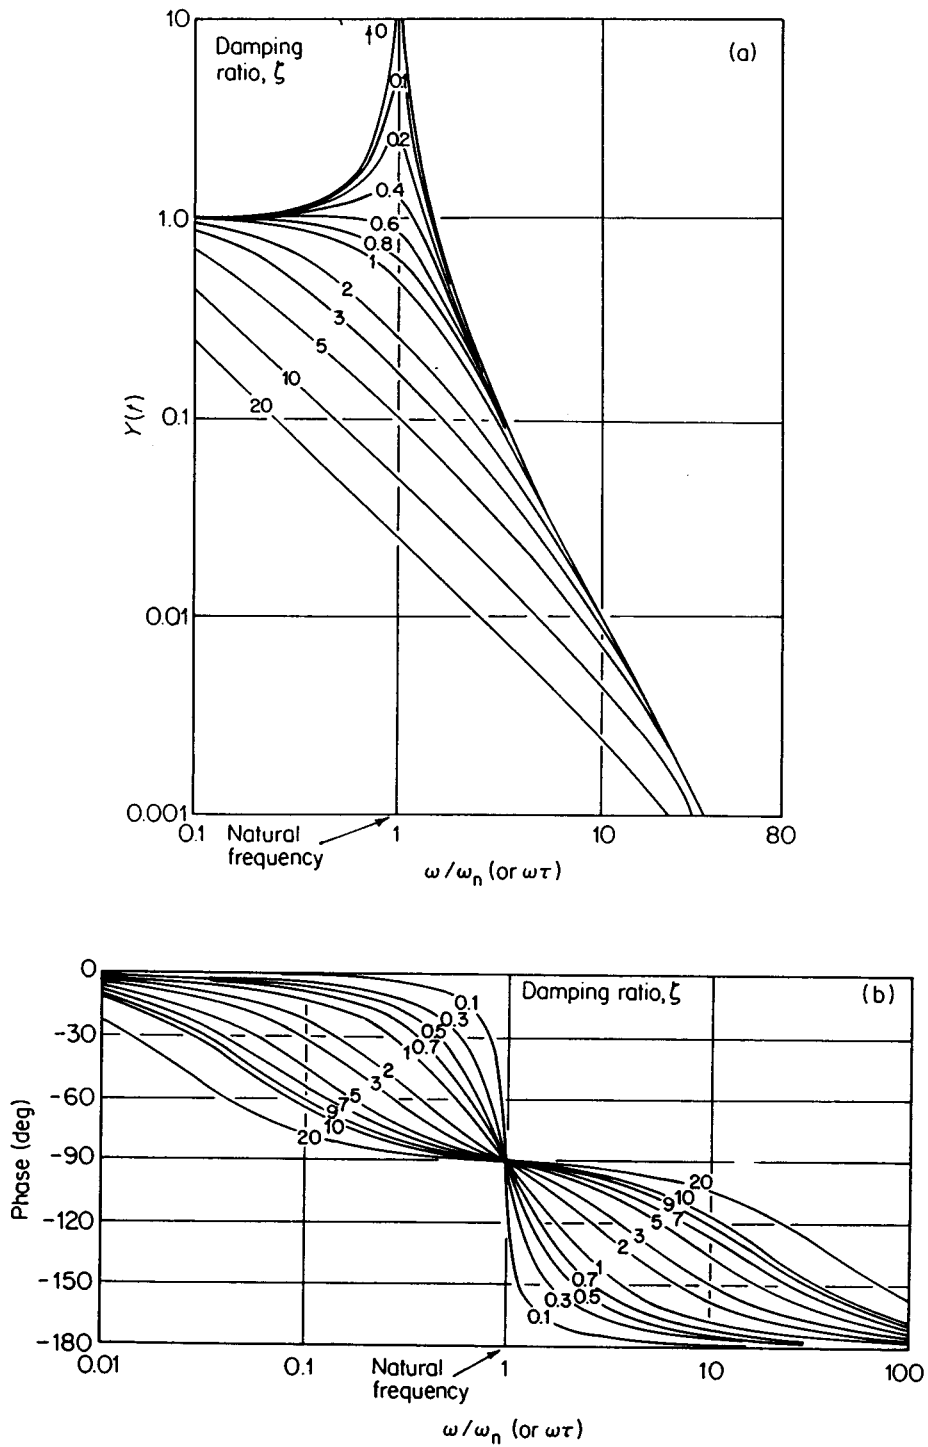

FIGURE 3.17 These two plots allow the behavior of second-order blocks with sine-wave inputs to be ascertained: (a) amplitude and (b) phase. (From P. H. Sydenham, *Handbook of Measurement Science*, Vol. 2, Chichester, U.K., John Wiley & Sons, 1983. With permission.)

FIGURE 3.18 This practical example illustrates how flow meters are calibrated by passing a known quantity of fluid through the meter over a given time. (Originally published in P. H. Sydenham, *Transducers in Measurement and Control*, Adam Hilger, Bristol, IOP Publishing, Bristol, 1984. Copyright P. H. Sydenham.)

of comparison must necessarily be less than that required. This means that calibration is often an expensive process. Conducting a good calibration requires specialist expertise.

The method and apparatus for performing measurement instrumentation calibrations vary widely. An illustrative example of the comparison concept underlying them all is given in the calibration of flow meters, shown diagrammatically in [Figure 3.18](#).

By the use of an overflowing vessel, the top tank provides a flow of water that remains constant because it comes from a constant height. The meter to be calibrated is placed in the downstream pipe.

The downstream is either deflected into the weigh tank or back to the supply. To make a measurement, the water is first set to flow to the supply. At the start of a test period, the water is rapidly and precisely deflected into the tank. After a given period, the water is again sent back to the supply. This then has filled the tank with a given amount of water for a given time period of flow. Calculations are then undertaken to work out the quantity of water flowing per unit time period, which is the *flow rate*. The meter was already registering a flow rate as a constant value. This is then compared with the weighed method to yield the error. Some thought will soon reveal many sources of error in the test apparatus, such as that the temperature of the water decides the volume that flows through and thus this must be allowed for in the calculations.

It will also be clear that this calibration may not be carried out under the same conditions as the measurements are normally used. The art and science and difficulties inherent in carrying out quality calibration for temperature sensors are well exposed [2].

Calibration of instrumentation is a must for, without it, measurement results may be misleading and lead to costly aftermath situations. Conducting good calibration adds overhead cost to measurement but it is akin to taking out insurance. If that investment is made properly, it will assist in mitigating later penalties. For example, an incorrectly calibrated automatic cement batcher was used in making concrete for the structural frame of a multistory building. It took several days before concrete strength tests revealed the batcher had been out of calibration for a day with the result that the concrete already poured for three floors was not of adequate strength. By then, more stories had been poured on top. The defective floors had to be fully replaced at great cost. More resource put into the calibration process would have ensured that the batcher was working properly.

Ronald H. Dieck
Pratt & Whitney

All test measurements are taken so that data may be acquired that are useful in decision making. No tests are run and no measurements made when the “answer” is already known. For data to be useful, it is necessary that their measurement errors be small in comparison to the changes or effect under evaluation. Measurement error is unknown and unknowable. This chapter addresses the techniques used to estimate, with some confidence, the expected limits of the measurement errors.

4.1 Error: The Normal Distribution and the Uniform Distribution

Error is defined as the difference between the measured value and the true value of the measurand [1]. That is,

$$E = (\text{measured}) - (\text{true}) \quad (4.1)$$

where E = the measurement error
(measured) = the value obtained by a measurement
(true) = the true value of the measurand

It is only possible to estimate, with some confidence, the expected limits of error. The most common method for estimating those limits is to use the *normal distribution* [2]. It is

$$Y = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{X-\mu}{\sigma}\right)^2/\sigma^2} \quad (4.2)$$

FIGURE 4.1

where X = the input variable, here the value obtained by a measurement
 μ = the average of the population of the X variable
 σ = the standard deviation of the population, expressed as:

$$\sigma = \sqrt{\frac{\sum_{i=1}^n (X_i - \mu)^2}{n}} \quad (4.3)$$

where X_i = the i^{th} X measurement
 n = the number of data points measured from the population

Typically, neither n , μ , nor σ are known.

Figure 4.1 illustrates this distribution. Here, for an infinite population ($N = \infty$), the standard deviation, σ , would be used to estimate the expected limits of a particular error with some confidence. That is, the average, plus or minus 2σ divided by the square root of the number of data points, would contain the true average, μ , 95% of the time.

However, in test measurements, one typically cannot sample the entire population and must make do with a sample of N data points. The sample standard deviation, S_X , is then used to estimate σ_X , the expected limits of a particular error. (That sample standard deviation divided by the square root of the number of data points is the starting point for the confidence interval estimate on μ .) For a large dataset (defined as having 30 or more degrees of freedom), plus or minus $2S_X$ divided by the square root of the number of data points in the reported average, M , would contain the true average, μ , 95% of the time. That S_X divided by the square root of the number of data points in the reported average is called the *standard deviation of the average* and is written as:

$$S_{\bar{X}} = \sqrt{\frac{\sum_{i=1}^N (X_i - \bar{X})^2}{N-1}} / \sqrt{M} = S_X / \sqrt{M} \quad (4.4)$$

where $S_{\bar{X}}$ = the standard deviation of the average; the sample standard deviation of the data divided by the square root of M
 S_X = the sample standard deviation
 \bar{X} = the sample average, that is,

FIGURE 4.2

$$\bar{X} = \sum_{i=1}^M (X_i / N) \quad (4.5)$$

X_i = the i^{th} data point used to calculate the sample standard deviation and the average, \bar{X} , from the data

N = the number of data points used to calculate the standard deviation

$(N - 1)$ = the degrees of freedom of S_x and $S_{\bar{x}}$

M = the number of data points in the reported average test result

Note in Equation 4.4 that N does not necessarily equal M . It is possible to obtain S_x from historical data with many degrees of freedom ($[N - 1]$ greater than 30) and to run the test only M times. The test result, or average, would therefore be based on M measurements, and the standard deviation of the average would still be calculated with Equation 4.4. In that case, there would be two averages, \bar{X} . One \bar{X} would be from the historical data used to calculate the sample standard deviation, and the other \bar{X} , the average test result for M measurements.

Note that the sample standard deviation, S_x , is simply:

$$S_x = \sqrt{\frac{\sum_{i=1}^N (X_i - \bar{X})^2}{N - 1}} \quad (4.6)$$

In some cases, a particular error distribution may be assumed or known to be a *uniform or rectangular distribution*, Figure 4.2, instead of a normal distribution. For those cases, the sample standard deviation of the data is calculated as:

$$S_x = L / \sqrt{3} \quad (4.7)$$

where L = the plus/minus limits of the uniform distribution for a particular error [3].

For those cases, the standard deviation of the average is written as:

$$S_{\bar{x}} = \frac{L / \sqrt{3}}{\sqrt{M}} \quad (4.8)$$

Although the calculation of the sample standard deviation (or its estimation by some other process) is required for measurement uncertainty analysis, all the analytical work computing the measurement uncertainty uses only the standard deviation of the average for each error source.

Uncertainty (Accuracy)

Since the error for any particular error source is unknown and unknowable, its limits, at a given confidence, must be estimated. This estimate is called the *uncertainty*. Sometimes, the term *accuracy* is used to describe the quality of test data. This is the positive statement of the expected limits of the data's errors. Uncertainty is the negative statement. Uncertainty is, however, unambiguous. Accuracy is sometimes ambiguous. (For example,; what is twice the accuracy of $\pm 2\%$? $\pm 1\%$ or $\pm 4\%$?) For this reason, this chapter will use the term *uncertainty* throughout to describe the quality of test data.

4.2 Measurement Uncertainty Model

Purpose

One needs an estimate of the uncertainty of test results to make informed decisions. Ideally, the uncertainty of a well-run experiment will be much less than the change or test result expected. In this way, it will be known, with high confidence, that the change or result observed is real or acceptable and not a result of the errors of the test or measurement process. The limits of those errors are estimated with uncertainty, and those error sources and their limit estimators, the uncertainties, may be grouped into classifications to ease their understanding.

Classifying Error and Uncertainty Sources

There are two classification systems in use. The final total uncertainty calculated at a confidence is identical no matter what classification system is used. The two classifications utilized are the *ISO classifications* and the *engineering classifications*. The former groups errors and their uncertainties by type, depending on whether or not there is data available to calculate the sample standard deviation for a particular error and its uncertainty. The latter classification groups errors and their uncertainties by their effect on the experiment or test. That is, the engineering classification groups errors and uncertainties by *random* and *systematic* types, with subscripts used to denote whether there are data to calculate a standard deviation or not for a particular error or uncertainty source. For this reason, engineering classification groups usually are more useful and recommended.

ISO Classifications

This error and uncertainty classification system is not recommended in this chapter, but will yield a total uncertainty in complete agreement with the recommended classification system — the engineering classification system. In this ISO system, errors and uncertainties are classified as Type A if there are data to calculate a sample standard deviation and Type B if there is not [4]. In the latter case, the sample standard deviation might be obtained from experience or manufacturer's specifications, to name two examples.

The impact of multiple sources of error is estimated by root-sum-squaring their corresponding multiple uncertainties. The operating equations are

Type A, data for the calculation of the standard deviation:

$$U_A = \left[\sum_{i=1}^{N_A} (\theta_i U_{A_i})^2 \right]^{1/2} \quad (4.9)$$

where U_{A_i} = the standard deviation (based on data) of the average for uncertainty source i of Type A each with its own degrees of freedom. U_A is in units of the test or measurement result. It is an $S_{\bar{x}}$.

N_A = the number of parameters with a Type A uncertainty

θ_i = the sensitivity of the test or measurement result, R , to the i^{th} Type A uncertainty. θ_i is the partial derivative of the result with respect to each i^{th} independent measurement.

The uncertainty of each error source in units of that source, when multiplied by the sensitivity for that source, converts that uncertainty to result units. Then the effect of several error sources may be estimated by root-sum-squaring their uncertainties as they are now all in the same units. The sensitivities, θ_p , are obtained for a measurement result, R , which is a function of several parameters, P_i . The basic equations are

R = the measurement result

where $R = f(P_1, P_2, P_3 \dots P_N)$

P = a measurement parameter used to calculate the result, R

$\theta_i = \partial R / \partial P_i$

Obtaining the θ_i is often called error propagation or uncertainty propagation.

Type B (no data for standard deviation) calculation

$$U_B = \left[\sum_{i=1}^{N_B} (\theta_i U_{B_i})^2 \right]^{1/2} \quad (4.10)$$

where U_{B_i} = the standard deviation (based on an estimate, not data) of the average for uncertainty source i of Type B; U_B is in units of the test or measurement result, R . It is an $S_{\bar{x}}$

N_B = the number of parameters with a Type B uncertainty

θ_i = the sensitivity of the test or measurement result to the i^{th} Type B uncertainty R

For these uncertainties, it is assumed that the U_{B_i} represent one standard deviation of the average for one uncertainty source with an assumed normal distribution. (They also represent one standard deviation as the square root of the “ M ” by which they are divided is one, that is, there is only one Type B error sampled from each of these distributions.) The degrees of freedom associated with this standard deviation (also standard deviation of the average) is infinity.

Note that θ_i , the sensitivity of the test or measurement result to the i^{th} Type B uncertainty, is actually the change in the result, R , that would result from a change, of the size of the Type B uncertainty, in the i^{th} input parameter used to calculate that result.

The **degrees of freedom** of the U_A and the U_{B_i} are needed to compute the degrees of freedom of the combined total uncertainty. It is calculated with the Welch–Satterthwaite approximation. The general formula for degrees of freedom [5] is

$$df_R = \nu_R = \frac{\left[\sum_{i=1}^N (S_{\bar{x}_i})^2 \right]^2}{\sum_{i=1}^N \frac{(S_{\bar{x}_i})^4}{\nu_i}} \quad (4.11)$$

where $df_R = \nu_R =$ degrees of freedom for the result
 $\nu_i =$ the degrees of freedom of the i^{th} standard deviation of the average

For the ISO model, Equation 4.11 becomes:

$$df_{R,ISO} = \nu_{R,ISO} = \frac{\left[\sum_{i=1}^{N_A} (\theta_i U_{A_i})^2 + \sum_{i=1}^{N_B} (\theta_i U_{B_i})^2 \right]^2}{\sum_{i=1}^{N_A} \frac{(\theta_i U_{A_i})^4}{(\nu_i)} + \sum_{i=1}^{N_B} \frac{(\theta_i U_{B_i})^4}{(\nu_i)}} \quad (4.12)$$

The degrees of freedom calculated with Equation 4.12 is often a fraction. This should be truncated to the next lower whole number to be conservative.

Note that in Equations 4.9, 4.10, and 4.12, N_A and N_B need not be equal. They are only the total number of parameters with uncertainty sources of Type A and B, respectively.

In computing a total uncertainty, the uncertainties noted by Equations 4.10 and 4.11 are combined. For the ISO model [3], this is calculated as:

$$U_{R,ISO} = \pm t_{95} \left[(U_A)^2 + (U_B)^2 \right]^{1/2} \quad (4.13)$$

where $t_{95} =$ Student's t for ν_R degrees of freedom

Student's t is obtained from Table 4.1.

Note that alternative confidences are permissible. 95% is recommended by the ASME [6], but 99% or 99.7% or any other confidence is obtained by choosing the appropriate Student's t . 95% confidence is, however, recommended for uncertainty analysis.

In all the above, the errors were assumed to be independent. Independent sources of error are those that have no relationship to each other. That is, an error in a measurement from one source cannot be used to predict the magnitude or direction of an error from the other, independent, error source. Nonindependent error sources are related. That is, if it were possible to know the error in a measurement from one source, one could calculate or predict an error magnitude and direction from the other,

TABLE 4.1 Student's t Statistic for 95% Confidence, t_{95} , Degrees of Freedom, ν . This is Frequently Written as: $t_{95,\nu}$

ν	t_{95}	ν	t_{95}	ν	t_{95}
1	12.706	11	2.201	21	2.080
2	4.303	12	2.179	22	2.074
3	3.182	13	2.160	23	2.069
4	2.776	14	2.145	24	2.064
5	2.571	15	2.131	25	2.060
6	2.447	16	2.120	26	2.056
7	2.365	17	2.110	27	2.052
8	2.306	18	2.101	28	2.048
9	2.262	19	2.093	29	2.045
10	2.228	20	2.086	≥ 30	2.000

nonindependent error source. These are sometimes called *dependent error sources*. Their degree of dependence may be estimated with the linear correlation coefficient. If they are nonindependent, whether Type A or Type B, Equation 4.13 becomes [7]:

$$U_{R,ISO} = t_{95} \left\{ \sum_{T=A}^B \sum_{i=1}^{N_{i,T}} \left[\left(\theta_i U_{i,T} \right)^2 + \sum_{j=1}^{N_{i,T}} \theta_i \theta_j U_{(i,T),(j,T)} \left(1 - \delta_{i,j} \right) \right] \right\}^{1/2} \quad (4.14)$$

- where: $U_{i,T}$ = the i^{th} elemental uncertainty of Type T (can be Type A or B)
 $U_{R,ISO}$ = the total uncertainty of the measurement or test result
 θ_i = the sensitivity of the test or measurement result to the i^{th} Type T uncertainty
 θ_j = the sensitivity of the test or measurement result to the j^{th} Type T uncertainty
 $U_{(i,T),(j,T)}$ = the covariance of $U_{i,T}$ on $U_{j,T}$
- $$= \sum_{l=1}^K U_{i,T}(l) U_{j,T}(l) \quad (4.15)$$
- = the sum of the products of the elemental systematic uncertainties that arise from a common source (l)
 l = an index or counter for common uncertainty sources
 K = the number of common source pairs of uncertainties
 $\delta_{i,j}$ = the Kronecker delta. $\delta_{i,j} = 1$ if $i = j$, and $\delta_{i,j} = 0$ if not [7]
 T = an index or counter for the ISO uncertainty type, A or B

This ISO classification equation will yield the same total uncertainty as the engineering classification, but the ISO classification does not provide insight into how to improve an experiment's or test's uncertainty. That is, whether to possibly take more data because the random uncertainties are too high or calibrate better because the systematic uncertainties are too large. The engineering classification now presented is therefore the preferred approach.

Engineering Classification

The engineering classification recognizes that experiments and tests have two major types of errors whose limits are estimated with uncertainties at some chosen confidence. These error types may be grouped as *random* and *systematic*. Their corresponding limit estimators are the random uncertainty and systematic uncertainties, respectively.

Random

The general expression for **random uncertainty** is the $(1S_{\bar{x}})$ standard deviation of the average [6]:

$$S_{\bar{x},R} = \left[\sum_{T=A}^B \sum_{i=1}^{N_{i,T}} \left(\theta_i S_{\bar{x}_{i,T}} \right)^2 \right]^{1/2} = \left[\sum_{T=A}^B \sum_{i=1}^{N_{i,T}} \left(\theta_i S_{x_{i,T}} / \sqrt{M_{i,T}} \right)^2 \right]^{1/2} \quad (4.16)$$

- where: $S_{x_{i,T}}$ = the sample standard deviation of the i^{th} random error source of Type T
 $S_{\bar{x}_{i,T}}$ = the random uncertainty (standard deviation of the average) of the i^{th} parameter random error source of Type T
 $S_{\bar{x},R}$ = the random uncertainty of the measurement or test result
 $N_{i,T}$ = the total number of random uncertainties, Types A and B, combined
 $M_{i,T}$ = the number of data points averaged for the i^{th} error source, Type A or B
 θ_i = the sensitivity of the test or measurement result to the i^{th} random uncertainty

Note that $S_{\bar{X},R}$ is in units of the test or measurement result because of the use of the sensitivities, θ_i . Here, the elemental random uncertainties have been root-sum-squared with due consideration for their sensitivities, or influence coefficients. Since these are all random uncertainties, there is, by definition, no correlation in their corresponding error data so these can always be treated as independent uncertainty sources.

Systematic

The **systematic uncertainty** of the result, B_R , is the root-sum-square of the elemental systematic uncertainties with due consideration for those that are correlated [7]. The general equation is

$$B_R = \left\{ \sum_{T=A}^B \sum_{i=1}^{N_T} \left[(\theta_i B_{i,T})^2 + \sum_{j=1}^{N_T} \theta_i \theta_j B_{(i,T),(j,T)} (1 - \delta_{i,j}) \right] \right\}^{1/2} \quad (4.17)$$

where: $B_{i,T}$ = the i^{th} parameter elemental systematic uncertainty of Type T
 B_R = the systematic uncertainty of the measurement or test result
 N = the total number of systematic uncertainties
 θ_i = the sensitivity of the test or measurement result to the i^{th} systematic uncertainty
 θ_j = the sensitivity of the test or measurement result to the j^{th} systematic uncertainty
 $B_{(i,T),(j,T)}$ = the covariance of B_i on B_j

$$= \sum_{l=1}^M B_{i,T}(l) B_{j,T}(l) \quad (4.18)$$

= the sum of the products of the elemental systematic uncertainties that arise from a common source (l)

l = an index or counter for common uncertainty sources

δ_{ij} = the Kronecker delta. $\delta_{ij} = 1$ if $i = j$, and $\delta_{ij} = 0$ if not [7]

T = an index or counter for the ISO uncertainty type, A or B

Here, each $B_{i,T}$ and $B_{j,T}$ are estimated as $2S_X$ for an assumed normal distribution of errors at 95% confidence with infinite degrees of freedom [6].

The random uncertainty, Equation 4.16, and the systematic uncertainty, Equation 4.17, must be combined to obtain a total uncertainty:

$$U_{R,ENG} = t_{95} \left[\left(B_R / 2 \right)^2 + \left(S_{\bar{X},R} \right)^2 \right]^{1/2} \quad (4.19)$$

Note that B_R is in units of the test or measurement result as was $S_{\bar{X},R}$.

The degrees of freedom will be needed for the engineering system total uncertainty. It is accomplished with the **Welch–Satterthwaite** approximation, the general form of which is Equation 4.10, and the specific formulation here is

$$df_R = \nu_R = \frac{\left\{ \sum_{T=A}^B \left[\sum_{i=1}^{N_{S_{\bar{X},T}}} (\theta_i S_{\bar{X},T})^2 + \sum_{i=1}^{N_{B_{i,T}}} (\theta_i B_{i,T}/t)^2 \right] \right\}^2}{\left\{ \sum_{T=A}^B \left[\sum_{i=1}^{N_{S_{\bar{X},T}}} \frac{(\theta_i S_{\bar{X},T})^4}{(\nu_{i,T})} + \sum_{i=1}^{N_{B_{i,T}}} \frac{(\theta_i B_{i,T}/t)^4}{(\nu_{i,T})} \right] \right\}} \quad (4.20)$$

where $N_{\bar{x}_{i,T}}$ = the number of random uncertainties of Type T
 $N_{B_i,T}$ = the number of systematic uncertainties of Type T
 $\nu_{i,T}$ = the degrees of freedom for the i^{th} uncertainty of Type T
 $\nu_{i,T}$ = infinity for all systematic uncertainties
 t = Student's t associated with the d.f. for each B_i

Symmetrical Systematic Uncertainties

Most times, all elemental uncertainties will be symmetrical. That is, their \pm limits about the measured average will be the same. That is, they will be $\pm 3^\circ\text{C}$ or $\pm 2.05\text{ kPa}$ and the like and not $+2.0^\circ\text{C}$, -1.0°C or, $+1.5\text{ kPa}$, -0.55 kPa . The symmetrical measurement uncertainty may therefore be calculated as follows. (For an elegant treatment of [nonsymmetrical uncertainties](#), see that section in Reference [6].)

Note that throughout these uncertainty calculations, all the uncertainties are expressed in engineering units. All the equations will work with relative units as well. That approach may be seen in Reference [6] also. However, it is often easier to express all the uncertainties and the uncertainty estimation calculations in engineering units and then, at the end, with the total uncertainty, convert the result into relative terms. That is what this section recommends.

4.3 Calculation of Total Uncertainty

ISO Total (Expanded) Uncertainty

The ISO total uncertainty for independent uncertainty sources (the most common) is Equation 4.13:

$$U_{R,ISO} = \pm t_{95} \left[(U_A)^2 + (U_B)^2 \right]^{1/2} \quad (4.21)$$

where: $U_{R,ISO}$ = the measurement uncertainty of the result
 U_A = the Type A uncertainty for the result
 U_B = the Type B uncertainty for the result
 t_{95} = Student's t_{95} is the recommended multiplier to assure 95% confidence

The ISO uncertainty with some nonindependent uncertainty sources is Equation 4.14:

$$U_{R,ISO} = \left\{ \sum_{T=A}^B \sum_{i=1}^{N_{i,T}} \left[(\theta_i U_{i,T})^2 + \sum_{j=1}^{N_{j,T}} \theta_i \theta_j U_{(i,T),(j,T)} (1 - \delta_{i,j}) \right] \right\}^{1/2} \quad (4.22)$$

Engineering System Total Uncertainty

The engineering system equation for total uncertainty for independent uncertainty sources (the most common) is

$$U_{R,ENG} = \pm t_{95} \left[(B_R/2)^2 + (S_{\bar{x},R})^2 \right]^{1/2} \quad (4.23)$$

Here, just the first term of Equation 4.23 is needed as all the systematic uncertainty sources are independent.

The engineering system equation for uncertainty for nonindependent uncertainty sources (those with correlated systematic uncertainties) is also Equation 4.23; but remember to use the full expression for B_R , Equation 4.17:

TABLE 4.2 Temperature Measurement Uncertainties, F

Defined measurement process	Systematic uncertainty, B_i	d.f. for B_i	Standard deviation, $S_{\bar{x}_i}$	Number of data points, N_i	Random uncertainty, $S_{\bar{x}_i}$	Degrees of freedom, d.f., ν_i
Calibration of tc	0.06 _B	∞	0.3 _A	10	0.095 _A	9
Reference junction	0.07 _A	12	0.1 _A	5	0.045 _A	4
Data acquisition	0.10 _B	∞	0.6 _A	12	0.173 _A	11

RSS

$$B_R = \left\{ \sum_{T=A}^B \sum_{i=1}^{N_T} \left[\left(\theta_i B_{i,T} \right)^2 + \sum_{j=1}^{N_T} \theta_i \theta_j B_{(i,T),(j,T)} \left(1 - \delta_{i,j} \right) \right] \right\}^{1/2} \quad (4.24)$$

The degrees of freedom for Equations 4.21 through 4.24 is calculated with the Welch–Satterthwaite approximation, Equation 4.12 for the ISO system and Equation 4.20 for the engineering system.

High Degrees of Freedom Approximation

It is often the case that it is assumed that the degrees of freedom are 30 or higher. In these cases, the equations for uncertainty simplify further by setting t_{95} equal to 2.000. This approach is recommended for a first-time user of uncertainty analysis procedures as it is a fast way to get to an approximation of the measurement uncertainty.

Calculation Example

The following calculation example is taken where all the uncertainties are independent and are in the units of the test result — temperature. It is a simple example that illustrates the combination of measurement uncertainties in their most basic case. More detailed examples are given in many of the references cited. Their review may be needed to assure a more comprehensive understanding of uncertainty analysis.

It has been shown [8] that there is often little difference in the uncertainties calculated with the different models. The data from Table 4.2 [9] will be used to calculate measurement uncertainty with these two models. These data are all in temperature units and thus the influence coefficients, or sensitivities, are all unity.

Note the use of subscripts “A” and “B” to denote where data exist to calculate a standard deviation. Note too that in this example, all errors (and therefore uncertainties) are independent and that all degrees of freedom for the systematic uncertainties are infinity except for the reference junction whose degrees of freedom are 12. Also note that B_R is calculated as:

$$B_R = 2 \left[\left(\frac{0.06}{2} \right)^2 + \left(\frac{0.07}{2.18} \right)^2 + \left(\frac{0.1}{2} \right)^2 \right]^{1/2} = 0.13 \quad (4.25)$$

Each uncertainty model will now be used to derive a measurement uncertainty.

For the U_{ISO} model one obtains, via Equation 4.13, the expression:

$$U_A = \left[\left(0.095 \right)^2 + \left(0.045 \right)^2 + \left(0.173 \right)^2 + \left(\frac{0.07}{2.18} \right)^2 \right]^{1/2} = 0.21 \quad (4.27)$$

$$U_B = \left[\left(\frac{0.06}{2} \right)^2 + \left(\frac{0.10}{2} \right)^2 \right]^{1/2} = 0.058 \quad (4.28)$$

$$U_{R,ISO} = \pm K \left[(U_A)^2 + (U_B)^2 \right]^{1/2} = \pm K \left[(0.21)^2 + (0.058)^2 \right]^{1/2} \quad (4.29)$$

Here, remember that the 0.21 is the root sum square of the $1S_{\bar{X}}$ Type A uncertainties in Table 4.2, and 0.058 that for the $1S_{\bar{X}}$ Type B uncertainties. Also note that in most cases, the Type B uncertainties have infinite degrees of freedom and represent an equivalent $2S_{\bar{X}}$. That is why they are divided by 2 — to get an equivalent $1S_{\bar{X}}$. Where there are less than 30 degrees of freedom, one needs to divide by the appropriate Student's t that gave the 95% confidence interval. For the reference junction systematic uncertainty above, that was 2.18.

If “ K ” is taken as Student's t_{95} , the degrees of freedom must first be calculated. Remember that all the systematic components of Type “B” have infinite degrees of freedom except for the 0.07, which has 12 degrees of freedom. Also, all the B_i in Table 4.1 represent an equivalent $2S_{\bar{X}}$ except for 0.07, which represents $2.18S_{\bar{X}}$, as its degrees of freedom are 12 and not infinity. To use their data here, divide them all but the 0.07 by 2 and the 0.07 by 2.18 so they all now represent $1S_{\bar{X}}$, as do the random components. All Type A uncertainties, whether systematic or random in Table 4.1, have degrees of freedom as noted in the table. The degrees of freedom for U_{ISO} is then:

$$df_R = \nu_R = \frac{\left[(0.095)^2 + (0.045)^2 + (0.173)^2 + (0.06/2)^2 + (0.07/2.18)^2 + (0.10/2)^2 \right]^2}{\left[\frac{(0.095)^4}{9} + \frac{(0.045)^4}{4} + \frac{(0.173)^4}{11} + \frac{(0.06)^4}{\infty} + \frac{(0.07/2.18)^4}{12} + \frac{(0.10/2)^4}{\infty} \right]} = 22.51 \approx 22 \quad (4.30)$$

t_{95} is therefore 2.07. $U_{R,ISO}$ is then:

$$U_{R,ISO} = \pm 2.07 \left[(0.21)^2 + (0.058)^2 \right]^{1/2} = 0.45 \text{ for 95\% confidence} \quad (4.31)$$

For a detailed comparison to the engineering system, here denoted as the $U_{R,ENG}$ model, three significant figures are carried so as not to be affected by round-off errors. Then:

$$U_{R,ISO} = \pm 2.074 \left[(0.205)^2 + (0.0583)^2 \right]^{1/2} = 0.442 \text{ for 95\% confidence} \quad (4.32)$$

For the engineering system, $U_{R,ENG}$, model, Equation 4.23, one obtains the expression:

$$U_{R,ENG} = \pm t_{95} \left[(0.13/2)^2 + (0.20)^2 \right]^{1/2} \quad (4.33)$$

Here, the (0.13/2) is the $B_R/2$ and the 0.20 is as before the random component. To obtain the proper t_{95} , the degrees of freedom need to be calculated just as in Equation 4.30. There, the degrees of freedom were 22 and t_{95} equals 2.07. $U_{R,ENG}$ is then:

$$U_{R,ENG} = \pm 2.07 \left[\left(0.13/2 \right)^2 + \left(0.20 \right)^2 \right]^{1/2} = 0.44 \text{ for 95\% confidence} \quad (4.34)$$

Carrying four significant figures for a comparison to $U_{R,ISO}$ not affected by round-off errors, one obtains:

$$U_{R,ENG} = \pm 2.074 \left[\left(0.133/2 \right)^2 + \left(0.202 \right)^2 \right]^{1/2} = 0.442 \text{ for 95\% confidence} \quad (4.35)$$

This is identical to $U_{R,ISO}$, Equation 4.32, as predicted.

4.4 Summary

Although these formulae for uncertainty calculations will not handle every conceivable situation, they will provide, for most experimenters, a useful estimate of test or measurement uncertainty. For more detailed treatment or specific applications of these principles, consult the references and the recommended “Further Information” section at the end of this chapter.

Defining Terms

Accuracy: The antithesis of uncertainty. An expression of the maximum possible limit of error at a defined confidence.

Confidence: A statistical expression of percent likelihood.

Correlation: The relationship between two datasets. It is not necessarily evidence of cause and effect.

Degrees of freedom: The amount of room left for error. It may also be expressed as the number of independent opportunities for error contributions to the composite error.

Error: [Error] = [Measured] – [True]. It is the difference between the measured value and the true value.

Influence coefficient: See sensitivity.

Measurement uncertainty: The maximum possible error, at a specified confidence, that may reasonably occur. Errors larger than the measurement uncertainty should rarely occur.

Non-symmetrical uncertainty: An uncertainty for which there is an uneven likelihood that the true value lies on one side of the average or the other.

Propagation of uncertainty: An analytical technique for evaluating the impact of an error source (and its uncertainty) on the test result. It employs the use of influence coefficients.

Random error: An error that causes scatter in the test result.

Random uncertainty: An estimate of the limits of random error, usually one standard deviation of the average.

Sensitivity: An expression of the influence an error source has on a test or measured result. It is the ratio of the change in the result to an incremental change in an input variable or parameter measured.

Standard deviation of the average or mean: The standard deviation of the data divided by the number of measurements in the average.

Systematic error: An error that is constant for the duration of a test or measurement.

Systematic uncertainty: An estimate of the limits of systematic error, usually taken as 95% confidence for an assumed normal error distribution.

True value: The desired result of an experimental measurement.

Welch–Satterthwaite: The approximation method for determining the number of degrees of freedom in the random uncertainty of a result.

DeWayne B. Sharp
Shape of Things

Measurement standards are those devices, artifacts, procedures, instruments, systems, protocols, or processes that are used to define (or to realize) measurement units and on which all lower echelon (less accurate) measurements depend. A measurement standard may also be said to store, embody, or otherwise provide a physical quantity that serves as the basis for the measurement of the quantity. Another definition of a standard is the physical embodiment of a measurement unit, by which its assigned value is defined, and to which it can be compared for [calibration](#) purposes. In general, it is not independent of physical environmental conditions, and it is a true embodiment of the unit only under specified conditions. Another definition of a standard is a unit of known quantity or dimension to which other measurement units can be compared.

5.1 A Historical Perspective

Many early standards were based on the human body: the length of man's hand, the width of his thumb, the distance between outstretched fingertips, the length of one's foot, a certain number of paces, etc. In the beginning, while groups were small, such standards were convenient and uniform enough to serve as the basis for measurements.

The logical person to impose a single standard was the ruler of the country — hence, our own 12-inch or other short measuring stick is still called a *ruler*. The establishment of measurement standards thus became the prerogative of the king or emperor, and this right has since been assumed by all governments.

History is replete with examples that show the importance of measurements and standards. In a report to the U.S. Congress in 1821, John Quincy Adams said, "Weights and measures may be ranked among the necessities to every individual of human society." Our founding fathers thought them so important that the United States Constitution expressly gives the Congress the power to fix uniform standards of weights and measures. The need for weights and measures (standards) dates back to earliest recorded history and are even mentioned in the Old Testament of the Bible. Originally, they were locally decreed

to serve the parochial needs of commerce, trade, land division, and taxation. Because the standards were defined by local or regional authorities, differences arose that often caused problems in commerce and early scientific investigation. The rapid growth of science in the late 17th century highlighted a number of serious deficiencies in the system of units then in use and, in 1790, led the French National Assembly to direct the French Academy of Sciences to “deduce an invariable standard for all measures and all the weights.” The Academy proposed a system of units, the metric system, to define the unit of length in terms of the earth’s circumference, with the units of volume and mass being derived from the unit of length. Additionally, they proposed that all multiples of each unit be a multiple of 10.

In 1875, the U.S. and 16 other countries signed the “Treaty of the Meter,” establishing a common set of units of measure. It also established an International Bureau of Weights and Measures (called the BIPM). That bureau is located in the Parisian suburb of Sèvres. It serves as the worldwide repository of all the units that maintain our complex international system of weights and measures. It is through this system that compatibility between measurements made thousands of miles apart is currently maintained.

The system of units set up by the BIPM is based on the meter and kilogram instead of the yard and the pound. It is called the *Système International d’Unités* (SI) or the [International System of Units](#). It is used in almost all scientific work in the U.S. and is the only system of measurement units in most countries of the world today.

Even a common system of units does not guarantee measurement agreement, however. Therein lies the crux of the problem. We must make measurements, and we must know how accurately (or, to be more correct, with what uncertainty) we made those measurements. In order to know that, there must be standards. Even more important, everyone must agree on the values of those standards and use the same standards.

As the level of scientific sophistication improved, the basis for the measurement system changed dramatically. The earliest standards were based on the human body, and then attempts were made to base them on “natural” phenomena. At one time, the basis for length was supposed to be a fraction of the circumference of the earth but it was “maintained” by the use of a platinum/iridium bar. Time was maintained by a pendulum clock but was defined as a fraction of the day and so on. Today, the meter is no longer defined by an artifact. Now, the meter is the distance that light travels in an exactly defined fraction of a second. Since the speed of light in a vacuum is now defined as a constant of nature with a specified numerical value (299, 792, 458 m/s), the definition of the unit of length is no longer independent of the definition of the unit of time.

Prior to 1960, the second was defined as 1/86,400th of a mean solar day. Between 1960 and 1967, the second was defined in terms of the unit of time implicit in the calculation of the ephemerides: “The second is the fraction 1/31, 556, 925.9747 of the tropical year for January 0 at 12 hours of ephemeris time.” With the advent of crystal oscillators and, later, atomic clocks, better ways were found of defining the second. This, in turn, allowed a better understanding of things about natural phenomena that would not have been possible before. For example, it is now known that the earth does not rotate on its axis in a uniform manner. In fact, it is erratically slowing down. Since the second is maintained by atomic clocks it is necessary to add “leap seconds” periodically so that the solar day does not gradually change with respect to the time used every day. It was decided that a constant frequency standard was preferred over a constant length of the day.

5.2 What Are Standards?

One problem with standards is that there are several kinds. In addition to “measurement standards,” there are “standards of practice or protocol standards” that are produced by the various standards bodies such as the International Organization for Standardization (ISO), the International Electrotechnical Commission (IEC), the American National Standards Institute (ANSI), and the Standards Council of Canada (SCC). See [Figure 5.1](#).

FIGURE 5.1

Standards of Practice (Protocol Standards)

These standards define everything from the dimensions and electrical characteristics of a flashlight battery to the shape of the threads on a machine screw and from the size and shape of an IBM punched card to the Quality Assurance Requirements for Measuring Equipment. Such standards can be defined as documents describing the operations and processes that must be performed in order for a particular end to be achieved. They are called a “protocol” by Europeans to avoid confusion with a physical standard.

Legal Metrology

The application of measurement standards to the control of the daily transactions of trade and commerce is known as Legal Metrology; within the U.S., it is more commonly known as Weights and Measures. Internationally, coordination among nations on Legal Metrology matters is, by international agreement, handled by a quasi-official body — the International Organization for Legal Metrology (OIML).

Within the U.S., domestic uniformity in legal metrology matters is the responsibility of [National Institute of Standards and Technology \(NIST\)](#) acting through its Office of Weights and Measures. Actual enforcement is the responsibility of each of the 50 states and the various territories. These, in turn, generally delegate the enforcement powers downward to their counties and, in some cases, to large cities.

Forensic Metrology

Forensic Metrology is the application of measurements and hence measurement standards to the solution and prevention of crime. It is practiced within the laboratories of law enforcement agencies throughout the world. Worldwide activities in Forensic Metrology are coordinated by Interpol (*International Police*; the international agency that coordinates the police activities of the member nations). Within the U.S., the Federal Bureau of Investigation (FBI), an agency of the Department of Justice, is the focal point for most U.S. forensic metrology activities.

Standard Reference Materials

Another type of standard that should be mentioned here are Standard Reference Materials (SRM). Standard Reference Materials are discrete quantities of substances or minor artifacts that have been certified as to their composition, purity, concentration, or some other characteristic useful in the calibration of the measurement devices and the measurement processes normally used in the process control of those substances. SRMs are the essential calibration standards in stoichiometry (the metrology of chemistry).

In the U.S., the National Institute of Standards and Technology (NIST), through its Standard Reference Materials Program, offers for sale over 1300 SRMs. These range from ores to pure metals and alloys. They also include many types of gases and gas mixtures; and many biochemical substances and organic compounds. Among the artifact devices available are optical filters with precise characteristics and standard lamps with known emission characteristics.

5.3 A Conceptual Basis of Measurements

Lord Kelvin’s oft-quoted statement may bear repeating here:

I often say that when you can measure what you are speaking about, and can express it in numbers, you know something about it; but when you cannot measure it, cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind; it may be the beginnings of knowledge, but you have scarcely, in your thoughts, advanced to the stage of science, whatever the matter may be. So therefore, if science is measurement, then without [metrology](#) there can be no science.

William Thomson (Lord Kelvin), May 6, 1886

FIGURE 5.2

Lord Kelvin’s statement has been quoted so many times that it has almost become trite, but looking at Figure 5.2 will show an interesting hierarchy. In order to achieve quality or “to do things right,” it is necessary to make some decisions. The correct decisions cannot be made unless there are good numerical data on which to base those decisions. Those numerical data, in turn, must come from measurements and if “correct” decisions are really needed, they must be based on the “right” numbers. The only way to get “good” numerical data is to make accurate measurements using calibrated instruments that have been properly utilized. Finally, if it is important to compare those measurements to other measurements made at other places and other times, the instruments must be calibrated using traceable standards.

5.4 The Need for Standards

Standards define the units and scales in use, and allow comparison of measurements made in different times and places. For example, buyers of fuel oil are charged by a unit of liquid volume. In the U.S., this would be the gallon; but in most other parts of the world, it would be the liter. It is important for the buyer that the quantity ordered is actually received and the refiner expects to be paid for the quantity shipped. Both parties are interested in accurate measurements of the volume and, therefore, need to agree on the units, conditions, and method(s) of measurement to be used.

Persons needing to measure a mass cannot borrow the primary standard maintained in France or even the national standard from the National Institute of Standards and Technology (NIST) in the U.S. They must use lower-level standards that can be checked against those national or international standards. Everyday measuring devices, such as scales and balances, can be checked (calibrated) against working level mass standards from time to time to verify their accuracy. These working-level standards are, in turn, calibrated against higher-level mass standards. This chain of calibrations or checking is called “traceability.” A proper chain of traceability must include a statement of uncertainty at every step.

5.5 Types of Standards

Basic or Fundamental Standards

In the SI system, there are seven basic measurement units from which all other units are derived. All of the units except one are defined in terms of their unitary value. The one exception is the unit of mass. It is defined as 1000 grams (g) or 1 kilogram (kg). It is also unique in that it is the only unit currently based on an artifact. The U.S. kilogram and hence all other standards of mass are based on one particular platinum/iridium cylinder kept at the BIPM in France. If that International Prototype Kilogram were to change, all other mass standards throughout the world would be wrong.

The seven basic units are listed in Appendix 1, Table 1. Their definitions are listed in Appendix 1, Table 2.

Derived Standards

All of the other units are derived from the seven basic units described in Appendix 1, Table 1. Measurement standards are devices that represent the SI standard unit in a measurement. (For example, one might use a zener diode together with a reference amplifier and a power source to supply a known voltage to calibrate a digital voltmeter. This could serve as a measurement standard for voltage and be used as a reference in a measurement.)

Appendix 1, Table 3 lists the most common derived SI units, together with the base units that are used to define the derived unit. For example, the unit of frequency is the hertz; it is defined as the reciprocal of time. That is, 1 hertz (1 Hz) is one cycle per second.

The Measurement Assurance System

Figure 5.3 illustrates the interrelationship of the various categories of standards throughout the world. While it gives more detail to U.S. structure, similar structures exist in other nations. Indeed, a variety of regional organizations exist that help relate measurements made in different parts of the world to each other.

5.6 Numbers, Dimensions, and Units

A measurement is always expressed as a multiple (or submultiple) of some unit quantity. That is, both a numeric value and a unit are required. If electric current were the measured quantity, it might be expressed as some number of milliamperes or even microamperes. It is easy to take for granted the existence of the units used, because their names form an indispensable part of the vocabulary.

5.7 Multiplication Factors

Since it is inconvenient to use whole units in many cases, a set of multiplication factors has been defined that can be used in conjunction with the units to bring a value being measured to a more reasonable size. It would be difficult to have to refer to large distances in terms of the meter; thus, one defines longer distances in terms of kilometers. Short distances are stated in terms of millimeters, micrometers, nanometers, etc. See Appendix 1, Table 4.

Defining Terms

Most of the definitions in this listing were taken from the *International Vocabulary of Basic and General Terms in Metrology*, published by the ISO, 1993 (VIM) [7]. They are indicated by the inclusion (in brackets) of their number designation in the VIM. The remainder of the definitions are not intended to

FIGURE 5.3

represent any official agency but are ones widely accepted and are included to help in the understanding of this material. More detailed and rigorous definitions can be found in other works available from ANSI, IEC, ISO, and NIST. Words enclosed in parentheses “(…)” may be omitted from the term if it is unlikely that such omission will cause confusion.

Accuracy of measurement [3.5]:* The closeness of the agreement between the result of a measurement and a true value of the measurand.

NOTES:

1. *Accuracy* is a qualitative concept.
2. The term *precision* should not be used for *accuracy*. (Precision only implies repeatability.)

Note, that to say an instrument is accurate to 5% (a common way of stating it) is wrong. One would not find such an instrument very useful if it, in fact, were only accurate 5% of the time. What is meant when such a statement is made is that the instrument’s inaccuracy is less than 5% and it is accurate to better than 95%. Unfortunately, this statement is almost as imprecise as “accurate to 5%.” An instrument would not be useful if it were accurate only 95% of the time; but this is not what is implied by “5% accuracy.” What is meant is that, (almost) all of the time, its indication is within 5% of the “true” value.

Calibration [6.11]: A set of operations that establish, under specified conditions, the relationship between values of quantities indicated by a measuring instrument or measuring system, or values represented by a material measure or a reference material, and the corresponding values realized by standards.

NOTES:

1. The result of a calibration permits either the assignment of values of measurands to the indicators or the determination of corrections with respect to indications.
2. A calibration can also determine other metrological properties, such as the effect of influence quantities.
3. The result of a calibration can be recorded in a document, sometimes called a *calibration certificate* or a *calibration report*.

Calibration Laboratory: A work space, provided with test equipment, controlled environment and trained personnel, established for the purpose of maintaining proper operation and accuracy of measuring and test equipment. *Calibration laboratories* typically perform many routine calibrations, often on a production-line basis.

Certified Reference Material (CRM) [6.14]: A *reference material*, accompanied by a certificate, one or more of whose property values are certified by a procedure that established traceability to an accurate realization of the unit in which the property values are expressed, and for which each certified value is accompanied by an uncertainty at a stated level of confidence.

1. The definition of a *reference material* is given elsewhere in this vocabulary.
2. CRMs are generally prepared in batches for which the property values are determined within stated uncertainty limits by measurements on samples representative of the entire batch.
3. The certified properties of certified reference materials are sometimes conveniently and reliably realized when the material is incorporated into a specifically fabricated device, e.g., a substance of known triple-point into a triple-point cell, a glass of known optical density into a transmission filter, spheres of uniform particle size mounted on a microscope slide. Such devices can also be considered CRMs.
4. All CRMs lie within the definition of “measurement standards” given in the International Vocabulary of basic and general terms in metrology (VIM).
5. Some RMs and CRMs have properties that, because they cannot be correlated with an established chemical structure or for other reasons, cannot be determined by exactly defined physical and chemical measurement methods. Such materials include certain biological materials such as vaccines to which an International unit has been assigned by the World Health Organization.

This definition, including the Notes, is taken from ISO Guide 30:1992.

Coherent (derived) unit (of measurement) [1.10]: A derived unit of measurement that may be expressed as a product of powers of base units with the proportionality factor one (1).

NOTE: Coherency can be determined only with respect to the base units of a particular system. A unit can be coherent with respect to one system but not to another.

Coherent system of units (of measurement) [1.11]: A system of units of measurement in which all of the derived units are coherent.

Conservation of a (measurement) standard [6.12]: A set of operations, necessary to preserve the metrological characteristics of a measurement standard within appropriate limits.

NOTE: The operations commonly include periodic calibration, storage under suitable conditions, and care in use.

Interlaboratory Standard: A device that travels between laboratories for the sole purpose of relating the magnitude of the physical unit represented by the standards maintained in the respective laboratories.

International (measurement) standard [6.2]: A standard recognized by an international agreement to serve internationally as the basis for assigning values to other standards of the quantity concerned.

International System of Units (SI) [1.12]: The coherent system of units adopted and recommended by the General Conference on Weights and Measures (CGPM).

NOTE: The SI is based at present on the following seven base units: meter, kilogram, second, ampere, kelvin, mole, and candela.

Measurand [2.6]: A particular quantity subject to measurement.

EXAMPLE: Vapor pressure of a given sample of water at 20°C.

NOTE: The specification of a measurand may require statements about quantities such as time, temperature, and pressure.

Measurement [2.1]: A set of operations having the object of determining a value of a quantity.

NOTE: The operations may be performed automatically.

Method of Measurement [2.4]: A logical sequence of operations, described generically, used in the performance of measurements.

NOTE: Methods of measurement may be qualified in various ways, such as:

- Substitution method
- Differential method
- Null method

Metrology [2.2]: The science of measurement.

NOTE: Metrology includes all aspects, both theoretical and practical, with reference to measurements, whatever their uncertainty, and in whatever fields of science or technology they occur.

National (measurement) Standard [6.3]: A standard recognized by a national decision to serve, in a country, as the basis for assigning values to other standards of the quantity concerned.

National Reference Standard: A standard maintained by national laboratories such as the National Institute of Standards and Technology (NIST) in Gaithersburg, MD; the National Research Council (NRC) located in Ottawa, Canada; the National Physical Laboratory (NPL) in Teddington, U.K.; the Physikalisch-Technische Bundesanstalt (PTB) at Braunschweig, Germany; and which are the legal standards of their respective countries.

National Institute of Standards and Technology (NIST): The U.S. national standards laboratory, responsible for maintaining the physical standards upon which measurements in the U.S. are based.

Primary Standard [6.4]: A standard that is designated or widely acknowledged as having the highest metrological qualities and whose value is accepted without reference to other standards of the same quantity.

NOTE: The concept of primary standard is equally valid for base quantities and derived quantities.

Principle of Measurement [2.3]: The scientific base of a measurement.

EXAMPLES:

- The thermoelectric effect applied to the measurement of temperature
- The Josephson effect applied to the measurement of electric potential difference
- The Doppler effect applied to the measurement of velocity
- The Raman effect applied to the measurement of the wave number of molecular vibrations

Reference Standard [6.6]: A standard, generally having the highest metrological quality available at a given location or in a given organization, from which measurements made there are derived.

Reference Material [6.13]: A material or substance, one or more of whose property values are sufficiently homogeneous and well established to be used for the calibration of an apparatus, the assessment of a measurement method, or for assigning values to materials.

NOTE: A reference material can be in the form of a pure or mixed gas, liquid or solid. Examples are water for the calibration of viscometers, sapphire as a heat-capacity calibrant in calorimetry, and solutions used for calibration in chemical analysis.

This definition, including the Note, is taken from ISO Guide 30:1992.

Repeatability (of results of measurements) [3.6]: The closeness of the agreement between the results of successive measurements of the same measurand carried out under the same conditions of measurement.

NOTES:

1. These conditions are called *repeatability conditions*.
2. Repeatability conditions include:
 - a. The same measurement process
 - b. The same observer
 - c. The same measuring instrument, used under the same conditions
 - d. The same location
 - e. Repetition over a short period of time
3. Repeatability can be expressed quantitatively in terms of the dispersion of characteristics of the results.

Reproducibility (of results of measurements) [3.7]: The closeness of the agreement between the results of measurements of the same measurand carried out under changed conditions of measurement.

NOTES:

1. A valid statement of reproducibility requires specification of the conditions changed.
2. The changed conditions include:
 - a. Principle of measurement
 - b. Method of measurement
 - c. Observer
 - d. Measuring instrument
 - e. Reference standard
 - f. Location
 - g. Condition of use
 - h. Time
3. Reproducibility can be expressed quantitatively in terms of the dispersion characteristics of the results.
4. Results here are usually understood to be corrected results.

Secondary Standard [6.5]: A standard whose value is assigned by comparison with a primary standard of the same quantity.

Standards Laboratory: A work space, provided with equipment and standards, a properly controlled environment, and trained personnel, established for the purpose of maintaining traceability of standards and measuring equipment used by the organization it supports. Standards laboratories typically perform fewer, more specialized and higher accuracy measurements than Calibration Laboratories.

Tolerance: In metrology, the limits of the range of values (the uncertainty) that apply to a properly functioning measuring instrument.

Traceability [6.10]: The property of the result of a measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties.

NOTE:

1. The concept is often expressed by the adjective *traceable*.
2. The unbroken chain of comparisons is called a *traceability chain*.

Even though the ISO has published (and accepted) the definition listed above, many practitioners endeavor to make this term more meaningful. They feel that the definition should introduce the aspect of evidence being presented on a continuing basis, to overcome the idea that if valid traceability is achieved, it could last forever. A definition similar to the following one would meet that requirement.

Traceability is a characteristic of a calibration or a measurement. A traceable measurement or calibration is achieved only when each instrument and standard, in a hierarchy stretching back to the national (or international) standard was itself properly calibrated and the results properly documented including statements of uncertainty on a continuing basis. The documentation must provide the information needed to show that all the calibrations in the chain of calibrations were appropriately performed.

Transfer Standard [6.8]: A standard used as an intermediary to compare standards.

NOTE: The term *transfer device* should be used when the intermediary is not a standard.

Traveling Standard [6.9]: A standard, sometimes of special construction, intended for transport between locations.

EXAMPLE: A portable battery-operated cesium frequency standard.

Uncertainty of Measurement [3.9]: A parameter, associated with the result of a measurement, that characterizes the dispersion of the values that could reasonably be attributed to the measurand.

NOTES:

1. The parameter can be, for example, a standard deviation (or a given multiple of it), or the half-width of an interval having a stated level of confidence.
2. Uncertainty of measurement comprises, in general, many components. Some of these components can be evaluated from the statistical distribution of the results of series of measurements and can be characterized by experimental standard deviations. The other components, which can also be characterized by standard deviations, are evaluated from assumed probability distributions based on experience or other information.
3. It is understood that the result of the measurement is the best estimate of the value of the measurand, and that all components of uncertainty (including those arising from systematic effects) such as components associated with corrections and reference standards, contribute to the dispersion.

This definition is that of the *Guide to the Expression of Uncertainty in Measurement*, in which its rationale is detailed (see, in particular, 2.2.4 and annex D).[4]

Value (of a quantity) [1.18]: The magnitude of a particular quantity generally expressed as a unit of measurement multiplied by a number.

EXAMPLES:

- Length of a rod: 5.34 m or 534 cm
- Mass of a body: 0.152 kg or 152 g
- Amount of substance of a sample of water (H₂O): 0.012 mol or 12 mmol

NOTES:

1. The value of a quantity can be positive, negative, or zero.
2. The value of a quantity can be expressed in more than one way.

3. The values of quantities of dimension one are generally expressed as pure numbers.
4. A quantity that cannot be expressed as a unit of measurement multiplied by a number can be expressed by reference to a conventional reference scale or to a measurement procedure or both.

Working Standard [6.7]: A standard that is used routinely to calibrated or check material measures, measuring instruments or reference materials.

NOTES:

1. A working standard is usually calibrated against a *reference standard*.
2. A working standard used routinely to ensure that a measurement is being carried out correctly is called a *check standard*.

6.1 Resistive Displacement Sensors

Keith Antonelli, James Ko, and Shyan Ku

Resistive displacement sensors are commonly termed potentiometers or “pots.” A pot is an electromechanical device containing an electrically conductive *wiper* that slides against a fixed *resistive element* according to the position or angle of an external shaft. See [Figure 6.1](#). Electrically, the resistive element is “divided” at the point of wiper contact. To measure displacement, a pot is typically wired in a “voltage divider” configuration, as shown in [Figure 6.2](#). The circuit’s output, a function of the wiper’s position, is an analog voltage available for direct use or digitization. Calibration maps the output voltage to units of displacement.

[Table 6.1](#) lists some attributes inherent to pots. This chapter describes the different types of pots available, their electrical and mechanical characteristics, and practical approaches to using them for precision measurement. Sources and typical prices are also discussed. Versatile, inexpensive, and easy-to-use, pots are a popular choice for precision measurement.

Precision Potentiometers

Pots are available in great variety, with specific kinds optimized for specific applications. Position measurement requires a high-quality pot designed for extended operation. Avoid pots classified as trimmers, rheostats, attenuators, volume controls, panel controls, etc. Instead, look for *precision potentiometers*.

FIGURE 6.1 Representative cutaways of linear-motion (a) and rotary (b) potentiometers.

FIGURE 6.2 (a) Schematic diagrams depict a potentiometer as a resistor with an arrow representing the wiper. This schematic shows a pot used as a variable voltage divider — the preferred configuration for precision measurement. R_p is the total resistance of the pot, R_L is the load resistance, v_r is the reference or supply voltage, and v_o is the output voltage. (b) shows an ideal linear output function where x represents the wiper position, and x_p is its maximum position.

TABLE 6.1 Fundamental Potentiometer Characteristics

Advantages	Disadvantages
Easy to use	Limited bandwidth
Low cost	Frictional loading
Nonelectronic	Inertial loading
High-amplitude output signal	Wear
Proven technology	

Types of Precision Potentiometers

Precision pots are available in *rotary*, *linear-motion*, and *string pot* forms. String pots — also called *cable pots*, *yo-yo pots*, *cable extension transducers*, and *draw wire transducers* — measure the extended length of a spring-loaded cable. Rotary pots are available with single- or multiturn abilities: commonly 3, 5, or 10 turns. Linear-motion pots are available with maximum strokes ranging from roughly 5 mm to over 4 m [1, 2]. String pots are available with maximum extensions exceeding 50 m [3]. Pot manufacturers usually specify a pot's type, dimensions, resistive element composition, electrical and mechanical parameters, and mounting method.

Resistive Element

Broadly, a pot's resistive element can be classified as either *wirewound*, or *nonwirewound*. Wirewound elements contain tight coils of resistive wire that quantize measurement in step-like increments. In contrast, nonwirewound elements present a continuous sheet of resistive material capable of essentially unlimited measurement resolution.

Wirewound elements offer excellent temperature stability and high power dissipation abilities. The coils quantize measurement according to wire size and spacing. Providing the resolution limits are acceptable, wirewound elements can be a satisfactory choice for precision measurement; however, conductive plastic or hybrid elements will usually perform better and for considerably more cycles. These and other popular nonwirewound elements are described in more detail below.

Conductive plastic elements feature a smooth film with unlimited resolution, low friction, low noise, and long operational life. They are sensitive to temperature and other environmental factors and their power dissipation abilities are low; however, they are an excellent choice for most precision measurement applications.

TABLE 6.2 Characteristics of Conductive Plastic, Wirewound, and Hybrid Resistive Elements

	Conductive plastic	Wirewound	Hybrid
Resolution	Infinitesimal	Quantized	Infinitesimal
Power rating	Low	High	Low
Temperature stability	Poor	Excellent	Very good
Noise	Very low	Low, but degrades with time	Low
Life	10 ⁶ –10 ⁸ cycles	10 ⁵ –10 ⁶ cycles	10 ⁶ –10 ⁷ cycles

TABLE 6.3 Potentiometer Terminal Markings

Terminal	Possible color codings			Rotary pot	Linear-motion pot
1	Yellow	Red	Black	CCW limit	Fully retracted limit
2	Red	Green	White	Wiper	Wiper
3	Green	Black	Red	CW limit	Fully extended limit

Hybrid elements feature a wirewound core with a conductive plastic coating, combining wirewound and conductive plastic technologies to realize some of the more desirable attributes of both. The plastic limits power dissipation abilities in exchange for low noise, long life, and unlimited resolution. Like wirewounds, hybrids offer excellent temperature stability. They make an excellent choice for precision measurement.

Cermet elements, made from a ceramic-metal alloy, offer unlimited resolution and reasonable noise levels. Their advantages include high power dissipation abilities and excellent stability in adverse conditions. Cermet elements are rarely applied to precision measurement because conductive plastic elements offer lower noise, lower friction, and longer life.

Carbon composition elements, molded under pressure from a carbon-plastic mixture, are inexpensive and very popular for general use, but not for precision measurement. They offer unlimited resolution and low noise, but are sensitive to environmental stresses (e.g., temperature, humidity) and are subject to wear.

Table 6.2 summarizes the distinguishing characteristics of the preferred resistive elements for precision measurement.

Electrical Characteristics

Before selecting a pot and integrating it into a measurement system, the following electrical characteristics should be considered.

Terminals and Taps

Table 6.3 shows the conventional markings found on the pot housing [4, 5]; CW and CCW indicate clockwise and counter-clockwise rotation as seen from the front end. Soldering studs and eyelets, integral connectors, and flying leads are common means for electrical connection. In addition to the wiper and end terminals, a pot may possess one or more terminals for *taps*. A tap enables an electrical connection to be made with a particular point along the resistive element. Sometimes, a *shunt resistor* is connected to a tap in order to modify the output function. End terminations and taps can exhibit different electrical characteristics depending on how they are manufactured. See [2] for more details.

Taper

Pots are available in a variety of different tapers that determine the shape of the output function. With a linear-taper pot, the output varies linearly with wiper motion, as shown in Figure 6.2. (Note that a pot with a linear taper should not be confused with a linear-motion pot, which is sometimes called a “linear pot.”) Linear-taper pots are the most commonly available, and are widely used in sensing and control

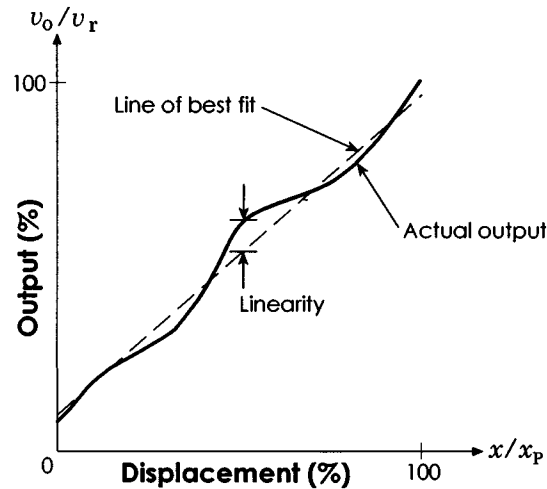

FIGURE 6.3 Independent linearity is the maximum amount by which the actual output function deviates from a line of best fit.

applications. Pots with nonlinear tapers (e.g., logarithmic, sine, cosine, tangent, square, cube) can also be useful, especially where computer control is not involved. Nonstandard tapers can be custom-manufactured or alternatively, certain types of output functions can be produced using shunt resistors, by combining outputs from ganged pots or by other means. (Refer to [6, 7] for more details.) Of course, if a computer is involved, the output function can always be altered through a software lookup table or mapping function.

Electrical Travel

Figure 6.2 shows how the ideal output of a pot changes with wiper position. In practice, there is a small region at both ends where output remains constant until the wiper hits a mechanical stop. *Mechanical travel* is the total motion range of the wiper, and *electrical travel* is the slightly smaller motion range over which the electrical output is “valid.” Thus, when using a pot as a sensor, it is important to ensure that the wiper motion falls within the electrical travel limits.

Linearity

Linearity is the maximum deviation of the output function from an ideal straight line. *Independent linearity* is commonly specified, where the straight line is defined as the line that minimizes the linearity error over a series of sampled points, not necessarily measured over the full range of the pot. See Figure 6.3. Other linearity metrics, such as *terminal-based linearity*, *absolute linearity*, and *zero-based linearity*, are also sometimes used. Refer to [8] for more details. Pots are commonly available with independent linearities ranging from under 0.1% to 1%. When dealing with nonlinear output functions, *conformity* is specified since it is the more general term used to describe deviation from any ideal function. Conformity and linearity are usually expressed as a percentage of full-scale output (FSO).

Electrical Loading

Loading can significantly affect the linearity of measurements, regardless of a pot’s quality and construction. Consider an ideal linear pot connected to an infinite load impedance (i.e., as in Figure 6.2). Since no current flows through the load, the output changes perfectly linearly as the wiper travels along the length of the pot. However, if the load impedance is finite, the load draws some current, thereby affecting the output as illustrated in Figure 6.4. Circuit analysis shows that:

FIGURE 6.4 Linearity can be greatly influenced by the ratio of load resistance, R_L , to potentiometer resistance, R_p .

$$\frac{v_o}{v_r} = \frac{(x/x_p)(R_L/R_p)}{(R_L/R_p) + (x/x_p) - (x/x_p)^2} \quad (6.1)$$

Therefore, R_L/R_p should be maximized to reduce loading effects (this also involves other trade-offs, to be discussed). A minimum R_L/R_p value of 10 is sometimes used as a guideline since loading error is then limited to under 1% of full-scale output. Also, some manufacturers recommend a minimum load impedance or maximum wiper current in order to minimize loading effects and prevent damage to the wiper contacts. The following are some additional strategies that can be taken:

- Use a regulated voltage source whose output is stable with load variations
- Use high input-impedance signal conditioning or data acquisition circuitry
- Use only a portion of the pot's full travel

Resolution

Resolution defines the smallest possible change in output that can be produced and detected. In wirewound pots, the motion of the wiper over the coil generates a quantized response. Therefore, the best attainable resolution is $r = (1/N) \times 100\%$, where N is the number of turns in the coil. Nonwirewound pots produce a smooth response with essentially unlimited resolution. Hybrid pots also fall into this category. In practice, resolution is always limited by factors such as:

- Electrical noise, usually specified as *noise* for wirewound pots and *smoothness* for nonwirewound pots, both expressed as a percentage of full-scale output [10]
- Stability of the voltage supply, which can introduce additional noise into the measurement signal
- Analog-to-digital converter (ADC) resolution, usually expressed in “bits” (e.g., 10 mm travel digitized using a 12-bit ADC results in $10 \text{ mm}/4096 = 0.0024 \text{ mm}$ resolution at best)
- Mechanical effects such as stiction

Power Rating

The power dissipated by a pot is $P = v_r^2/R_p$. Therefore, power rating determines the maximum voltage that can be applied to the pot at a given temperature. With greater voltage supplied to the pot, greater

output (and noise) is produced but more power is dissipated, leading to greater thermal effects. In general, wirewound and cermet pots are better able to dissipate heat, and thus have the highest power ratings.

Temperature Coefficient

As temperature increases, pot resistance also increases. However, a pot connected as shown in Figure 6.2 will divide the voltage equally well, regardless of its total resistance. Thus, temperature effects are not usually a major concern as long as the changes in resistance are uniform and the pot operates within its ratings. However, an increase in pot resistance also increases loading nonlinearities. Therefore, temperature coefficients can become an important consideration. The temperature coefficient, typically specified in ppm °C⁻¹, can be expressed as $\alpha = (\Delta R_p/R_p)/\Delta t$, where Δt is the change in temperature and ΔR_p is the corresponding change in total resistance. In general, wirewound pots possess the lowest temperature coefficients. Temperature-compensating signal-conditioning circuitry can also be used.

Resistance

Since a pot divides voltage equally well regardless of its total resistance, resistance tolerance is not usually a major concern. However, total resistance can have a great impact on loading effects. If resistance is large, less current flows through the pot, thus reducing temperature effects, but also increasing loading.

AC Excitation

Pots can operate using either a dc or an ac voltage source. However, wirewound pots are susceptible to capacitive and inductive effects that can be substantial at moderate to high frequencies.

Mechanical Characteristics

The following mechanical characteristics influence measurement quality and system reliability, and thus should be considered when selecting a pot.

Mechanical Loading

A pot adds inertia and friction to the moving parts of the system that it is measuring. As a result, it increases the force required to move these parts. This effect is referred to as *mechanical loading*. To quantify mechanical loading, rotary pot manufacturers commonly list three values: the equivalent *mass moment of inertia* of the pot's rotating parts, the *dynamic (or running) torque* required to maintain rotation in a pot shaft, and the *starting torque* required to initiate shaft rotation. For linear-motion pots, the three analogous loading terms are *mass*, *starting force*, and *dynamic (or running) force*.

In extreme cases, mechanical loading can adversely affect the operating characteristics of a system. When including a pot in a design, ensure that the inertia added to the system is insignificant or that the inertia is considered when analyzing the data from the pot. The starting and running force or torque values might also be considered, although they are generally small due to the use of bearings and low-friction resistive elements.

Mechanical Travel

Distinguished from electrical travel, *mechanical travel* is the wiper's total motion range. A mechanical stop delimits mechanical travel at each end of the wiper's range of motion. Stops can withstand small loads only and therefore should not be used as mechanical limits for the system. Manufacturers list maximum loads as the *static stopping strength* (for static loads) and the *dynamic stopping strength* (for moving loads).

Rotary pots are also available without mechanical stops. The shaft of such an "unlimited travel" pot can be rotated continuously in either direction; however, electrical travel is always less than 360° due to the discontinuity or "dead-zone" where the resistive element begins and ends. (See Figure 6.1.) Multiple revolutions can be measured with an unlimited travel pot in conjunction with a counter: the counter maintains the number of full revolutions while the pot measures subrevolution angular displacement.

Operating Temperature

When operated within its specified temperature range, a pot maintains good electrical linearity and mechanical integrity. Depending on construction, pots can operate at temperatures from as low as -65°C

to as high as 150°C. Operating outside specified limits can cause material failure, either directly from temperature or from thermally induced misalignment.

Vibration, Shock, and Acceleration

Vibration, shock, and acceleration are all potential sources of contact discontinuities between the wiper and the resistive element. In general, a contact failure is considered to be a discontinuity equal to or greater than 0.1 ms [2]. The values quoted in specification sheets are in *gs* and depend greatly on the particular laboratory test. Some characterization tests use sinusoidal vibration, random vibration, sinusoidal shock, sawtooth shock, or acceleration to excite the pot. Manufacturers use mechanical design strategies to eliminate weaknesses in a pot's dynamic response. For example, one technique minimizes vibration-induced contact discontinuities using multiple wipers of differing resonant frequencies.

Speed

Exceeding a pot's specified maximum speed can cause premature wear or discontinuous values through effects such as wiper bounce. As a general rule, the slower the shaft motion, the longer the unit will last (in total number of cycles). Speed limitations depend on the materials involved. For rotary pots, wirewound models have preferred maximum speeds on the order of 100 rpm, while conductive plastic models have allowable speeds as high as 2000 rpm. Linear-motion pots have preferred maximum velocities up to 10 m s⁻¹.

Life

Despite constant mechanical wear, a pot's expected lifetime is on the order of a million cycles when used under proper conditions. A quality film pot can last into the hundreds of millions of cycles. Of wirewound, hybrid, and conductive plastic pots, the uneven surface of a wirewound resistive element inherently experiences the most wear and thus has the shortest expected operating life. Hybrids improve on this by using a wirewound construction in combination with a smooth conductive film coating. Conductive plastic pots generally have the longest life expectancy due to the smooth surface of their resistive element.

Contamination and Seals

Foreign material contaminating pots can promote wear and increase friction between the wiper and the resistive element. Consequences range from increased mechanical loading to outright failure (e.g., seizing, contact discontinuity). Fortunately, sealed pots are available from most manufacturers for industrial applications where dirt and liquids are often unavoidable. To aid selection, specifications often include the type of *case sealing* (i.e., mechanisms and materials) and the *seal resistance* to cleaning solvents and other commonly encountered fluids.

Misalignment

Shaft misalignment in a pot can prematurely wear its bearing surfaces and increase its mechanical loading effects. A good design minimizes misalignment. (See *Implementation*, below.) Manufacturers list a number of alignment tolerances. In linear-motion pots, *shaft misalignment* is the maximum amount a shaft can deviate from its axis. The degree to which a shaft can rotate around its axis is listed under *shaft rotation*. In rotary pots, *shaft end play* and *shaft radial play* both describe the amount of shaft deflection due to a radial load. *Shaft runout* denotes the shaft diameter eccentricity when a shaft is rotated under a radial load.

Mechanical Mounting Methods

Hardware features on a pot's housing determine the mounting method. Options vary with manufacturer, and among rotary, linear-motion, and string pots. Offerings include custom bases, holes, tabs, flanges, and brackets — all of which secure with machine screws — and threaded studs, which secure with nuts. Linear-motion pots are available with rod or slider actuation, some with internal or external return springs. Mounting is typically accomplished by movable clamps, often supplied by the pot manufacturer. Other linear-motion pots mount via a threaded housing. For rotary pots, the two most popular mounting methods are the *bushing mount* and the *servo mount*. See [Figure 6.5](#).

FIGURE 6.5 The two most common rotary pot mounts are the bushing mount (a), and the servo mount (b).

Bushing mount

The pot provides a shaft-concentric, threaded sleeve that invades a hole in a mounting fixture and secures with a nut and lock-washer. An off-axis tab or pin prevents housing rotation. Implementing a bushing mount requires little more than drilling a hole; however, limited rotational freedom and considerable play before tightening complicate precise setup.

Servo mount

The pot provides a flanged, shaft-concentric, precision-machined rim that slips into a precision-bored hole in a mounting fixture. The flange secures with symmetrically arranged, quick-releasing *servo mount clamps*, available from Timber-Top, Inc. [9] and also from the sources listed in Table 6.4. (These clamps are also called *synchro mount clamps* and *motor mount cleats*, since servo-mounting synchros and stepper motors are also available.) Servo mounts are precise and easy to adjust, but entail the expense of precision machining.

Measurement Techniques

To measure displacement, a pot must attach to mechanical fixtures and components. The housing typically mounts to a stationary reference frame, while the shaft couples to a moving element. The *input motion* (i.e., the motion of interest) can couple directly or indirectly to the pot's shaft. A direct connection, although straightforward, carries certain limitations:

FIGURE 6.6 Mechanisms that extend a precision potentiometer's capabilities include belts and pulleys (a), rack-and-pinions (b), lead-screws (c), cabled drums (d), cams (e), bevel gears (f), and spur gears (g).

- The input motion maps 1:1 to the shaft motion
- The input motion cannot exceed the pot's mechanical travel limits
- Angle measurement requires a rotary pot; position measurement requires a linear-motion pot
- The pot must mount close to the motion source
- The input motion must be near-perfectly collinear or coaxial with the shaft axis

Figure 6.6 shows ways to overcome these limitations. Mechanisms with a mechanical advantage scale motion and adjust travel limits. Mechanisms that convert between linear and rotary motion enable any type of pot to measure any kind of motion. Transmission mechanisms distance a pot from the measured motion. Compliant mechanisms compensate for misalignment. Examples and more details follow. Most of the described mechanisms can be realized with components available from the sources in Table 6.4.

Gears scale the mapping between input and pot shaft motions according to gear ratio. They also displace rotation axes to a parallel or perpendicular plane according to type of gear (e.g., spur vs. bevel). Gears introduce backlash. Friction rollers are a variation on the gear theme, immune to backlash but prone to slippage. The ratio of roller diameters scales the mapping between input and pot shaft motions.

Rack-and-pinion mechanisms convert between linear and rotary motion. Mapping is determined by the rack's *linear pitch* (i.e., tooth-to-tooth spacing) compared to the number of teeth on the pinion. Backlash is inevitable.

Lead-screws convert rotary motion to linear motion via the screw principle. Certain low-friction types (e.g., ball-screws) are also capable of the reverse transformation (i.e., linear to rotary). Either way, mapping is controlled by the screw's *lead* — the distance the nut travels in one revolution. Lead-screws are subject to backlash.

Cabled drums convert between linear and rotary motion according to the drum circumference, since one turn of diameter D wraps or unwraps a length πD of cable. An external force (e.g., supplied by a spring or a weight) might be necessary to maintain cable tension.

Pulleys can direct a string pot's cable over a complex path to a motion source. Mapping is 1:1 unless the routing provides a mechanical advantage.

Pulleys and *belts* transmit rotary motion scaled according to relative pulley diameters. The belt converts between linear and rotary motion. (See Figure 6.6(a)) The empty area between pulleys provides a convenient passageway for other components. Sprocket wheels and chain have similar characteristics. Matched pulley-belt systems are available that operate with negligible slip, backlash, and stretch.

Cams map rotary motion into linear motion according to the function “programmed” into the cam profile. See [10] for more information.

Linkages can be designed to convert, scale, and transmit motion. Design and analysis can be quite complex and mapping characteristics tend to be highly nonlinear. See [11] for details.

Flexible shafts transmit rotary motion between two non-parallel axes with a 1:1 mapping, subject to torsional windup and hysteresis if the motion reverses.

Conduit, like a bicycle brake cable or *Bowden cable*, can route a cable over an arbitrary path to connect a pot to a remote motion source. The conduit should be incompressible and fixed at both ends. Mapping is 1:1 with some mechanical slop. Lubrication helps mitigate friction.

A mechanism's mapping characteristics impact measurement resolution and accuracy. Consider a stepper motor turning a lead-screw to translate a nut. A linear-motion pot could measure the nut's position directly to some resolution. Alternatively, a rotary pot linked to the lead-screw could measure the position with increased resolution if the mechanism mapped the same amount of nut travel to considerably more wiper travel. Weighing the resolution increase against the uncertainty due to backlash would determine which approach was more accurate.

Implementation

Integrating a pot into a measurement system requires consideration of various design issues, including the impact of the pot's physical characteristics, error sources, space restrictions, and wire-routing. The pot's shaft type and bearings must be taken into consideration and protected against excessive loading. A good design will:

- Give the pot mount the ability to accommodate minor misalignment
- Protect the shaft from thrust, side, and bending loads (i.e., not use the pot as a bearing)
- Provide hard limit stops within the pot's travel range (i.e., not use the pot's limit stops)
- Protect the pot from contaminants
- Strain-relieve the pot's electrical connections

A thorough treatment of precision design issues appears in [12].

Coupling to the Pot

Successful implementation also requires practical techniques for mechanical attachment. A string pot's cable terminator usually fastens to other components with a screw. For other types of pots, coupling technique is partly influenced by the nature of the shaft. Rotary shafts come with various endings, including plain, single-flatted, double-flatted, slotted, and knurled. Linear-motion shafts usually terminate in threads, but are also available with roller ends (to follow surfaces) or with spherical bearing ends (to accommodate misalignment). With care, a shaft can be cut, drilled, filed, threaded, etc.

In a typical measurement application, the pot shaft couples to a mechanical component (e.g., a gear, a pulley), or to another shaft of the same or different diameter. Successful couplings provide a positive link to the shaft without stressing the pot's mechanics. Satisfying these objectives with rotary and linear-motion pots requires a balance between careful alignment and compliant couplings. Alignment is not as critical with a string pot. Useful coupling methods include the following.

Compliant couplings. It is generally wise to put a compliant coupling between a pot's shaft and any other shafting. A compliant coupling joins two misaligned shafts of the same or different diameter. Offerings from the companies in Table 6.4 include bellows couplings, flex couplings, spring couplings, spider couplings, Oldham couplings, wafer spring couplings, flexible shafts, and universal joints. Each type has idiosyncrasies that impact measurement error; manufacturer catalogs provide details.

Sleeve couplings. Less expensive than a compliant coupling, a rigid sleeve coupling joins two shafts of the same or different diameter with the requirement that the shafts be perfectly aligned. Perfect alignment is difficult to achieve initially, and impossible to maintain as the system ages. Imperfect alignment accelerates wear and risks damaging the pot. Sleeve couplings are available from the companies listed in Table 6.4.

Press fits. A press fit is particularly convenient when the bore of a small plastic part is nominally the same as the shaft diameter. Carefully force the part onto the shaft. Friction holds the part in place, but repeated reassembly will compromise the fit.

Shrink fits. Components with a bore slightly under the shaft diameter can be heated to expand sufficiently to slip over the shaft. A firm grip results as the part cools and the bore contracts.

Pinning. Small hubbed components can be pinned to a shaft. The pin should extend through the hub partway into the shaft, and the component should fit on the shaft without play. Use roll pins or spiral pins combined with a thread-locking compound (e.g., Loctite 242).

Set-screws. Small components are available with hubs that secure with set-screws. The component should fit on the shaft without play. For best results, use two set-screws against a shaft with perpendicular flats. Dimple a plain shaft using the component's screw hole(s) as a drill guide. Apply a thread-locking compound (e.g., Loctite 242) to prevent the set-screws from working loose.

Clamping. Small components are also available with split hubs that grip a shaft when squeezed by a matching hub clamp. Clamping results in a secure fit without marring the shaft.

Adhesives. Retaining compounds (e.g., Loctite 609) can secure small components to a shaft. Follow manufacturer's instructions for best results.

Spring-loaded contact. A spring-loaded shaft will maintain positive contact against a surface that moves at reasonable speeds and without sudden acceleration.

Costs and Sources

Precision pots are inexpensive compared to other displacement measurement technologies. Table 6.5 lists approximate costs for off-the-shelf units in single quantity. Higher quality generally commands a higher price; however, excellent pots are often available at bargain prices due to volume production or surplus conditions. Electronic supply houses offer low-cost pots (i.e., under \$20) that can suffice for short-term projects. Regardless of price, always check the manufacturer's specifications to confirm a pot's suitability for a given application.

Table 6.6 lists several sources of precision pots. Most manufacturers publish catalogs, and many have Web sites. In addition to a standard product line, most manufacturers will custom-build pots for high-volume applications.

TABLE 6.5 Typical Single-quantity Prices (\$US) for Commercially Available Pots

Potentiometer type	Approximate price range
Rotary	\$10–\$350
Linear-motion	\$20–\$2000
String	\$250–\$1000

Evaluation

Precision pots are a mature technology, effectively static except for occasional developments in materials, packaging, manufacturing, etc. Recent potentiometric innovations — including momentary-contact membrane pots [13] and solid-state digital pots [14] — are unavailing to precision measurement.

The variable voltage divider is the traditional configuration for precision measurement. The circuit's output, a high-amplitude dc voltage, is independent of variations in the pot's total resistance, and is highly compatible with other circuits and systems. Other forms of output are possible with a precision pot configured as a variable resistor. For example, paired with a capacitor, a pot could supply a position-dependent RC time constant to modulate an oscillator's output frequency or duty cycle. In this setup, the pot's stability and ac characteristics would be important.

An alternative resistive displacement sensing technology is the *magneto-resistive potentiometer*, available in rotary and linear-motion forms. Magneto-resistive pots incorporate a noncontacting, permanent magnet "wiper" that rides above a pair of magneto-resistive elements. The elements, configured as a voltage divider, change their resistances according to the strength of the applied magnetic field, and thus divide the voltage as a function of the magnet's position. The output is approximately linear over a limited range of motion (e.g., 90° in rotary models). Magneto-resistive pots offer unlimited resolution and exceptionally long life, but may require temperature compensation circuitry. See [15] for more information.

6.2 Inductive Displacement Sensors

Halit Eren

Inductive sensors are widely used in industry in many diverse applications. They are robust and compact, and are less affected by environmental factors (e.g., humidity, dust) in comparison to their capacitive counterparts.

Inductive sensors are primarily based on the principles of magnetic circuits. They can be classified as self-generating or passive. The self-generating types utilize an electrical generator principle; that is, when there is a relative motion between a conductor and a magnetic field, a voltage is induced in the conductor. Or, a varying magnetic field linking a stationary conductor produces voltage in the conductor. In instrumentation applications, the magnetic field may be varying with some frequency and the conductor may also be moving at the same time. In inductive sensors, the relative motion between field and conductor is supplied by changes in the measurand, usually by means of some mechanical motion. On the other hand, the passive transducer requires an external source of power. In this case, the action of the transducer is simply the modulation of the excitation signal.

For the explanation of the basic principles of inductive sensors, a simple magnetic circuit is shown in [Figure 6.7](#). The magnetic circuit consists of a core, made from a ferromagnetic material, with a coil of n number of turns wound on it. The coil acts as a source of magnetomotive force (mmf) which drives the flux Φ through the magnetic circuit. If one assumes that the air gap is zero, the equation for the magnetic circuit can be expressed as:

$$\text{mmf} = \text{Flux} \times \text{Reluctance} = \Phi \times \mathfrak{R} \quad \text{A-turns} \quad (6.2)$$

such that the reluctance \mathfrak{R} limits the flux in a magnetic circuit just as resistance limits the current in an electric circuit. By writing the mmf in terms of current, the magnetic flux may be expressed as:

$$\Phi = ni/\mathfrak{R} \quad \text{weber} \quad (6.3)$$

In [Figure 6.7](#), the flux linking a single turn is by [Equation 6.3](#); but the total flux linking by the entire n number of the turns of the coil is

FIGURE 6.7 A basic inductive sensor consists of a magnetic circuit made from a ferromagnetic core with a coil wound on it. The coil acts as a source of magnetomotive force (mmf) that drives the flux through the magnetic circuit and the air gap. The presence of the air gap causes a large increase in circuit reluctance and a corresponding decrease in the flux. Hence, a small variation in the air gap results in a measurable change in inductance.

$$\Psi = n\Phi = n^2 i / \mathfrak{R} \quad \text{weber} \quad (6.4)$$

Equation 6.4 leads to self inductance L of the coil, which is described as the total flux (Ψ weber) per unit current for that particular coil; that is

$$L = \Psi / I = n^2 / \mathfrak{R} \quad (6.5)$$

This indicates that the self inductance of an inductive element can be calculated by magnetic circuit properties. Expressing \mathfrak{R} in terms of dimensions as:

$$\mathfrak{R} = l / \mu \mu_0 A \quad (6.6)$$

- where l = the total length of the flux path
- μ = the relative permeability of the magnetic circuit material
- μ_0 = the permeability of free space ($= 4\pi \times 10^{-7}$ H/m)
- A = the cross-sectional area of the flux path

The arrangement illustrated in Figure 6.7 becomes a basic inductive sensor if the air gap is allowed to vary. In this case, the ferromagnetic core is separated into two parts by the air gap. The total reluctance of the circuit now is the addition of the reluctance of core and the reluctance of air gap. The relative permeability of air is close to unity, and the relative permeability of the ferromagnetic material is of the order of a few thousand, indicating that the presence of the air gap causes a large increase in circuit reluctance and a corresponding decrease in the flux. Hence, a small variation in the air gap causes a measurable change in inductance. Most of the inductive transducers are based on these principles and are discussed below in greater detail.

FIGURE 6.8 A typical single-coil, variable-reluctance displacement sensor. The sensor consists of three elements: a ferromagnetic core in the shape of a semicircular ring, a variable air gap, and a ferromagnetic plate. The reluctance of the coil is dependent on the single variable. The reluctance increases nonlinearly with increasing gap.

Linear and Rotary Variable-Reluctance Transducer

The variable-reluctance transducers are based on change in the reluctance of a magnetic flux path. This type of transducer finds application particularly in acceleration measurements. However, they can be constructed to be suitable for sensing displacements as well as velocities. They come in many different forms, as described below.

The Single-Coil Linear Variable-Reluctance Sensor

A typical single-coil variable-reluctance displacement sensor is illustrated in [Figure 6.8](#). The sensor consists of three elements: a ferromagnetic core in the shape of a semicircular ring, a variable air gap, and a ferromagnetic plate. The total reluctance of the magnetic circuit is the sum of the individual reluctances:

$$\mathfrak{R}_T = \mathfrak{R}_C + \mathfrak{R}_G + \mathfrak{R}_A \quad (6.7)$$

where \mathfrak{R}_C , \mathfrak{R}_G , and \mathfrak{R}_A are the reluctances of the core, air gap, and armature, respectively.

Each one of these reluctances can be determined by using the properties of materials involved, as in Equation 6.6. In this particular case, the reluctance \mathfrak{R}_T can be approximated as:

$$\mathfrak{R}_T = R/\mu_C \mu_0 r^2 + 2d/\mu_0 \pi r^2 + R/\mu_A \mu_0 r t \quad (6.8)$$

In obtaining Equation 6.8, the length of flux path in the core is taken as πR . The cross-sectional area is assumed to be uniform, with a value of πr^2 . The total length of the flux path in air is $2d$, and it is assumed that there is no fringing or bending of the flux through the air gap, such that the cross-sectional area of the flux path in air will be close to that of the cross section of the core. The length of an average central flux path in the armature is $2R$. The calculation of the appropriate cross section area of the armature is difficult, but it may be approximated to $2rt$, where t is the thickness of the armature.

In Equation 6.8 all of the parameters are fixed except for the one independent variable — the air gap. Hence, it can be simplified as:

$$\mathfrak{R}_T = \mathfrak{R}_0 + kd \quad (6.9)$$

where $\mathfrak{R}_0 = R/\mu_0 r [1/\mu_C r + 1/\mu_A t]$, and
 $k = 2/\mu_0 \pi r^2$

Using Equations 6.5 and 6.9, the inductance can be written as:

$$L = n^2 / (\mathfrak{R}_0 + kd) = L_0 / (1 + \alpha d) \quad (6.10)$$

where $L_0 =$ the inductance at zero air gap
 $\alpha = k/\mathfrak{R}_0$

The values of L_0 and α can be determined mathematically: they depend on the core geometry, permeability, etc., as explained above. It can be seen from Equation 6.10 that the relationship between L and α is nonlinear. Despite this nonlinearity, these types of single coil sensors find applications in some areas, such as force measurements and telemetry. In force measurements, the resultant change in inductance can be made to be a measure of the magnitude of the applied force. The coil usually forms one of the components of an LC oscillator, for which the output frequency varies with the applied force. Hence, the coil modulates the frequency of the local oscillator.

The Variable-Differential Reluctance Sensor

The problem of the nonlinearity can be overcome by modifying the single coil system into a variable-differential reluctance sensor (also known as push-pull sensor), as shown in [Figure 6.9](#). This sensor consists of an armature moving between two identical cores, and separated by a fixed distance of $2d$. Now, Equation 6.10 can be written for both coils as:

$$\begin{aligned} L_1 &= L_{01} / [1 + \alpha(d - x)], \\ L_2 &= L_{02} / [1 + \alpha(d + x)] \end{aligned} \quad (6.11)$$

Although the relationship between L_1 and L_2 is still nonlinear, the sensor can be incorporated into an ac deflection bridge to give a linear output for small movements. The hysteresis errors of these transducers are almost entirely limited to the mechanical components. These sensors respond to both static and dynamic measurements. They have continuous resolution and high outputs, but they may give erratic performance in response to external magnetic fields. A typical sensor of this type has an input span of 1 cm, a coil inductance of 25 mH, and a coil resistance of 75 Ω . The resistance of the coil must be carefully considered when designing oscillator circuits. The maximum nonlinearity is 0.5%.

A typical commercially available variable differential sensor is shown in [Figure 6.10](#). The iron core is located halfway between the two E-shaped frames. The flux generated by primary coils depends on the reluctance of the magnetic path, the main reluctance being the air gap. Any motion of the core increases the air gap on one side and decreases it on the other side, thus causing reluctance to change, in accordance

FIGURE 6.9 A variable-differential reluctance sensor consists of an armature moving between two identical cores separated by a fixed distance. The armature moves in the air gap in response to a mechanical input. This movement alters the reluctance of coils 1 and 2, thus altering their inductive properties. This arrangement overcomes the problem of nonlinearity inherent in single coil sensors.

with the principles explained above, and thereby inducing more voltage on one of the coils than on the other. Motion in the other direction reverses the action with a 180° phase shift occurring at null. The output voltage can be modified, depending on the requirements in signal processing, by means of rectification, demodulation, or filtering. In these instruments, full-scale motion may be extremely small — on the order of few thousandths of a centimeter.

In general, variable reluctance transducers have small ranges and are used in specialized applications such as pressure transducers. Magnetic forces imposed on the armature are quite large and this severely limits their application. However, the armature can be constructed as a diaphragm; hence, suitable for pressure measurements.

Variable-Reluctance Tachogenerators

Another example of a variable reluctance sensor is shown in [Figure 6.11](#). These sensors are based on Faraday's law of electromagnetic induction; therefore, they may also be referred to as electromagnetic sensors. Basically, the induced emf in the sensor depends on the linear or angular velocity of the motion.

The variable-reluctance tachogenerator consists of a ferromagnetic, toothed wheel attached to a rotating shaft, and a coil wound onto a permanent magnet, extended by a soft iron pole piece. The wheel moves in close proximity to the pole piece, causing the flux linked by the coil to change, thus inducing an emf in the coil. The reluctance of the circuit depends on the width of the air gap between the rotating wheel and the pole piece. When the tooth is close to the pole piece, the reluctance is minimum and it

FIGURE 6.10 A typical commercial variable differential sensor. The iron core is located half-way between the two E frames. Motion of the core increases the air gap for one of the E frames while decreasing the other side. This causes reluctances to change, thus inducing more voltage on one side than the other. Motion in the other direction reverses the action, with a 180° phase shift occurring at null. The output voltage can be processed, depending on the requirements, by means of rectification, demodulation, or filtering. The full-scale motion may be extremely small, on the order of few thousandths of a centimeter.

increases as the tooth moves away from the pole. When the wheel rotates with a velocity ω , the flux may mathematically be expressed as:

$$\Psi(\theta) = A + B \cos m\theta \quad (6.12)$$

where A = the mean flux
 B = the amplitude of the flux variation
 m = the number of teeth

The induced emf is given by:

$$E = -d\Psi(\theta)/dt = -(d\Psi(\theta)/d\theta) \times (d\theta/dt) \quad (6.13)$$

or

$$E = bm\omega \sin m\omega t \quad (6.14)$$

FIGURE 6.11 A variable-reluctance tachogenerator is a sensor which is based on Faraday's law of electromagnetic induction. It consists of a ferromagnetic toothed wheel attached to the rotating shaft and a coil wound onto a permanent magnet extended by a soft iron pole piece. The wheel rotates in close proximity to the pole piece, thus causing the flux linked by the coil to change. The change in flux causes an output in the coil similar to a square waveform whose frequency depends on the speed of the rotation of the wheel and the number of teeth.

Both amplitude and frequency of the generated voltage at the coil are proportional to the angular velocity of the wheel. In principle, the angular velocity ω can be found from either the amplitude or the frequency of the signal. In practice, the amplitude measured may be influenced by loading effects and electrical interference. In signal processing, the frequency is the preferred option because it can be converted into digital signals easily.

The variable-reluctance tachogenerators are most suitable for measuring angular velocities. They are also used in the volume flow rate measurements and the total volume flow determination of fluids.

Microsyn

Another commonly used example of variable-reluctance transducer is the Microsyn, as illustrated in Figure 6.12. In this arrangement, the coils are connected in such a manner that at the null position of the rotary element, the voltages induced in coils 1 and 3 are balanced by voltages induced in coils 2 and 4. The motion of the rotor in the clockwise direction increases the reluctance of coils 1 and 3 while decreasing the reluctance of coils 2 and 4, thus giving a net output voltage e_o . The movement in the counterclockwise direction causes a similar effect in coils 2 and 4 with a 180° phase shift. A direction-sensitive output can be obtained by using phase-sensitive demodulators, as explained in LVDT section of this chapter.

Microsyn transducers are used extensively in applications involving gyroscopes. By the use of microsins, very small motions can be detected, giving output signals as low as 0.01° of changes in angles. The sensitivity of the device can be made as high as 5 V per degree of rotation. The nonlinearity may vary from 0.5% to 1.0% full scale. The main advantage of these transducers is that the rotor does not have windings and slip-rings. The magnetic reaction torque is also negligible.

Synchros

The term *synchro* is associated with a family of electromechanical devices that can be discussed under different headings. They are used primarily in angle measurements and are commonly applied in control engineering as parts of servomechanisms, machine tools, antennas, etc.

The construction of synchros is similar to that of wound-rotor induction motors, as shown in Figure 6.13. The rotation of the motor changes the mutual inductance between the rotor coil and the three stator coils. The three voltage signals from these coils define the angular position of the rotor.

FIGURE 6.12 A microsyn is a variable reluctance transducer that consists of a ferromagnetic rotor and a stator carrying four coils. The stator coils are connected such that at the null position, the voltages induced in coils 1 and 3 are balanced by voltages induced in coils 2 and 4. The motion of the rotor in one direction increases the reluctance of two opposite coils while decreasing the reluctance in others, resulting in a net output voltage e_o . The movement in the opposite direction reverses this effect with a 180° phase shift.

Synchros are used in connection with variety of devices, including: control transformers, Scott T transformers, resolvers, phase-sensitive demodulators, analog to digital converters, etc.

In some cases, a control transformer is attached to the outputs of the stator coils such that the output of the transformer produces a resultant mmf aligned in the same direction as that of the rotor of the synchro. In other words, the synchro rotor acts as a search coil in detecting the direction of the stator field of the control transformer. When the axis of this coil is aligned with the field, the maximum voltage is supplied to the transformer.

In other cases, ac signals from the synchros are first applied to a Scott T transformer, which produces ac voltages with amplitudes proportional to the sine and cosine of the synchro shaft angle. It is also possible to use phase-sensitive demodulations to convert the output signals to make them suitable for digital signal processing.

Linear-Variable Inductor

There is a little distinction between variable-reluctance and variable-inductance transducers. Mathematically, the principles of linear-variable inductors are very similar to the variable-reluctance type of transducer. The distinction is mainly in the pickups rather than principles of operations. A typical linear variable inductor consists of a movable iron core that provides the mechanical input and two coils forming two legs of a bridge network. A typical example of such a transducer is the variable coupling transducer, which is discussed next.

FIGURE 6.13 A synchro is similar to a wound-rotor induction motor. The rotation of the rotor changes the mutual inductance between the rotor coil and the stator coils. The voltages from these coils define the angular position of the rotor. They are primarily used in angle measurements and are commonly applied in control engineering as parts of servomechanisms, machine tools, antennas, etc.

Variable-Coupling Transducers

These transducers consist of a former holding a center tapped coil and a ferromagnetic plunger, as shown in Figure 6.14.

The plunger and the two coils have the same length l . As the plunger moves, the inductances of the coils change. The two inductances are usually placed to form two arms of a bridge circuit with two equal balancing resistors, as shown in Figure 6.15. The bridge is excited with ac of 5 V to 25 V with a frequency of 50 Hz to 5 kHz. At the selected excitation frequency, the total transducer impedance at null conditions is set in the 100 Ω to 1000 Ω range. The resistors are set to have about the same value as transducer impedances. The load for the bridge output must be at least 10 times the resistance, R , value. When the plunger is in the reference position, each coil will have equal inductances of value L . As the plunger moves by δL , changes in inductances $+\delta L$ and $-\delta L$ creates a voltage output from the bridge. By constructing the bridge carefully, the output voltage can be made as a linear function displacement of the moving plunger within a rated range.

In some transducers, in order to reduce power losses due to heating of resistors, center-tapped transformers can be used as a part of the bridge network, as shown in Figure 6.15(b). In this case, the circuit becomes more inductive and extra care must be taken to avoid the mutual coupling between the transformer and the transducer.

FIGURE 6.14 A typical linear-variable inductor consists of a movable iron core inside a former holding a center-tapped coil. The core and both coils have the same length l . When the core is in the reference position, each coil will have equal inductances of value L . As the core moves by δl , changes in inductances $+\delta L$ and $-\delta L$ create voltage outputs from the coils.

Center-tapped transformer

FIGURE 6.15 The two coils of a linear-variable inductor are usually placed to form two arms of a bridge circuit, also having two equal balancing resistors as in circuit (a). The bridge is excited with ac of 5 V to 25 V with a frequency of 50 Hz to 5 kHz. At a selected excitation frequency, the total transducer impedance at null conditions is set in the 100 Ω to 1000 Ω range. By careful construction of the bridge, the output voltage can be made a linear function displacement of the core within a limited range. In some cases, in order to reduce power losses due to heating of resistors, center-tapped transformers may be used as a part of the bridge network (b).

It is particularly easy to construct transducers of this type, by simply winding a center-tapped coil on a suitable former. The variable-inductance transducers are commercially available in strokes from about 2 mm to 500 cm. The sensitivity ranges between 1% full scale to 0.02% in long stroke special constructions. These devices are also known as linear displacement transducers or LDTs, and they are available in various shape and sizes.

Apart from linear-variable inductors, there are rotary types available too. Their cores are specially shaped for rotational applications. Their nonlinearity can vary between 0.5% to 1% full scale over a range of 90° rotation. Their sensitivity can be up to 100 mV per degree of rotation.

FIGURE 6.16 An induction potentiometer is a linear-variable inductor with two concentrated windings wound on the stator and on the rotor. The rotor winding is excited with ac, inducing voltage in the stator windings. The amplitude of the output voltage is dependent on the relative positions of the coils, as determined by the angle of rotation. For concentrated coils, the variation of the amplitude is sinusoidal, but linearity is restricted in the region of the null position. Different types of induction potentiometers are available with distributed coils that give linear voltages over an angle of 180° of rotation.

Induction Potentiometer

One version of a rotary type linear inductor is the induction potentiometer shown in [Figure 6.16](#). Two concentrated windings are wound on the stator and rotor. The rotor winding is excited with an ac, thus inducing voltage in the stator windings. The amplitude of the output voltage is dependent on the mutual inductance between the two coils, where mutual inductance itself is dependent on the angle of rotation. For concentrated coil type induction potentiometers, the variation of the amplitude is sinusoidal, but linearity is restricted in the region of the null position. A linear distribution over an angle of 180° can be obtained by carefully designed distributed coils.

Standard commercial induction pots operate in a 50 to 400 Hz frequency range. They are small in size, from 1 cm to 6 cm, and their sensitivity can be on the order of 1 V/deg rotation. Although the ranges of induction pots are limited to less than 60° of rotation, it is possible to measure displacements in angles from 0° to full rotation by suitable arrangement of a number of induction pots. As in the case of most

FIGURE 6.17 A linear-variable-differential-transformer LVDT is a passive inductive transducer consisting of a single primary winding positioned between two identical secondary windings wound on a tubular ferromagnetic former. As the core inside the former moves, the magnetic paths between primary and secondaries change, thus giving secondary outputs proportional to the movement. The two secondaries are made as identical as possible by having equal sizes, shapes, and number of turns.

inductive sensors, the output of an induction pot may need phase-sensitive demodulators and suitable filters. In many cases, additional dummy coils are used to improve linearity and accuracy.

Linear Variable-Differential Transformer (LVDT)

The linear variable-differential transformer, LVDT, is a passive inductive transducer finding many applications. It consists of a single primary winding positioned between two identical secondary windings wound on a tubular ferromagnetic former, as shown in [Figure 6.17](#). The primary winding is energized by a high-frequency 50 Hz to 20 kHz ac voltage. The two secondary windings are made identical by having an equal number of turns and similar geometry. They are connected in series opposition so that the induced output voltages oppose each other.

In many applications, the outputs are connected in opposing form, as shown in [Figure 6.18\(a\)](#). The output voltages of individual secondaries v_1 and v_2 at null position are illustrated in [Figure 6.18\(b\)](#). However, in opposing connection, any displacement in the core position x from the null point causes amplitude of the voltage output v_o and the phase difference α to change. The output waveform v_o in relation to core position is shown in [Figure 6.18\(c\)](#). When the core is positioned in the middle, there is

FIGURE 6.18 The voltages induced in the secondaries of a linear-variable differential-transformer (a) may be processed in a number of ways. The output voltages of individual secondaries v_1 and v_2 at null position are illustrated in (b). In this case, the voltages of individual coils are equal and in phase with each other. Sometimes, the outputs are connected opposing each other, and the output waveform v_o becomes a function of core position x and phase angle α , as in (c). Note the phase shift of 180° as the core position changes above and below the null position.

an equal coupling between the primary and secondary windings, thus giving a null point or reference point of the sensor. As long as the core remains near the center of the coil arrangement, output is very linear. The linear ranges of commercial differential transformers are clearly specified, and the devices are seldom used outside this linear range.

The ferromagnetic core or plunger moves freely inside the former, thus altering the mutual inductance between the primary and secondaries. With the core in the center, or at the reference position, the induced emfs in the secondaries are equal; and since they oppose each other, the output voltage is zero. When the core moves, say to the left, from the center, more magnetic flux links with the left-hand coil than with the right-hand coil. The voltage induced in the left-hand coil is therefore larger than the induced voltage on the right-hand coil. The magnitude of the output voltage is then larger than at the null position and is equal to the difference between the two secondary voltages. The net output voltage is in phase with the voltage of the left-hand coil. The output of the device is then an indication of the displacement of the core. Similarly, movement in the opposite direction to the right from the center reverses this effect, and the output voltage is now in phase with the emf of the right-hand coil.

For mathematical analysis of the operation of LVDTs, Figure 6.18(a) can be used. The voltages induced in the secondary coils are dependent on the mutual inductance between the primary and individual secondary coils. Assuming that there is no cross-coupling between the secondaries, the induced voltages may be written as:

$$v_1 = M_1 s i_p \quad \text{and} \quad v_2 = M_2 s i_p \quad (6.15)$$

where M_1 and M_2 are the mutual inductances between primary and secondary coils for a fixed core position; s is the Laplace operator; and i_p is the primary current

(b)

FIGURE 6.18 (continued)

In the case of opposing connection, no load output voltage v_o without any secondary current may be written as:

$$v_o = v_1 - v_2 = (M_1 - M_2) s i_p \quad (6.16)$$

writing

$$v_s = i_p (R + sL_p) \quad (6.17)$$

Substituting i_p in Equation 6.15 gives the transfer function of the transducer as:

$$v_o / v_s = (M_1 - M_2) s / (R + sL_p) \quad (6.18)$$

FIGURE 6.18 (continued)

However, if there is a current due to output signal processing, then describing equations may be modified as:

$$v_o = R_m i_s \quad (6.19)$$

where $i_s = (M_1 - M_2) s i_p / (R_s + R_m + sL_s)$
and

$$v_s = i_p (R + sL_p) - (M_1 - M_2) s i_s \quad (6.20)$$

Eliminating i_p and i_s from Equations 4.19 and 4.20 results in a transfer function as:

$$v_o/v_s = R_m (M_1 - M_2) s / \left\{ \left[(M_1 - M_2)^2 + L_s L_p \right] s^2 + \left[L_p (R + R_m) + R L_s \right] s + (R_s + R_m) + R \right\} \quad (6.21)$$

This is a second-order system, which indicates that due to the effect of the numerator of Eq. 6.21, the phase angle of the system changes from $+90^\circ$ at low frequencies to -90° at high frequencies. In practical applications, the supply frequency is selected such that at the null position of the core, the phase angle of the system is 0° .

The amplitudes of the output voltages of secondary coils are dependent on the position of the core. These outputs may directly be processed from each individual secondary coil for slow movements of the core, and when the direction of the movement of the core does not bear any importance. However, for fast movements of the core, the signals can be converted to dc and the direction of the movement from the null position can be detected. There are many options to do this; however, a *phase-sensitive demodulator*

FIGURE 6.19 Phase-sensitive demodulator and (a) are commonly used to obtain displacement proportional signals from LVDTs and other differential type inductive sensors. They convert the ac outputs from the sensors into dc values and also indicate the direction of movement of the core from the null position. A typical output of the phase-sensitive demodulator is shown in (b). The relationship between output voltage v_o and phase angle α is also shown against core position x .

and filter arrangement is commonly used, as shown in [Figure 6.19\(a\)](#). A typical output of the phase-sensitive demodulator is illustrated in [Figure 6.19\(b\)](#), in relation to output voltage v_o , displacement x , and phase angle α .

The phase-sensitive demodulators are used extensively in differential type inductive sensors. They basically convert the ac outputs to dc values and also indicate the direction of movement of the core

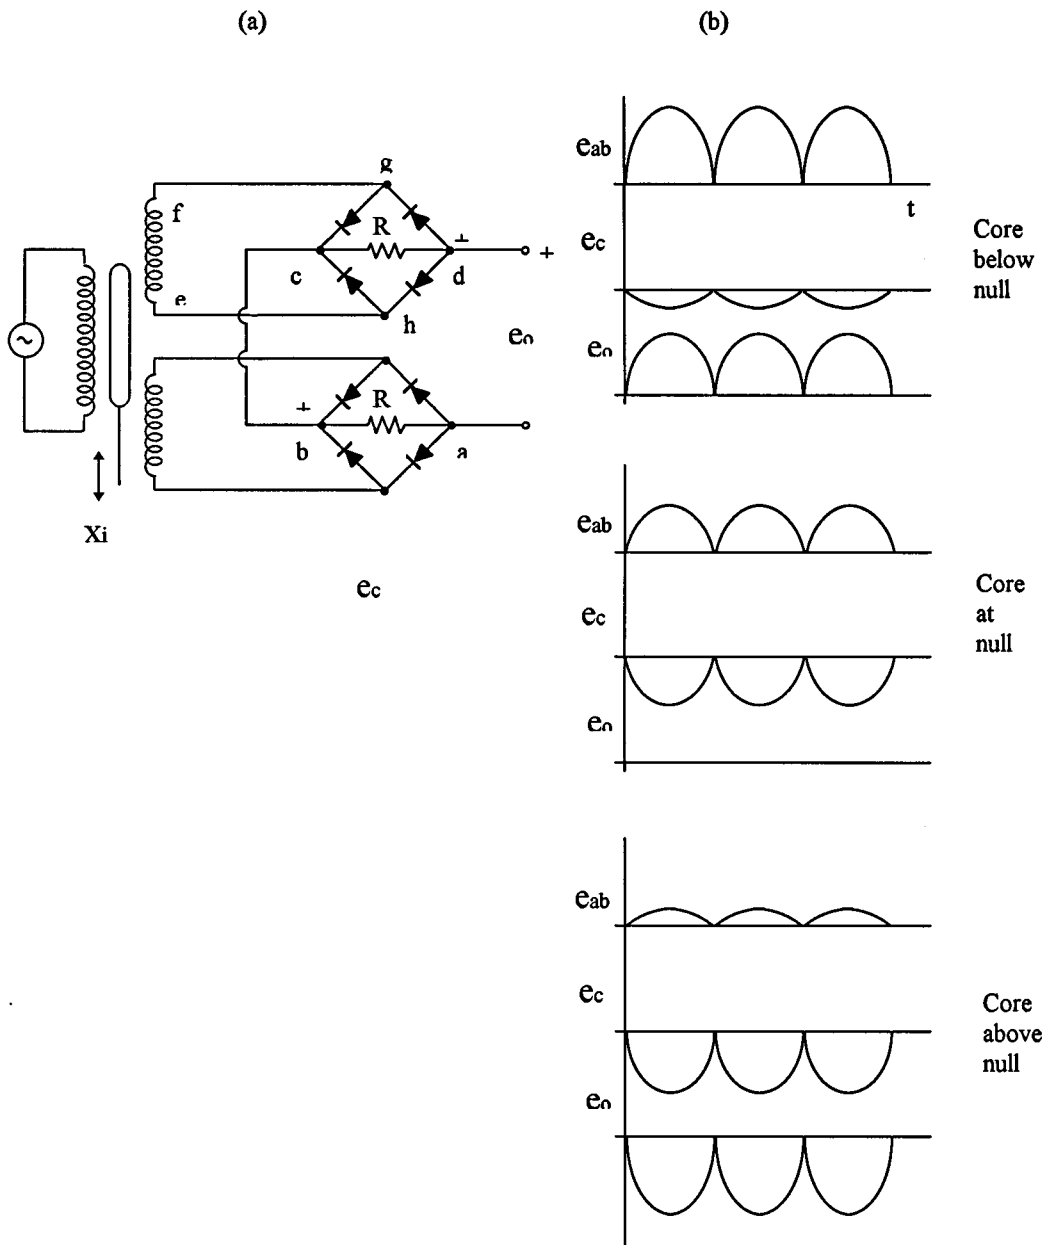

FIGURE 6.20 A typical phase-sensitive demodulation circuit based on diode bridges as in (a). Bridge 1 acts as a rectification circuit for secondary 1, and bridge 2 acts as a rectifier for secondary 2 where the net output voltage is the difference between the two bridges, as in (b). The position of the core can be determined from the amplitude of the dc output, and the direction of the movement of the core can be determined from the polarity of the voltage. For rapid movements of the core, the output of the diode bridges must be filtered, for this, a suitably designed simple RC filter may be sufficient.

from the null position. A typical phase-sensitive demodulation circuit may be constructed, based on diodes shown in Figure 6.20(a). This arrangement is useful for very slow displacements, usually less than 1 or 2 Hz. In this figure, bridge 1 acts as a rectification circuit for secondary 1, and bridge 2 acts as a rectifier for secondary 2. The net output voltage is the difference between the outputs of two bridges, as

in [Figure 6.20\(b\)](#). The position of the core can be determined from the amplitude of the dc output, and the direction of the movement of the core can be determined from the polarity of the dc voltage. For rapid movements of the core, the outputs of the diode bridges need to be filtered, wherein only the frequencies of the movement of the core pass through and all the other frequencies produced by the modulation process are filtered. For this purpose, a suitably designed simple RC filter may be sufficient.

There are phase-sensitive demodulator chips available in the marketplace, such as AD598 offered by Analog Devices Inc. These chips are highly versatile and flexible to use to suit particular application requirements. These chips offer many advantages over conventional phase-sensitive demodulation devices; for example, frequency of excitation may be adjusted to any value between 20 Hz and 20 kHz by connecting an external capacitor between two pins. The amplitude of the excitation voltage can be set up to 24 V. The internal filters may be set to required values by external capacitors. Connections to analog-to-digital converters are easily made by converting the bipolar output to unipolar scale.

The frequency response of LVDTs is primarily limited by the inertia characteristics of the device. In general, the frequency of the applied voltage should be 10 times the desired frequency response. Commercial LVDTs are available in a broad range of sizes and they are widely used for displacement measurements in a variety of applications. These displacement sensors are available to cover ranges from ± 0.25 mm to ± 7.5 cm. They are sensitive enough to be used to respond to displacements well below 0.0005 mm. They have operational temperature ranges from -265°C to 600°C . They are also available in radiation-resistant designs for operation in nuclear reactors. For a typical sensor of ± 25 mm range, the recommended supply voltage is 4 V to 6 V, with a nominal frequency of 5 kHz, and a maximum non-linearity of 1% full scale. Several commercial models are available that can produce a voltage output of 300 mV for 1 mm displacement of the core.

One important advantage of the LVDT is that there is no physical contact between the core and the coil form, and hence no friction or wear. Nevertheless, there are radial and longitudinal magnetic forces on the core at all times. These magnetic forces may be regarded as magnetic springs that try to displace the core to its null position. This may be a critical factor in some applications.

One problem with LVDTs is that it may not be easy to make the two halves of the secondary identical; their inductance, resistance, and capacitance may be different, causing a large unwanted quadrature output in the balance position. Precision coil winding equipment may be required to reduce this problem to an acceptable value.

Another problem is associated with null position adjustments. The harmonics in the supply voltage and stray capacitances result in small null voltages. The null voltage may be reduced by proper grounding, which reduces the capacitive effects and center-tapped voltage source arrangements. In center-tapped supplies, a potentiometer may be used to obtain a minimum null reading.

The LVDTs have a variety of applications, including control for jet engines in close proximity to exhaust gases and measuring roll positions in the thickness of materials in hot-slab steel mills. Force and pressure measurements may also be made by LVDTs after some mechanical modifications.

Rotary Variable-Differential Transformer

A variation from the linear-variable differential transformer is the rotary core differential transformer shown in [Figures 6.21\(a\) and 6.21\(b\)](#). Here, the primary winding is wound on the center leg of an E core, and the secondary windings are wound on the outer legs of the core. The armature is rotated by an externally applied force about a pivot point above the center leg of the core. When the armature is displaced from its reference or balance position, the reluctance of the magnetic circuit through one secondary coil decreases, simultaneously increasing the reluctance through the other coil. The induced emfs in the secondary windings, which are equal in the reference position of the armature, are now different in magnitude and phase as a result of the applied displacement. The induced emfs in the secondary coils are made to oppose each other and the transformer operates in the same manner as an LVDT. The rotating variable transformers may be sensitive to vibrations. If a dc output is required, a demodulator network can be used, as in the case of LVDTs.

Rotational differential transformer

FIGURE 6.21 A rotary core differential transformer has an E-shaped core, carrying the primary winding on the center leg and the two secondaries on the outer legs, as in (a). The armature is rotated by an externally applied force about a pivot point above the center leg of the core (b). When the armature is displaced from its reference or balance position, the reluctance of the magnetic circuit through one secondary coil is decreased, increasing the reluctance through the other coil. The induced emfs in the secondary windings are different in magnitude and phase as a result of the applied displacement.

FIGURE 6.22 Eddy current transducers are inductive transducers using probes. The probes contain one active and one balance coil. The active coil responds to the presence of a conducting target, while the balance coil completes a bridge circuit and provides temperature compensation. When the probe is brought close the target, the flux from the probe links with the target, producing eddy currents within the target that alter the inductance of the active coil. This change in inductance is detected by a bridge circuit.

In most rotary linear-variable differential transformers, the rotor mass is very small, usually less than 5 g. The nonlinearity in the output ranges between $\pm 1\%$ and $\pm 3\%$, depending on the angle of rotation. The motion in the radial direction produces a small output signal that can affect the overall sensitivity. However, this transverse sensitivity is usually kept below 1% of the longitudinal sensitivity.

Eddy Current

Inductive transducers based on eddy currents are mainly probe types, containing two coils as shown in [Figure 6.22](#). One of the coils, known as the active coil, is influenced by the presence of the conducting target. The second coil, known as the balance coil, serves to complete the bridge circuit and provides temperature compensation. The magnetic flux from the active coil passes into the conductive target by means of a probe. When the probe is brought close to the target, the flux from the probe links with the target, producing eddy currents within the target.

The eddy current density is greatest at the target surface and become negligibly small, about three skin depths below the surface. The skin depth depends on the type of material used and the excitation frequency. While thinner targets can be used, a minimum of three skin depths is often necessary to minimize the temperature effects. As the target comes closer to the probe, the eddy currents become stronger, causing the impedance of the active coil to change and altering the balance of the bridge in relation to the target position. This unbalance voltage of the bridge may be demodulated, filtered, and linearized to produce a dc output proportional to target displacement. The bridge oscillation may be as high as 1 MHz. High frequencies allow the use of thin targets and provide good system frequency response.

Probes are commercially available with full-scale diameter ranging from 0.25 to 30 mm with a non-linearity of 0.5% and a maximum resolution of 0.0001 mm. Targets are usually supplied by the clients, involving noncontact measurements of machine parts. For nonconductive targets, conductive materials of sufficient thickness must be attached to the surface by means of commercially available adhesives. Since the target material, shape, etc. influence the output, it is necessary to calibrate the system statistically

for a specific target. The recommended measuring range of a given probe begins at a standoff distance equal to about 20% of the stated range of the probe. In some cases, a standoff distance of 10% is recommended for which the system is calibrated as standard. A distance greater than 10% of the measuring range can be used as long as the calibrated measuring range is reduced by the same amount.

Flat targets must be of the same diameter as the probe or larger. If the target diameter is smaller than the probe diameter, the output drops considerably, thus becoming unreliable. Curved-surface targets can behave similar to flat surfaces if the diameter exceeds about three or four times the diameter of the probe. In this case, the target essentially becomes an infinite plane. This also allows some cross-axis movement without affecting the system output. Target diameters comparable to the sensor could result in detrimental effects in measurements due to cross-axis movements.

For curved or irregular shaped targets, the system must be calibrated using the exact target that is seen in the operation. This tends to eliminate any errors caused by the curved surfaces during application. However, special multiprobe systems are available for orbital motions of rotating shafts. If the curved (shaft) target is about 10 times larger than the sensor diameter, it acts as an infinite plane and does not need special calibrations. Care must be exercised to deal with electrical runout due to factors such as inhomogeneities in hardness, etc., particularly valid for ferrous targets. However, nonferrous targets are free from electrical runout concerns.

Shielding and Sensitivity of Inductive Sensors to Electromagnetic Interference

Magnetic fields are produced by currents in wires and more strongly by the coils. The fields due to coils are important due to magnetic coupling, particularly when there are two or more coils in the circuit. The magnetic coupling between coils may be controlled by large spacing between coils, orientation of coils, the shape of the coils, and by shielding.

Inductive sensors come in different shape and sizes. While some sensors have closed cores such as toroidal shapes, others have open cores and air gaps between cores and coils. Closed cores can have practically zero external fields, except for small leakage fluxes. Even if the sensors do not have closed cores, most variable inductor sensors have rather limited external fields, due to two neighboring sets of coils connected in opposite directions that minimize the external fields.

Inductive sensors are made from closed conductors. This implies that if the conductor moves in a magnetic field, a current will flow. Alternatively, a magnetic change produces current in a stationary closed conductor. Unless adequate measures are taken, there may be external magnetic fields linking (interference) with the sensor coils, thus producing currents and unwanted responses.

Due to inherent operations, inductive sensors are designed to have high sensitivity to magnetic flux changes. External electromagnetic interference and external fields can seriously affect the performance of the sensors. It is known that moderate magnetic fields are found near power transformers, electrical motors, and power lines. These small fields produce current in the inductive sensors elements. One way of eliminating external effects is accomplished by magnetic shielding of the sensors and by grounding appropriately. In magnetic shielding, one or more shells of high-permeability magnetic materials surround the part to be shielded. Multiple shells may be used to obtain very complete shielding. The ends of each individual shell are separated by insulation so that the shell does not act as a single shorted turn, thus accommodating high current flows. Similarly, in the case of multiple shielding, shells are isolated from each other by proper insulation.

Alternating magnetic fields are also screened by interposing highly conductive metal sheets such as copper or aluminum on the path of the magnetic flux. The eddy currents induced in the shield give a counter mmf that tends to cancel the interfering magnetic field. This type of shielding is particularly effective at high frequencies. Nevertheless, appropriate grounding must still be observed.

In many inductive sensors, stray capacitances can be a problem, especially at the null position of the moving core. If the capacitive effect is greater than a certain value, say 1% of the full-scale output, this effect may be reduced by the use of center-tapped supply and appropriate grounding.

6.3 Capacitive Sensors—Displacement

Halit Eren and Wei Ling Kong

Capacitive sensors are extensively used in industrial and scientific applications. They are based on changes in capacitance in response to physical variations. These sensors find many diverse applications — from humidity and moisture measurements to displacement sensing. In some cases, the basic operational and sensing principles are common in dissimilar applications; and in other cases, different principles can be used for the same applications. For example, capacitive microphones are based on variations of spacing between plates in response to acoustical pressure, thus turning audio signals to variations in capacitance. On the other hand, a capacitive level indicator makes use of the changes in the relative permittivity between the plates. However, capacitive sensors are best known to be associated with displacement measurements for rotational or translational motions, as will be described next. Other applications of capacitance sensors such as humidity and moisture will be discussed.

Capacitive Displacement Sensors

The measurement of distances or displacements is an important aspect of many industrial, scientific, and engineering systems. The displacement is basically the vector representing a change in position of a body or point with respect to a reference point. Capacitive displacement sensors satisfy the requirements of applications where high linearity and wide ranges (from a few centimeters to a couple of nanometers) are needed.

The basic sensing element of a typical displacement sensor consists of two simple electrodes with capacitance C . The capacitance is a function of the distance d (cm) between the electrodes of a structure, the surface area A (cm²) of the electrodes, and the permittivity ϵ (8.85×10^{-12} F m⁻¹ for air) of the dielectric between the electrodes; therefore:

$$C = f(d, A, \epsilon) \quad (6.22)$$

There are three basic methods for realizing a capacitive displacement sensor: by varying d , A , or ϵ , as discussed below.

Variable Distance Displacement Sensors

A capacitor displacement sensor, made from two flat coplanar plates with a variable distance x apart, is illustrated in [Figure 6.23](#). Ignoring fringe effects, the capacitance of this arrangement can be expressed by:

FIGURE 6.23 A variable distance capacitive displacement sensor. One of the plates of the capacitor moves to vary the distance between plates in response to changes in a physical variable. The outputs of these transducers are nonlinear with respect to distance x having a hyperbolic transfer function characteristic. Appropriate signal processing must be employed for linearization.

$$C(x) = \epsilon A/x = \epsilon_r \epsilon_0 A/x \quad (6.23)$$

where ϵ = the dielectric constant or permittivity
 ϵ_r = the relative dielectric constant (in air and vacuum $\epsilon_r \approx 1$)
 $\epsilon_0 = 8.854188 \times 10^{-12}$ F/m⁻¹, the dielectric constant of vacuum
 x = the distance of the plates in m
 A = the effective area of the plates in m²

The capacitance of this transducer is nonlinear with respect to distance x , having a hyperbolic transfer function characteristic. The sensitivity of capacitance to changes in plate separation is

$$dC/dx = -\epsilon_r \epsilon_0 A/x^2 \quad (6.24)$$

Equation 6.24 indicates that the sensitivity increases as x decreases. Nevertheless, from Equations 6.23 and 6.24, it follows that the percent change in C is proportional to the percent change in x . This can be expressed as:

$$dC/C = -dx/x \quad (6.25)$$

This type of sensor is often used for measuring small incremental displacements without making contact with the object.

Variable Area Displacement Sensors

Alternatively, the displacements may be sensed by varying the surface area of the electrodes of a flat plate capacitor, as illustrated in Figure 6.24. In this case, the capacitance would be:

$$C = \epsilon_r \epsilon_0 (A - wx)/d \quad (6.26)$$

where w = the width
 wx = the reduction in the area due to movement of the plate

Then, the transducer output is linear with displacement x . This type of sensor is normally implemented as a rotating capacitor for measuring angular displacement. The rotating capacitor structures are also used as an output transducer for measuring electric voltages as capacitive voltmeters.

FIGURE 6.24 A variable area capacitive displacement sensor. The sensor operates on the variation in the effective area between plates of a flat-plate capacitor. The transducer output is linear with respect to displacement x . This type of sensor is normally implemented as a rotating capacitor for measuring angular displacement.

FIGURE 6.25 A variable dielectric capacitive displacement sensor. The dielectric material between the two parallel plate capacitors moves, varying the effective dielectric constant. The output of the sensor is linear.

Variable Dielectric Displacement Sensors

In some cases, the displacement may be sensed by the relative movement of the dielectric material between the plates, as shown in Figure 6.25. The corresponding equations would be:

$$C = \epsilon_0 w \left[\epsilon_2 l - (\epsilon_2 - \epsilon_1) x \right] \quad (6.27)$$

where ϵ_1 = the relative permittivity of the dielectric material
 ϵ_2 = the permittivity of the displacing material (e.g., liquid)

In this case, the output of the transducer is also linear. This type of transducer is predominantly used in the form of two concentric cylinders for measuring the level of fluids in tanks. A nonconducting fluid forms the dielectric material. Further discussion will be included in the level measurements section.

Differential Capacitive Sensors

Some of the nonlinearity in capacitive sensors can be eliminated using differential capacitive arrangements. These sensors are basically three-terminal capacitors, as shown in Figure 6.26. Slight variations in the construction of these sensors find many different applications, including differential pressure measurements. In some versions, the central plate moves in response to physical variables with respect to the fixed plates. In others, the central plate is fixed and outer plates are allowed to move. The output from the center plate is zero at the central position and increases as it moves left or right. The range is equal to twice the separation d . For a displacement d , one obtains:

$$2\delta C = C_1 - C_2 = \epsilon_r \epsilon_0 l w / (d - \delta d) - \epsilon_r \epsilon_0 l w / (d + \delta d) = 2\epsilon_r \epsilon_0 l w \delta d / (d^2 + \delta d^2) \quad (6.28)$$

and

$$C_1 + C_2 = 2C = \epsilon_r \epsilon_0 l w / (d - \delta d) + \epsilon_r \epsilon_0 l w / (d + \delta d) = 2\epsilon_r \epsilon_0 l w d / (d^2 + \delta d^2) \quad (6.29)$$

Giving approximately:

$$\delta C / C = \delta d / d \quad (6.30)$$

FIGURE 6.26 A differential capacitive sensor. They are essentially three terminal capacitors with one fixed center plate and two outer plates. The response to physical variables is linear. In some versions, the central plate moves in response to physical variable with respect to two outer plates, and in the others, the central plate is fixed and outer plates are allowed to move.

This indicates that the response of the device is more linear than the response of the two plate types. However, in practice some nonlinearity is still observed due to defects in the structure. Therefore, the outputs of these type of sensors still need to be processed carefully, as explained in the signal processing section.

In some differential capacitive sensors, the two spherical depressions are ground into glass disks; then, these are gold-plated to form the fixed plates of a differential capacitor. A thin, stainless-steel diaphragm is clamped between the disks and serves as a movable plate. With equal pressure applied to both ports, the diaphragm is then in neutral position and the output is balanced at a corresponding bridge. If one pressure is greater than the other, the diaphragm deflects proportionally, giving an output due to the differential pressure. For the opposite pressure difference, there is a phase change of 180° . A direction-sensitive dc output can be obtained by conventional phase-sensitive demodulation and appropriate filtering. Details of signal processing are given at the end of this chapter. In general, the differential capacitors exhibit better linearity than single-capacitor types.

Integrated Circuit Smart Capacitive Position Sensors

Figure 6.27 shows a typical microstructure capacitive displacement sensor. The sensor consists of two electrodes with capacitance, C_x . Since the system is simple, the determination of the capacitance between the two electrodes is straightforward. The smaller electrode is surrounded by a guard electrode to make C_x independent of lateral and rotational movements of the system parallel to the electrode surface. However, the use of a guard electrode introduces relative deviations in the capacitance C_x between the two electrodes. This is partially true if the size of the guard electrode is smaller than:

FIGURE 6.27 A typical smart capacitive position sensor. This type of microstructure position sensor contains three electrodes, two of which are fixed and the third electrode moves infinitesimally relative to the others. Although the response is highly nonlinear the integrated chip contains linearization circuits. They feature a 0 mm to 1 mm measuring range with 1 μm accuracy.

$$\delta < \exp(-\pi x/d) \quad (6.31)$$

where x is the width of the guard and d is the distance between the electrodes. Since this deviation introduces nonlinearity, δ is required to be less than 100 ppm. Another form of deviation also exists between the small electrode and the surrounding guard, particularly for gaps

$$\delta < \exp(-\pi d/s) \quad (6.32)$$

where s is the width of the gap. When the gap width, s , is less than 1/3 of the distance between electrodes, this deviation is negligible.

For signal processing, the system uses the three-signal concept. The capacitor C_x is connected to an inverting operational amplifier and oscillator. If the external movements are linear, by taking into account the parasitic capacitors and offsetting effects, the following equation can be written:

$$M_x = mC_x + M_{\text{off}} \quad (6.33)$$

where m is the unknown gain and M_{off} is the unknown offset. By performing the measurement of a reference C_{ref} by measuring the offset, M_{off} , and by making $m = 0$, the parameters m and M_{off} can be eliminated. The final measurement result for the position, P_{os} , can be defined as:

$$P_{\text{os}} = \frac{M_{\text{ref}} - M_{\text{off}}}{M_x - M_{\text{off}}} \quad (6.34)$$

In this case, the sensor capacitance C_x can be simplified to:

$$C_x = \frac{\epsilon A_x}{d_0 + \Delta d} \quad (6.35)$$

where A_x is the area of the electrode, d_0 is the initial distance between them, ϵ is the dielectric constant, and Δd is the displacement to be measured. For the reference electrodes, the reference capacitance may be found by:

$$C_{\text{ref}} = \frac{\epsilon A_{\text{ref}}}{d_{\text{ref}}} \quad (6.36)$$

with A_{ref} the area and d_{ref} the distance. Substitution of Equations 6.35 and 6.36 into Equations 6.33 and 6.34 yields:

$$P_{\text{os}} = \frac{A_{\text{ref}}(d_0 + \Delta d)}{A_x d_{\text{ref}}} = a_1 \frac{\Delta d}{d_{\text{ref}}} + a_0 \quad (6.37)$$

P_{os} is a value representing the position if the stable constants a_1 and a_0 are unknown. The constant $a_1 = A_{\text{ref}}/A_x$ becomes a stable constant so long as there is good mechanical matching between the electrode areas. The constant $a_0 = (A_{\text{ref}} d_0)/(A_x d_{\text{ref}})$ is also a stable constant for fixed d_0 and d_{ref} . These constants are usually determined by calibration repeated over a certain time span. In many applications, these calibrations are omitted if the displacement sensor is part of a larger system where an overall calibration is necessary. This overall calibration usually eliminates the requirement for a separate determination of a_1 and a_0 .

The accuracy of this type of system could be as small as 1 μm over a 1 mm range. The total measuring time is better than 0.1 s. The capacitance range is from 1 pF to 50 fF. Interested readers should refer to [4] at the end of this chapter.

Capacitive Pressure Sensors

A commonly used two-plate capacitive pressure sensor is made from one fixed metal plate and one flexible diaphragm, as shown in Figure 6.28. The flat circular diaphragm is clamped around its circumference and bent into a curve by an applied pressure P . The vertical displacement y of this system at any radius r is given by:

$$y = 3(1 - \nu^2) \left(a^2 - r^2 \right) P / 16 E t^3 \quad (6.38)$$

FIGURE 6.28 A capacitive pressure sensor. These pressure sensors are made from a fixed metal plate and a flexible diaphragm. The flat flexible diaphragm is clamped around its circumference. The bending of the flexible plate is proportional to the applied pressure P . The deformation of the diaphragm results in changes in capacitance.

where a = the radius of diaphragm
 t = the thickness of diaphragm
 E = Young's modulus
 ν = Poisson's ratio

Deformation of the diaphragm means that the average separation of the plates is reduced. Hence, the resulting increase in the capacitance ΔC can be calculated by:

$$\Delta C/C = (1 - \nu^2) a^4 P / 16 E t^3 \quad (6.39)$$

where d is the initial separation of the plates and C is the capacitance at zero pressure.

Another type of sensor is the differential capacitance pressure sensor shown in Figure 6.29. The capacitances C_1 and C_2 of the sensor change with respect to the fixed central plate in response to the applied pressures P_1 and P_2 . Hence, the output of the sensor is proportional to $(P_1 - P_2)$. The signals are processed using one of the techniques described in the "Signal Processing" section of this chapter.

Capacitive Accelerometers and Force Transducers

In recent years, capacitive-type micromachined accelerometers, as illustrated in Figure 6.30, are gaining popularity. These accelerometers use the proof mass as one plate of the capacitor and use the other plate as the base. When the sensor is accelerated, the proof mass tends to move; thus, the voltage across the capacitor changes. This change in voltage corresponds to the applied acceleration.

In Figure 6.30, let $F(x)$ be the positive force in the direction in which x increases. Neglecting all losses (due to friction, resistance, etc.), the energy balance of the system can be written for an infinitesimally small displacement dx , electrical energy dE_e , and field energy dE_f of the electrical field between the electrodes as:

$$dE_m + dE_e = dE_f \quad (6.40)$$

in which:

$$dE_m = F(x) dx \quad (6.41)$$

FIGURE 6.29 A differential capacitive pressure sensor. The capacitances C_1 and C_2 of the sensor changes due to deformation in the outer plates, with respect to the fixed central plate in response to the applied pressures P_1 and P_2 .

FIGURE 6.30 A capacitive force transducer. A typical capacitive micromachined accelerometer has one of the plates as the proof mass. The other plate is fixed, thus forming the base. When the sensor is accelerated, the proof mass tends to move, thus varying the distance between the plates and altering the voltage across the capacitor. This change in voltage is made to be directly proportional to the applied acceleration.

Also,

$$dE_m = d(QV) = Q dV + V dQ \quad (6.42)$$

If the supply voltage V across the capacitor is kept constant, it follows that $dV = 0$. Since $Q = VC(x)$, the Coulomb force is given by:

$$F(x) = -V^2 \frac{dC(x)}{dx} \quad (6.43)$$

Thus, if the movable electrode has complete freedom of motion, it will have assumed a position in which the capacitance is maximal; also, if C is a linear function of x , the force $F(x)$ becomes independent of x .

Capacitive silicon accelerometers are available in a wide range of specifications. A typical lightweight sensor will have a frequency range of 0 to 1000 Hz, and a dynamic range of acceleration of ± 2 g to ± 500 g.

Capacitive Liquid Level Measurement

The level of a nonconducting liquid can be determined by capacitive techniques. The method is generally based on the difference between the dielectric constant of the liquid and that of the gas or air above it. Two concentric metal cylinders are used for capacitance, as shown in [Figure 6.31](#). The height of the liquid, h , is measured relative to the total height, l . Appropriate provision is made to ensure that the space between the cylindrical electrodes is filled by the liquid to the same height as the rest of the container. The usual operational conditions dictate that the spacing between the electrodes, $s = r_2 - r_1$, should be much less than the radius of the inner electrode, r_1 . Furthermore, the tank height should be much greater than r_2 . When these conditions apply, the capacitance is approximated by:

$$C = \frac{\epsilon_1(l) + \epsilon_g(h-l)}{4.61 \log \left[1 - \left(\frac{s}{r} \right) \right]} \quad (6.44)$$

FIGURE 6.31 A capacitive liquid level sensor. Two concentric metal cylinders are used as electrodes of a capacitor. The value of the capacitance depends on the permittivity of the liquid and that of the gas or air above it. The total permittivity changes depending on the liquid level. These devices are usually applied in nonconducting liquid applications.

where ϵ_l and ϵ_g are the dielectric constants of the liquid and gas (or air), respectively. The denominator of the above equation contains only terms that relate to the fixed system. Therefore, they become a single constant. A typical application is the measurement of the amount of gasoline in a tank in airplanes. The dielectric constant for most compounds commonly found in gasoline is approximately equal to 2, while that of air is approximately unity. A linear change in capacitance with gasoline level is expected for this situation. Quite high accuracy can be achieved if the denominator is kept quite small, thus accentuating the level differences. These sensors often incorporate an ac deflection bridge.

Capacitive Humidity and Moisture Sensors

The permittivities of atmospheric air, of some gases, and of many solid materials are functions of moisture content and temperature. Capacitive humidity devices are based on the changes in the permittivity of the dielectric material between plates of capacitors. The main disadvantage of this type sensor is that a relatively small change in humidity results in a capacitance large enough for a sensitive detection.

Capacitive humidity sensors enjoy wide dynamic ranges, from 0.1 ppm to saturation points. They can function in saturated environments for long periods of time, a characteristic that would adversely affect many other humidity sensors. Their ability to function accurately and reliably extends over a wide range of temperatures and pressures. Capacitive humidity sensors also exhibit low hysteresis and high stability with minimal maintenance requirements. These features make capacitive humidity sensors viable for many specific operating conditions and ideally suitable for a system where uncertainty of unaccounted conditions exists during operations.

FIGURE 6.32 A typical capacitive humidity sensor. The sensors have pore or cracked mosaic structure for the moisture in air or gas to reach the dielectric material. The characteristics of the dielectric material change with the amount of water absorbed, thus reducing the resistance and increasing the capacitance. The quantity measured can be either resistance, capacitance, or impedance.

There are many types of capacitive humidity sensors. Aluminum, tantalum, silicon, and polymer types are introduced here.

Aluminum Type Capacitive Humidity Sensors

The majority of capacitive humidity sensors are aluminum oxide type sensors. In these type of sensors, high-purity aluminum is chemically oxidized to produce a prefilled insulating layer of partially hydrated aluminum oxide, which acts as the dielectric. A water-permeable but conductive gold film is deposited onto the oxide layer, usually by vacuum deposition, which forms the second electrode of the capacitor.

In another type, the aluminum-aluminum oxide sensor has a pore structure as illustrated in [Figure 6.32](#). The oxide, with its pore structure, forms the active sensing material. Moisture in the air reaching the pores reduces the resistance and increases the capacitance. The decreased resistance can be thought of as being due to an increase in the conduction through the oxide. An increase in capacitance can be viewed as due to an increase in the dielectric constant. The quantity measured can be either resistance, capacitance, or impedance. High humidities are best measured by capacitance because resistance changes are vanishingly small in this region.

In addition to the kind of transducer design illustrated here, there are many others available with a number of substantial modifications for particular properties, such as increased sensitivity or faster response. Although most of these modifications result in a change in physical dimensions or appearance, the sensing material of the transducer — the aluminum oxide — remains the same.

In some versions, the oxide layer is formed by parallel tubular pores that are hexagonally packed and perpendicular to the plane of the base layer. These pores stop just before the aluminum layer, forming a very thin pore base. Water absorbed in these tubules is directly related to the moisture content of the gas in contact with it. The porous nature of the oxide layer produces a large area for the absorption of water vapor. At low humidities, the capacitance is due entirely to the mixed dielectric formed between the

oxide, water vapor, and air. However, at higher humidities, parallel conductance paths through the absorbed water are formed down the pore surfaces. Near saturation, this pore surface resistance becomes negligible, implying that the measured capacitance is virtually that between the very thin pore base and the aluminum core.

Tantalum Type Capacitive Humidity Sensors

In some versions of capacitive humidity sensors, one of the capacitor plates consists of a layer of tantalum deposited on a glass substrate. A layer of polymer dielectric is then added, followed by a second plate made from a thin layer of chromium. The chromium layer is under high tensile stress such that it cracks into a fine mosaic structure that allows water molecules to pass into the dielectric. The stress in the chromium also causes the polymer to crack into a mosaic structure. A sensor of this type has an input range of 0% to 100% relative humidity, RH. The capacitance is 375 pF at 0% RH and a linear sensitivity of 1.7 pF per % RH. The error is usually less than 2% due to nonlinearity and 1% due to hysteresis.

Silicon Type Capacitive Humidity Sensors

In other capacitive humidity sensors, silicon is used as the dielectric. The structure and operation of silicon humidity sensors are very similar to the aluminum oxide types. Some silicon-type humidity sensors also use the aluminum base and a thin-film gold layer as the two electrodes. The silicon dielectric has a very large surface area, which means that the sensitivity is still relatively large even if the sensing area is very small. This is an important feature with the increasing trend of miniaturization. Both sensor types are now typically found as extremely small wafer-shaped elements, placed on a mechanical mount with connecting lead wires. The formation of porous silicon is a very simple anodization process and, since no elaborate equipment is needed, devices can be made at relatively low cost. Also, by controlling the formation conditions, the structure of the porous silicon can easily be modified so devices can be tailored to suit particular applications.

In both the silicon and the aluminum oxide capacitive humidity sensors, the radii of the pores in the dielectric are such that they are specifically suited for water molecules. Most possible contaminants are too large in size to pollute the dielectric. However, contaminants can block the flow of water vapor into the sensor material, thus affecting the accuracy of the instrument. For example, in dust-contaminated streams, it may be possible to provide a simple physical barrier such as a sintered metal or plastic hoods for the sensor heads. Many sensors come with some form of casing to provide protection.

Polymer Type Capacitive Humidity Sensors

In some sensors, the dielectric consists of a polymer material that has the ability to absorb water molecules. The absorption of water vapor of the material results in changes in the dielectric constant of the capacitor. By careful design, the capacitance can be made directly proportional to percentage relative humidity of the surrounding gas or atmosphere.

In general, an important key feature of capacitive humidity sensors is the chemical stability. Often, humidity sensing is required in an air sample that contains vapor contaminants (e.g., carbon monoxide) or the measurements are performed on a gas sample other than air (e.g., vaporized benzene). The performance of these sensors, and in particular the silicon types, is not affected by many of these gases. Hydrocarbons, carbon dioxide, carbon monoxide, and CFCs do not cause interference. However, the ionic nature of the aluminum oxide dielectric makes it susceptible to certain highly polar, corrosive gases such as ammonia, sulphur trioxide, and chlorine. Silicon is inert; its stable nature means that these polar gases affect the sensor element to a far lesser degree.

Capacitive Moisture Sensors

Capacitive moisture measurements are based on the changes in the permittivity of granular or powder type dielectric materials such as wheat and other grains containing water. Usually, the sensor consists of a large cylindrical chamber, (e.g., 150 mm deep and 100 mm in diameter), as shown in [Figure 6.33](#). The chamber is filled with samples under test. The variations in capacitance with respect to water content are processed. The capacitor is incorporated into an oscillatory circuit operating at a suitable frequency.

FIGURE 6.33 A capacitive moisture sensor. The permittivity of material between two cylindrical or parallel plates with fixed dimensions changes, depending on the moisture level of the materials in the chamber. The variations in capacitance values with respect to water content is processed. The capacitor is incorporated as a part of an oscillatory circuit operating at a suitable frequency, usually at radio frequencies.

Capacitive moisture sensors must be calibrated for samples made from different materials, as the materials themselves demonstrate different permittivities. Accurate temperature is necessary as the dielectric constant may be highly dependent on temperature. Most of these devices are built to operate at temperature ranges of 0°C to 50°C, supported by tight temperature compensation circuits. Once calibrated for a specific application, they are suitable for measuring moisture in the range of 0% to 40%.

Signal Processing

Generally, capacitive type pickups require relatively complex circuitry in comparison to many other sensor types, but they have the advantage of mechanical simplicity. They are also sensitive, having minimum mechanical loading effects. For signal processing, these sensors are usually incorporated either in ac deflection bridge circuits or oscillator circuits. In practice, capacitive sensors are not pure capacitances but have associated resistances representing losses in the dielectric. This can have an important influence in the design of circuits, particularly in oscillator circuits. Some of the signal processing circuits are discussed below.

Operational Amplifiers and Charge Amplifiers

One method of eliminating the nonlinearity of the relationship between the physical variable, (e.g., two-plate displacement sensors) and capacitance C is through the use of operational amplifiers, as illustrated in [Figure 6.34](#). In this circuit, if the input impedance of the operational amplifier is high, the output is not saturated, and the input voltage is small, it is possible to write:

FIGURE 6.34 An operational amplifier signal processor. This method is useful to eliminate the nonlinearity in the signals generated by capacitive sensors. By this type of arrangement, the output voltage can be made directly proportional to variations in the signal representing the nonlinear operation of the device.

$$1/C_f = \int i_f dt = e_{ex} - e_{ai} = e_{ex} \quad (6.45)$$

$$1/C_x = \int i_x dt = e_o - e_{ai} = e_o \quad (6.46)$$

$$i_f + i_x - i_{ai} = 0 = i_f + i_x \quad (6.47)$$

Manipulation of these equations yields:

$$e_o = -C_f e_{ex} / C_x \quad (6.48)$$

Substituting the value of C_x yields:

$$e_o = -C_f x e_{ex} / \epsilon A \quad (6.49)$$

Equation 6.49 shows that the output voltage is directly proportional to the plate separation x , thus giving linearity for all variations in motion.

However, a practical circuit requires a resistance across C_f to limit output drift. The value of this resistance must be greater than the impedance of C_f at the lowest frequency of interest. Also, because the transducer impedance is assumed to be purely capacitive, the effective gain is independent of frequency.

A practical charge amplifier circuit is depicted in [Figure 6.35](#). In this case, the effective feedback resistance R_{ef} is given by:

$$R_{ef} = R_3 (R_1 + R_2) / R_2 \quad (6.50)$$

It is possible to reduce the output drift substantially by selecting the resistors suitably. The accuracy of this circuit can be improved further by cascading two or more amplifiers. In this way, a substantial improvement in the signal-to-noise ratio can also be achieved. In the inverting input, the use of resistor R_4 is necessary because of bias currents.

FIGURE 6.35 A practical charge amplifier. The effective feedback resistance is a function of other resistances. It is possible to reduce the output drift substantially by selecting the resistors suitably. The accuracy of this circuit can be improved further by cascading two or more amplifiers, thereby substantially improving the signal-to-noise ratio.

Pulse Width Modulation

As in the case of some capacitive vibrational displacement sensors, the output of the sensor may be an amplitude-modulated wave as shown in Figure 6.36. When rectified, the average value of this wave gives the mean separation of the plates. The vibration amplitude around this mean position may be extracted by a demodulator and a low-pass filter circuit. The output of the low-pass filter is a direct indication of vibrations, and the waveform can be viewed on an oscilloscope.

Square Wave Linearization

Another linearization technique applied in capacitive pressure transducers and accelerometers is pulse width modulation. The transducer consists of two differential capacitors as shown in Figure 6.37. The voltages of these capacitors, e_1 and e_2 , switch back and forth with a high excitation frequency (e.g., 400 kHz) between excitation voltage and ground. The system is arranged in such a way that the output voltage is the average voltage difference between e_1 and e_2 . At null position, $e_1 = e_2$, the output is a symmetrical square wave with zero average value. As the relative positions of the plates change, due to vibration, the average value of the output voltage shifts from the zero average value and becomes positive or negative depending on the direction of the displacement. Hence, the output voltage can be expressed by:

$$e_o = e_{ex} (C_1 - C_2) / (C_1 + C_2) \quad (6.51)$$

Substituting:

$$C_1 = C_0 x_0 / (x_0 - x_i) \quad \text{and} \quad C_2 = C_0 x_0 / (x_0 + x_i)$$

FIGURE 6.36 A amplitude modulated signal. It is possible to configure some sensors to give a amplitude-modulated signals, as in the case of capacitive vibrational displacement sensors. When rectified, the average value of this wave gives the mean separation of the plates. The vibration amplitude around this mean position can be extracted by a demodulator and low-pass filter circuit. The output of the low-pass filter is a direct indication of vibrations.

FIGURE 6.37 Block diagram of a square-wave linearization circuit. This is particularly useful for differential capacitance type sensors. The voltages of these two capacitors are made to switch back and forth with a high excitation frequency between excitation voltage and ground. As the relative positions of the plates change due to vibration, the average value of the output voltage becomes positive or negative, depending on the direction of the displacement.

yields

$$e_o = e_{ex} x_1 / x_0 \quad (6.52)$$

Thus, the output is directly proportional to the variable x_1 .

Feedback Linearization

Linearization of a capacitance transducer can also be obtained using a feedback system that adjusts capacitor current amplitude so that it stays constant at a reference value for all displacements. This is accomplished by obtaining a dc signal proportional to capacitor current from a demodulator, comparing this current with the reference current, and adjusting the voltage amplitude of the system excitation oscillator until the two currents agree. If the capacitor current is kept constant irrespective of capacitor motion, then the voltage amplitude is linearly related to x as:

$$e = K x_i \quad (6.53)$$

where

$$K = \left| \dot{i}_c \right| / \omega C_0 x_0 \quad (6.54)$$

Oscillator Circuits

In many applications, the resultant changes in the capacitance of capacitive transducers can be measured with a suitable ac bridge such as Wein bridge or Schering bridge. However, in a majority of cases, improvised versions of bridges are used as oscillator circuits for capacitive signal processing. The transducer is configured as a part of the oscillatory circuit that causes changes in the frequency of the oscillations. This change in frequency is scaled to be a measure of the magnitude of the physical variable.

As part of the oscillator circuits, the capacitive transducer has excellent frequency response and can measure both static and dynamic phenomena. Its disadvantages include sensitivity to temperature variations and the possibility of erratic or distorted signals due to long lead lengths. Also, the receiving instrumentation may be large and complex, and it often includes a second fixed-frequency oscillator for heterodyning purposes. The difference frequency thus produced can be read by an appropriate output device such as an electronic counter.

6.4 Piezoelectric Transducers and Sensors

*Ahmad Safari, Victor F. Janas, Amit Bandyopadhyay,
and Andrei Kholkin*

Piezoelectricity, discovered in Rochelle salt in 1880 by Jacques and Pierre Curie, is the term used to describe the ability of certain materials to develop an electric charge that is proportional to a direct applied mechanical stress. These materials also show the converse effect; that is, they will deform (strain) proportionally to an applied electric field. Some crystalline materials show piezoelectric behavior due to their unique crystal structure. The lattice structure of a crystal is described by the Bravais unit cell [1]. There are 230 microscopic symmetry types (space groups) in nature, based on the several symmetry elements such as translation, inversion center, mirror plane, or rotation axes. Combinations of these symmetry elements yield the macroscopic symmetry known as point groups. All natural crystals can be grouped into 32 different classes (point groups) based on their symmetry elements. The 32 point groups can be further classified into two subgroups: (1) crystals with a center of symmetry, and (2) crystals with no center of symmetry. The 11 centrosymmetric subgroups do not show piezoelectricity. Of the 21 non-centrosymmetric groups, 20 show the piezoelectric effect along unique directional axes. An important class of piezoelectric materials includes ferroelectrics, in which the piezoelectric effect is closely related to the ferroelectric polarization that can be reversed by the application of sufficiently high electric field [2, 3]. To induce piezoelectric properties in ferroelectric materials, a poling procedure is often required, which consists of the temporary application of a strong electric field. Poling is analogous to the magnetizing of a permanent magnet.

Governing Equations and Coefficients

The phenomenological master equation describing the deformations of an insulating crystal subject to both elastic and electric stress is given by:

$$x_{ij} = s_{ijkl} X_{kl} + d_{mij} E_m + M_{mnij} E_m E_n, \quad (6.55)$$

where x_{ij} are components of elastic strain, s_{ijkl} is the elastic compliance tensor, X_{kl} are the stress components, d_{mij} are the piezoelectric tensor components, M_{mnij} is the electrostrictive tensor, and E_m and E_n are components of the electric field.

Neglecting the second-order effects (electrostriction) and assuming that the material is under no stress ($X_{kl} = 0$), the elastic strain is given by:

$$x_{ij} = d_{mij} E_m \quad (6.56)$$

Equation 6.56 is the mathematical definition of the converse piezoelectric effect, where induced strain is directly proportional to the first power of the field. The thermodynamically equivalent direct piezoelectric effect is given by:

$$P_m = d_{mij} X_{ij}, \quad (6.57)$$

where P_m is the component of electrical polarization. The difference between the direct and converse piezoelectric effect is shown schematically in [Figure 6.38](#). The converse effect describes the actuating function of a piezoelectric, where a controlled electric field accurately changes the shape of a piezoelectric material. The sensing function of a piezoelectric is described by the direct effect, where a controlled stress on a piezoelectric material yields a charge proportional to the stress.

FIGURE 6.38 Schematic representations of the direct and converse piezoelectric effect: (a) an electric field applied to the material changes its shape; (b) a stress on the material yields a surface charge.

The third rank tensor d_{mij} may be simplified using matrix notation [1] to d_{ij} , a second rank tensor. In this form, d_{ij} is simply known as the piezoelectric charge coefficient, with units of coulombs per newton (CN^{-1}) or meters per volt (mV^{-1}). Another set of moduli that may be used to characterize piezoelectric materials are the piezoelectric voltage coefficients, g_{ij} , defined in matrix notation as:

$$E_i = g_{ij} X_j, \quad (6.58)$$

where E_i is the component of electric field arising due to the stress X_j . The d_{ij} and g_{ij} coefficients are related by:

$$g_{ij} = d_{ij} / (\epsilon_0 \epsilon_{ii}), \quad (6.59)$$

where ϵ_{ii} is the dielectric constant (relative permittivity), and ϵ_0 is the permittivity of free space ($8.854 \times 10^{-12} \text{ F m}^{-1}$). Another key property of piezoelectric materials is their electromechanical **coupling coefficient** k , defined as:

$$k^2 = \text{resulting mechanical energy} / \text{input electrical energy} \quad (6.60)$$

or

$$k^2 = \text{resulting electrical energy} / \text{input mechanical energy} \quad (6.61)$$

The value of k represents the efficiency of the piezoelectric in converting one form of energy to another. Since energy conversion is never complete, the value of k^2 is always less than unity, so k is always less than 1.

Two final important parameters for piezoelectric (**ferroelectric**) materials are their Curie point (T_0) and Curie temperature (T_c). The Curie point is the temperature above which the material loses its ferroelectric and piezoelectric behavior. The Curie temperature is defined by the Curie-Weiss law:

$$\epsilon = \epsilon_0 + \frac{C}{T - T_c} \quad \text{for } T > T_c, \quad (6.62)$$

where ϵ is the dielectric constant of the material, C is the Curie-Weiss constant, and T is the temperature. It represents the temperature where the material tends to have its highest dielectric constant. The Curie temperature is always lower (often within 10°C) than the Curie point.

Piezoelectric Materials

Single Crystals

A number of single-crystal materials have demonstrated piezoelectricity. These materials dominate certain applications, such as frequency-stabilized oscillators in watches and radars, and surface acoustic wave devices in television filters and analog signal correlators. A list of single-crystal piezoelectric materials includes quartz, lithium niobate and lithium tantalate, ammonium dihydrogen sulfate, lithium sulfate monohydrate, and Rochelle salt. Recently, it was discovered that some relaxor-based ferroelectric single crystals of lead zinc niobate and lead magnesium niobate, and their solid solutions with lead titanate possess superior piezoelectric properties when compared to other piezoelectric materials.

Quartz, which is crystalline SiO_2 , has a low value of d_{11} (12.3×10^{-12} C N⁻¹) [1]. Right-handed quartz develops a positive charge when put under compression, and a negative charge when put under tension. The coupling coefficient k for quartz is also very low, typically around 0.1 [4]. In addition, the dielectric constant ϵ for quartz is small (~ 4) [5]. The Curie point, however, is relatively high ($T_0 \sim 573^\circ\text{C}$) [5], so quartz is stable for high-temperature applications. Despite the low piezoelectric properties, quartz is very abundant and inexpensive, and has found a strong position in low-cost or high-temperature applications.

Piezoelectric behavior in lithium niobate (LiNbO_3) and lithium tantalate (LiTaO_3) was first studied in the mid-1960s [2]. Under shear, the d_{15} of LiNbO_3 and LiTaO_3 are 73 and 26 ($\times 10^{-12}$ C N⁻¹), respectively. Both have ϵ values of approximately 40. If cut correctly, they have coupling coefficient (k) values of 0.65 and 0.4, respectively. In addition, the Curie points for both are extremely high ($T_0 \sim 1210^\circ\text{C}$ for LiNbO_3 , and 620°C for LiTaO_3). Both LiNbO_3 and LiTaO_3 are commonly used in infrared detectors.

Rochelle salt ($\text{KNaC}_4\text{H}_4\text{O}_6 \cdot \text{H}_2\text{O}$) was first found to be piezoelectric in 1880 [2]. The d_{31} and k_{31} are 275×10^{-12} C N⁻¹ and 0.65, respectively. The relative dielectric constant is approximately 350. Rochelle salt has two Curie points (lower $T_0 \sim 18^\circ\text{C}$, and upper $T_0 \sim 24^\circ\text{C}$). It is highly soluble in water, and is still extensively used in electroacoustic transducers.

Lead zinc niobate, $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$, and lead magnesium niobate, $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$, are typical relaxor materials characterized by the broad frequency-dependent maximum of dielectric constant vs. temperature. The solid solutions of these materials with lead titanate, PbTiO_3 , were shown to possess excellent piezoelectric properties when oriented along the [001] direction [6]. The piezoelectric charge coefficient d_{33} of 25×10^{-10} C N⁻¹, coupling coefficient k of more than 0.9, and ultrahigh strain of 1.7% were achieved in $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$ - PbTiO_3 solid solution. These single-crystal relaxor materials are now being intensively investigated and show great promise for future generations of piezoelectric transducers and sensors.

Other types of piezoelectric materials dominate the market for transducers. These materials include piezoelectric ceramics, piezoelectric polymers, and composites of piezoelectric ceramic with inactive polymers. The focus of the remainder of this chapter will be on non-single-crystal piezoelectric materials.

Piezoelectric Ceramics

In polycrystalline ceramics with polar grains, the randomness of the grains, as shown schematically in [Figure 6.39\(a\)](#), yields a nonpiezoelectric material. Piezoelectric behavior is induced by “**poling**” the

FIGURE 6.39 Schematic of the poling process in piezoelectric ceramics: (a) in the absence of an electric field, the domains have random orientation of polarization; (b) the polarization within the domains are aligned in the direction of the electric field.

ceramic. By applying a strong dc electric field at a temperature just below the Curie temperature, the spontaneous polarization in each grain gets oriented toward the direction of the applied field. This is schematically shown in Figure 6.39(b). Although all of the domains in a ceramic can never be fully aligned along the poling axis due to symmetry limitations, the ceramic ends up with a net polarization along the poling axis.

The largest class of piezoelectric ceramics is made up of mixed oxides containing corner-sharing octahedra of O^{2-} ions. The largest structure type, built with corner-shared oxygen octahedra, is the perovskite family, which is discussed in the following section.

Perovskites

Perovskite is the name given to a group of materials with general formula ABO_3 having the same structure as the mineral calcium titanate ($CaTiO_3$). Piezoelectric ceramics having this structure include barium titanate ($BaTiO_3$), lead titanate ($PbTiO_3$), lead zirconate titanate ($PbZr_xTi_{1-x}O_3$, or PZT), lead lanthanum zirconate titanate [$Pb_{1-x}La_x(Zr_yTi_{1-y})_{1-x/4}O_3$, or PLZT], and lead magnesium niobate [$PbMg_{1/3}Nb_{2/3}O_3$, or PMN]. Several of these ceramics are discussed below.

The piezoelectric effect in $BaTiO_3$ was discovered in the 1940s [4], and it became the first piezoelectric ceramic developed. It replaced Rochelle salt because it is more stable, has a wider temperature range of operation, and is easily manufacturable. The Curie point, T_0 , is about $130^\circ C$. Above $130^\circ C$, a nonpiezoelectric cubic phase is stable, where the center of positive charge (Ba^{2+} and Ti^{4+}) coincides with the center of the negative charge (O^{2-}) (Figure 6.40(a)). When cooled below the Curie point, a tetragonal structure (shown in Figure 6.40(b)) develops where the center of positive charge is displaced relative to the O^{2-} ions, leading to the formation of electric dipoles. Barium titanate has a relative dielectric constant ϵ_{33} of 1400 when unpoled, and 1900 when poled [2, 4]. The d_{15} and d_{33} coefficients of $BaTiO_3$ are 270 and $191 \times 10^{-12} C/N$, respectively. The k for $BaTiO_3$ is approximately 0.5. The large room temperature dielectric constant in barium titanate has led to its wide use in multilayer capacitor applications.

Lead titanate, $PbTiO_3$, first reported to be ferroelectric in 1950 [4], has a similar structure to $BaTiO_3$, but with a significantly higher Curie point ($T_0 = 490^\circ C$). Pure lead titanate is difficult to fabricate in bulk form. When cooled through the Curie point, the grains go through a cubic to tetragonal phase change, leading to large strain and ceramic fracturing. This spontaneous strain can be decreased by the addition of dopants such as Ca, Sr, Ba, Sn, and W. Calcium-doped $PbTiO_3$ [7] has a relative dielectric constant ϵ_{33} of 200, a d_{33} of $65 \times 10^{-12} C/N$, and a k of approximately 0.5. The addition of calcium results in a lowering of the Curie point to $225^\circ C$. The main applications of lead titanate are hydrophones and sonobuoys.

Lead zirconate titanate (PZT) is a binary solid solution of $PbZrO_3$ (an antiferroelectric orthorhombic structure) and $PbTiO_3$ (a ferroelectric tetragonal perovskite structure) [2–4]. It has a perovskite structure, with the Zr^{4+} and Ti^{4+} ions occupying the B site of the ABO_3 structure at random. At the morphotropic

FIGURE 6.40 The crystal structure of BaTiO₃; (a) above the Curie point, the cell is cubic; (b) below the Curie point, the cell is tetragonal with Ba²⁺ and Ti⁴⁺ ions displaced relative to O²⁻ ions.

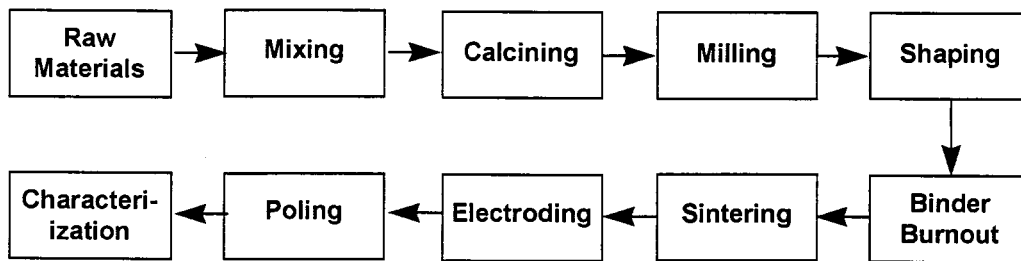

FIGURE 6.41 Flow chart for the processing of piezoelectric ceramics.

phase boundary (MPB) separating the tetragonal and orthorhombic phases, PZT shows excellent piezoelectric properties. At room temperature, the MPB is at a Zr/Ti ratio of 52/48, resulting in a piezoelectric ceramic which is extremely easy to pole. Piezoelectric PZT at the MPB is usually doped by a variety of ions to form what are known as “hard” and “soft” PZTs. Hard PZT is doped with acceptor ions, such as K⁺ or Na⁺ at the A site, or Fe³⁺, Al³⁺, or Mn³⁺ at the B site. This doping lowers the piezoelectric properties, and makes the PZT more difficult to pole or depole. Typical piezoelectric properties of hard PZT include [5, 7]: Curie point, T_0 , of 365°C, ϵ_{33} of 1700–1750 (poled), a piezoelectric charge coefficient d_{33} of 360 to 370×10^{-12} C N⁻¹, and a coupling coefficient of about 0.7. Soft PZT is doped with donor ions such as La³⁺ at the A site, or Nb⁵⁺ or Sb⁵⁺ at the B site. It has very high piezoelectric properties, and is easy to pole or depole. Typical piezoelectric properties of soft PZT include [5, 7]: Curie point, T_0 , of 210°C, relative dielectric constant ϵ_{33} of 3200–3400 (poled), a d_{33} of 580 to 600×10^{-12} C N⁻¹, and a coupling coefficient k_{33} of 0.7.

Processing of Piezoelectric Ceramics

The electromechanical properties of piezoelectric ceramics are largely influenced by their processing conditions. Each step of the process must be carefully controlled to yield the best product. Figure 6.41 is a flow chart of a typical oxide manufacturing process for piezoelectric ceramics. The high-purity raw materials are accurately weighed according to their desired ratio, and mechanically or chemically mixed. During the calcination step, the solid phases react to yield the piezoelectric phase. After calcining, the solid mixture is ground into fine particles by milling. Shaping is accomplished by a variety of ceramic

TABLE 6.7 Advantages (+) and Disadvantages (–) of Piezoelectric Ceramics, Polymers and Composites

Parameter	Ceramic	Polymer	Ceramic/Polymer Composite
Acoustic impedance	High (–)	Low (+)	Low (+)

processing techniques, including powder compaction, tape casting, slip casting, or extrusion. During the shaping operation, organic materials are typically added to the ceramic powder to improve its flow and binding characteristics. These organics are removed in a low temperature (500 to 600°C) binder burn-off step.

After burnout, the ceramic structure is sintered to an optimum density at an elevated temperature. For the lead-containing piezoelectric ceramics (PbTiO₃, PZT, PLZT), sintering is performed in sealed crucibles with an optimized PbO atmosphere. This is because lead loss occurs in these ceramics above 800°C. As mentioned earlier (Figure 6.39), the randomness of the ceramic grains yields a nonpiezoelectric material. By electroding the ceramic and applying a strong dc electric field at high temperature, the ceramic is poled. At this point, the piezoelectric ceramic is ready for final finishing and characterization.

Piezoelectric Polymers

The piezoelectric behavior of polymers was first reported in 1969 [8]. The behavior results from the crystalline regions formed in these polymers during solidification from the melt. When the polymer is drawn, or stretched, the regions become polar, and can be poled by applying a high electric field. The most widely known piezoelectric polymers are polyvinylidene fluoride [9, 10], also known as PVDF, polyvinylidene fluoride — trifluoroethylene copolymer, or P(VDF-TrFE) [9, 10], and odd-number nylons, such as Nylon-11 [11].

The electromechanical properties of piezoelectric polymers are significantly lower than those of piezoelectric ceramics. The d_{33} values for PVDF and P(VDF-TrFE) are approximately $33 (\times 10^{-12} \text{ C N}^{-1})$, and the dielectric constant ϵ is in the range 6 to 12 [12, 13]. They both have a coupling coefficient (k) of 0.20, and a Curie point (T_0) of approximately 100°C. For Nylon-11, ϵ is around 2 [11], while k is approximately 0.11.

Piezoelectric Ceramic/Polymer Composites

As mentioned above, a number of single-crystal, ceramic, and polymer materials exhibit piezoelectric behavior. In addition to the monolithic materials, composites of piezoelectric ceramics with polymers have also been formed. Table 6.7 [14] summarizes the advantages and disadvantages of each type of material. Ceramics are less expensive and easier to fabricate than polymers or composites. They also have relatively high dielectric constants and good electromechanical coupling. However, they have high acoustic impedance, and are therefore a poor acoustic match to water, the media through which it is typically transmitting or receiving a signal. Also, since they are stiff and brittle, monolithic ceramics cannot be formed onto curved surfaces, limiting design flexibility in the transducer. Finally, they have a high degree of noise associated with their resonant modes. Piezoelectric polymers are acoustically well matched to water, are very flexible, and have few spurious modes. However, applications for these polymers are limited by their low electromechanical coupling, low dielectric constant, and high cost of fabrication. Piezoelectric ceramic/polymer composites have shown superior properties when compared to single-phase materials. As shown in Table 6.7, they combine high coupling, low impedance, few spurious modes, and an intermediate dielectric constant. In addition, they are flexible and moderately priced.

Suppliers of Piezoelectric Materials

Table 6.8 lists a number of the suppliers of piezoelectric materials, their addresses, and whether they supply piezoelectric ceramic, polymers, or composites. Most of them tailor the material to specific applications.

Measurements of Piezoelectric Effect

Different means have been proposed to characterize the piezoelectric properties of materials. The resonance technique involves the measurement of the characteristic frequencies when the suitably shaped specimen (usually ceramic) is driven by a sinusoidally varying electric field. To a first approximation, the behavior of a piezoelectric sample close to its fundamental resonance frequency can be represented by an equivalent circuit as shown in Figure 6.42(a). The schematic behavior of the reactance of the sample as a function of frequency is represented in Figure 6.42(b). By measuring the characteristic frequencies

a)

b)

FIGURE 6.42 (a) Equivalent circuit of the piezoelectric sample near its fundamental electromechanical resonance (top branch represents the mechanical part and bottom branch represents the electrical part of the circuit); (b) electrical reactance of the sample as a function of frequency.

of the sample, the material constants including piezoelectric coefficients can be calculated. The equations used for the calculations of the electromechanical properties are described in the IEEE Standard on piezoelectricity [15]. The simplest example of piezoelectric measurements by resonance technique relates to a piezoelectric ceramic rod (typically 6 mm in diameter and 15 mm long) poled along its length. It can be shown that the coupling coefficient k_{33} is expressed as a function of the series and parallel resonance frequencies, f_s and f_p , respectively:

$$k_{33}^2 = \frac{\pi}{2} \frac{f_s}{f_p} \tan \left(\frac{\pi}{2} \frac{f_p - f_s}{f_p} \right) \quad (6.63)$$

The longitudinal piezoelectric coefficient d_{33} is calculated using k_{33} , elastic compliance s_{33}^E and low-frequency dielectric constant ϵ_{33}^X :

$$d_{33} = k_{33} \left(\epsilon_{33}^X s_{33}^E \right)^{1/2} \quad (6.64)$$

Similarly, other electromechanical coupling coefficients and piezoelectric moduli can be derived using different vibration modes of the sample. The disadvantage of the resonance technique is that measurements are limited to the specific frequencies determined by the electromechanical resonance. It is used mostly for the rapid evaluation of the piezoelectric properties of ceramic samples whose dimensions can be easily adjusted for specific resonance conditions.

Subresonance techniques are frequently used to evaluate piezoelectric properties of materials at frequencies much lower than the fundamental resonance frequency of the sample. They include both the measurement of piezoelectric charge under the action of external mechanical force (direct effect) and the

FIGURE 6.43 Full (a) and simplified (b) equivalent electrical circuits of the piezoelectric sensor connected to the voltage amplifier.

measurement of electric field-induced displacements (converse effect). In the latter case, the displacements are much smaller than in resonance; however, they still can be measured by using strain gages, capacitive sensors, LVDT (linear variable differential transformer) sensors or by optical interferometry [16, 17].

A direct method is widely used to evaluate the sensor capabilities of piezoelectric materials at sufficiently low frequency. The mechanical deformations can be applied in different modes such as thickness expansion, transverse expansion, thickness shear, and face shear to obtain different components of the piezoelectric tensor. In the simplest case, the metal electrodes are placed onto the major surfaces of the piezoelectric transducer normal to its poling direction (direction of ferroelectric polarization) and the mechanical force is applied along this direction (Figure 6.38(b)). Thus, the charge is produced on the electrode plates under mechanical loading, which is proportional to the longitudinal piezoelectric coefficient d_{33} of the material. To relate the output voltage of the transducer to the piezoelectric charge, it is necessary to consider the equivalent circuit (Figure 6.43(a)). A circuit includes the charge generator, $Q = d_{33}F$, leakage resistor of the transducer, R_s , transducer capacitance, C_s , capacitance of the connecting cables, C_c , and input resistance and capacitance of the amplifier, R_a and C_a , respectively. Here, F denotes the force applied to the transducer (tensile or compressive). All the resistances and capacitances shown in Figure 6.43(a) can be combined, as shown in Figure 6.43(b). A charge generator can be converted to a current generator, I , according to:

$$I = \frac{dQ}{dt} = d_{33} \frac{dF}{dt} \quad (6.65)$$

Assuming that the amplifier does not draw any current, the output voltage V at a given frequency ω can be calculated:

$$V = \frac{d_{33}F}{C} \frac{j\omega\tau}{1 + j\omega\tau}, \quad (6.66)$$

FIGURE 6.44 Equivalent electrical circuit of the piezoelectric sensor connected to the charge amplifier.

where $\tau = RC$ is the time constant that depends on all resistances and capacitances of the circuit. For sufficiently high frequency, the measured response is frequency independent and d_{33} can be easily evaluated from Equation 6.66 if the equivalent capacitance C is known. Since C is determined by the parallel capacitances of the sample, connecting cables, and amplifier (typically not exactly known), the standard capacitance is often added to the circuit, which is much greater than all the capacitances involved. However, according to Equation 6.66, the sensitivity of the circuit is greatly reduced with decreasing C . If τ is not large enough, the low-frequency cut-off does not allow piezoelectric measurements in quasi-static or low-frequency conditions.

To overcome the difficulties of using voltage amplifiers for piezoelectric measurements, a so-called charge amplifier was proposed. The idealized circuit of a charge amplifier connected with the piezoelectric transducer is shown in Figure 6.44. Note that a FET-input operational amplifier is used with a capacitor C_f in the feedback loop. Assuming that the input current and voltage of the operational amplifier are negligible, one can relate the charge on the transducer with the output voltage:

$$V = -Q/C_f = -d_{33}F/C_f \quad (6.67)$$

Equation 6.67 gives frequency-independent response where the output voltage is determined only by the piezoelectric coefficient d_{33} and the known capacitance C_f . Unfortunately, this advantage is difficult to realize since even a small input current of the amplifier will charge the feedback capacitor, leading to saturation of the amplifier. Therefore, a shunt resistor R_f is added to the circuit (dotted line in Figure 6.44), which prevents such charging. If one takes into account the RC circuit of the feedback loop, the output voltage will have the form of Equation 6.66, i.e., becomes frequency dependent. In this case, the time constant τ is determined by the parameters of the feedback loop and does not depend on the capacitance of the transducer, connecting cables, or the input capacitance of the amplifier. This gives an important advantage to the charge amplifier when it is compared to the ordinary voltage amplifier.

Applications

The direct and converse piezoelectric effects in a number of materials have led to their use in electromechanical transducers. Electromechanical transducers convert electrical energy to mechanical energy, and vice versa. These transducers have found applications where they are used in either passive or active modes. In the passive (sensor) mode, the transducer only receives signals. Here, the direct piezoelectric properties of the material are being exploited to obtain a voltage from an external stress. Applications in the passive mode include hydrophones, or underwater listening devices, microphones, phonograph pickups, gas igniters, dynamic strain gages, and vibrational sensors. In the active (actuator) mode, the

a)

b)

FIGURE 6.45 Schematic designs of the displacement sensor based on piezoelectric ceramic (a) and of the pressure sensor based on piezoelectric polymer film (b). Arrows indicate the directions of ferroelectric polarization in the piezoelectric material.

transducer, using the converse piezoelectric properties of the material, changes its dimensions and sends an acoustic signal into a medium. Active mode applications include nondestructive evaluation, fish/depth finders, ink jet printers, micropositioners, micropumps, and medical ultrasonic imaging. Often, the same transducer is used for both sensor and actuator functions.

Two examples of piezoelectric sensors are given below. The first example is the ceramic transducer, which relates the deformation of the piezoelectric sensor to the output voltage via direct piezoelectric effect. Piezoceramics have high Young's moduli; therefore, large forces are required to generate strains in the transducer to produce measurable electric response. Compliance of the piezoelectric sensor can be greatly enhanced by making long strips or thin plates of the material and mounting them as cantilevers or diaphragms. Displacement of the cantilever end will result in a beam bending, leading to the mechanical stress in the piezoelectric material and the electric charge on the electrodes. A common configuration of the piezoelectric bender is shown in Figure 6.45(a). Two beams poled in opposite directions are cemented together with one common electrode in the middle and two electrodes on the outer surfaces. Bending of such a bimorph will cause the upper beam to stretch and the lower beam to compress, resulting in a piezoelectric charge of the same polarity for two beams connected in series. To the first approximation, the charge Q appearing on the electrodes is proportional to the displacement Δl of the end of the bimorph via Equation 6.68 [18]:

$$Q = \frac{3}{8} \frac{Hw}{L} e_{31} \Delta l, \quad (6.68)$$

where H , w , and L are the thickness, the width, and the length of the bimorph, respectively, and e_{31} is the transverse piezoelectric coefficient relating electric polarization and strain in a deformed piezoelectric material. The charge can be measured either by the voltage amplifier (Figure 6.43) or by the charge amplifier (Figure 6.44).

In certain applications, the parameters of piezoelectric sensors can be improved by using ferroelectric polymers instead of single crystals and piezoceramics. Although the electromechanical properties of polymers are inferior to those of piezoelectric ceramics, their low dielectric constant offers the higher voltage response since they possess higher g piezoelectric coefficients. Also, the polymers are more mechanically robust and can be made in the form of thin layers (down to several micrometers). An example using the polymer bimorph as a pressure sensor is shown in Figure 6.45(b). A circular diaphragm composed of two oppositely poled polymer films is clamped along its edges to a rigid surround, forming a microphone. The voltage appearing on the electrodes is proportional to the applied pressure p by Equation 6.69 [19]:

$$V = \frac{3}{16} \frac{d_{31}}{\epsilon_{33}} \frac{D^2}{h} (1 - \nu) p \quad (6.69)$$

where D and h are the diameter and thickness of the diaphragm, respectively, and ν is the Poisson ratio. The high d_{31}/ϵ_{33} value for polymer sensors is advantageous to obtain higher voltage response. According to Equation 6.66, this advantage can be realized only if the high input impedance amplifier is used in close proximity to the transducer to reduce the influence of the connecting cables.

Defining Terms

Piezoelectric transducer: Device that converts the input electrical energy into mechanical energy and vice versa via piezoelectric effect.

Coupling coefficients: Materials constants that describe an ability of piezoelectric materials to convert electrical energy into mechanical energy and vice versa.

Piezoelectric coefficients: Materials constants that are used to describe the linear coupling between electrical and mechanical parameters of the piezoelectric.

Ferroelectrics: Subgroup of piezoelectric materials possessing a net dipole moment (ferroelectric polarization) that can be reversed by the application of sufficiently high electric field.

Poling: Process of aligning the ferroelectric polarization along a unique (poling) direction.

Piezoelectric composites: Materials containing two or more components with different piezoelectric properties.

Charge amplifier: An operational amplifier used to convert the input charge into output voltage by means of the capacitor in the feedback loop.

6.5 Laser Interferometer Displacement Sensors

Bernhard Günther Zagar

In the past few years, very high precision, numerically controlled machine tools have been developed. To achieve the potential precision of these tools, length and displacement measurements whose resolution exceeds the least significant digit of the tool must be made. The measurement equipment typically would not rely on mechanical scales.

Laser interferometers compare the changes in optical path length to the wavelength of light, which can be chosen from atomic constants that can be determined with very little uncertainty.

In 1983, there was a redefinition of the meter [1] that was previously defined in 1960. The old definition was based on the wavelength of a certain radiation (the krypton-86 standard) that could not be realized to better than 4 parts in 10^9 . The new definition, being based on frequency but not related to any particular radiation, opened the way to significant improvements in the precision with which the meter can be realized. As recommended in resolution 2 for the practical realization of the meter, the wavelength in vacuum λ_v of a plane electromagnetic wave of frequency f is $\lambda_v = c/f$, where c is the speed of light in vacuum, $c = 299,792,458 \text{ m s}^{-1}$ exactly. This way, the wavelength is related to *frequency and time*, which can be measured with the highest precision of all units within the *Système International (SI)*.

In order to be independent of any environmental parameters, the meter is defined using the speed of light in a vacuum. However, interferometers usually must operate in ambient air. Thus, environmental parameters that influence the speed of light in a particular medium (air) will affect and degrade the precision of the measurement.

Three major factors limit the absolute accuracy attainable with laser interferometers operating in ambient air: (1) the uncertainties of the vacuum wavelength, λ_v , of the laser source; (2) the uncertainty of the refractive index of the ambient air; and (3) the least count resolution of the interferometer.

This chapter section is organized as follows. First, some basic laser principles are detailed, including ways to stabilize the vacuum wavelength of the *laser*. The effect most often used to stabilize lasers in commercial interferometers is the *Zeeman effect*, which yields relative uncertainties of 10^{-8} .

FIGURE 6.46 Schematics of the helium–neon laser (Reprinted with permission of University Science Books [3]).

Second, the refractive index of air as another major factor limiting the attainable accuracy of laser interferometers operated in air is addressed. It is shown that it cannot be determined currently with uncertainty better than 5×10^{-8} .

And finally, the chapter section describes the most widely used Michelson interferometer and two of its variants for long-travel length measurement and gives their resolution.

Helium–Neon Laser

In order to attain the best possible accuracy, great care must be taken to ensure the highest wavelength stability of the light source. Almost all interferometric dimensional gages utilize a helium–neon laser because it has proven reliable, its emitted wavelength is in the visible range at about 633 nm, and it can be stabilized sufficiently well utilizing the Zeeman effect and to an even higher degree with the use of a very well-defined iodine absorption line also at ≈ 633 nm [1, 2].

The helium–neon laser consists of a discharge tube as shown in Figure 6.46 [3] filled with the single-isotope gases helium (He^3) at a partial pressure of ≈ 105 Pa and neon (Ne^{20}) with a partial pressure of ≈ 13 Pa. It is pumped electrically using a voltage on the order of kilovolts with a current of a few milliamperes to excite both helium and neon atoms. Since the helium gas is the majority component, it dominates the discharge properties of the laser tube. Neutral helium atoms collide with free electrons that are accelerated by the axial voltage and become excited and remain in two rather long-lived metastable states. These are close enough to the energy levels of certain excited states of neon atoms so that collisional energy transfer can take place between these two groups of atoms. Excited helium atoms may drop down to the ground state, while simultaneously neon atoms take up almost exactly the same amount of energy. Therefore helium only serves to excite neon atoms, they do not contribute to the emission of light. The excited neon atoms remain in the excited state for a rather long period of time (on the order of 10^{-3} s). They return to lower energetic levels by stimulated emission of highly coherent light. This stimulated emission comes into effect when light emitted by some neon atoms also prompts other atoms to emit. The mirrors of the laser cavity, by reflecting most of the incident light cause the light to traverse multiple paths through the active laser volume, thereby greatly amplifying the light if the cavity length L is an integer multiple m of half the wavelength λ .

$$L = m \frac{\lambda}{2} \quad (6.70)$$

The emitted light is fairly monochromatic, but still has some finite spectral linewidth determined by the random emissions of Ne^{20} .

FIGURE 6.47 A He–Ne laser can have multiple resonating modes (shown for ≈ 20 cm cavity length) (Reprinted with permission of University Science Books [3]).

Brewster angle [4] end windows of the discharge tube transmit light of the proper linear polarization if desired. The end mirrors have to be carefully polished. Their curvature radii have to satisfy the condition for stability. They have wavelength–selective dielectric coatings of very high reflectivity sometimes exceeding 99%.

Unless special precautions are taken, a He–Ne laser will emit several axial modes as shown schematically in Figure 6.47, resulting in a beat frequency that limits the temporal coherence and renders the laser unsuitable for interferometric purposes. Also, due to thermal expansion of the laser tube, the end mirrors will change their relative distance, thereby effectively tuning the wavelength within the linewidth of the gain curve.

Another important property of a high-quality He–Ne laser is its Gaussian cross-sectional profile, which is maintained along a propagating wave, i.e., fundamental lateral mode. It is also a necessary condition for the wavefronts to remain quasiplanar.

Frequency Stabilization of He–Ne Lasers

The resonant frequency (and the wavelength λ) of the laser is determined in part by the distance between the two end mirrors and also by the refractive index n_M of the active medium (the He–Ne mixture). Since the linewidth of the gain profile of the active medium is usually in the gigahertz range, multiple axial modes can resonate in the cavity as is shown in Figure 6.47. The frequency difference Δf between two adjacent longitudinal modes is the *free spectral range* (FSR), which is given by Equation 6.71 and depends only on the cavity length, L , the refractive index of the active medium, n_M , and the speed of light in vacuum, c .

$$\Delta f = \frac{c}{2n_M L} \quad (6.71)$$

Due to thermal expansion of the laser cavity and/or thermally induced change in refractive index of the active medium, all resonating laser modes will move within the envelope of the gain profile. The effort undertaken in stabilizing the laser wavelength or equivalently stabilizing its frequency is aimed at locking the modes with respect to the gain profile and reducing the number of modes resonating simultaneously.

Longitudinal Zeeman Effect

One of the most often used effects in stabilizing the frequency of a He–Ne laser for distance measurements is the Zeeman effect [3, 5].

FIGURE 6.48 Laser wavelengths can be stabilized by utilizing the Zeeman-effect (Courtesy of Spindler & Hoyer Inc.).

The tube of the laser whose frequency is to be stabilized is mounted inside an axial permanent magnet as shown in Figure 6.48. Because of a short cavity length chosen, the free spectral range Δf of the laser is large. Therefore, the laser emission appears as a single longitudinal mode when the cavity length is properly controlled. An externally applied magnetic field in longitudinal direction causes the transition frequencies of the neon atoms to split symmetrically to the nominal frequency, the separation in frequency being proportional to the magnetic field strength. This phenomenon is called the *longitudinal Zeeman effect*.

With the applied field strength, the single longitudinal laser mode of the He–Ne laser is split into right and left circularly polarized modes with a frequency difference of typically 1.5 MHz. The frequency difference depends on the laser frequency and exhibits an extreme value when the laser frequency matches exactly the atomic transition frequency. Frequency stabilization is accomplished with control of the cavity length so that the frequency is locked to the extreme value corresponding to the nominal frequency of the laser. In order to determine the actual laser frequency within the gain profile, the cavity length is periodically modulated with a piezoelectric actuator shown in Figure 6.48. The frequency difference is constantly monitored at the minimum and maximum elongation of the modulation cycle. In the case when the extremal values are identical, the difference frequency will assume a maximum and thus the nominal value of the laser frequency is attained. This is achieved by controlling the length of the laser cavity. The cavity length is controlled both by using the thermal expansion of the laser tube, which is in close proximity to an electric heater whose operating current can be varied on a less dynamic scale, and on a very short time basis with a piezoelectric actuator attached to one of the end faces of the cavity [5].

This fast actuator allows for only a limited amplitude, typically on the order of less than a wavelength. Therefore, the thermal expansion must be used to attain greater modulation amplitude. To obtain the highest possible stability of the laser frequency, the frequency differences are measured within a very short time interval, and the determined deviations from the nominal value are fed back in a closed control loop to the electromechanical and thermal positioning devices.

The short- and long-term frequency stability $\Delta f/f$ of such a stabilized laser can be as high as 2×10^{-8} , depending also on the parameters of the feedback loop.

Another phenomenon that exceeds the stabilization attainable with the Zeeman effect by far uses a particular absorption line of an iodine isotope ($^{127}\text{I}_2$, transition 11-5, R(127), component i) and locks the He–Ne laser [2, 6] in that very well-defined frequency. Its wavelength $\lambda_1 = 632.9913981$ nm is very close to one of the nominal wavelengths of the He–Ne laser, so this can easily be accomplished; however, the necessary equipment including the sophisticated electronics is rather involved [2]. For this reason, iodine-stabilized He–Ne lasers are only used where very high precision is required.

TABLE 6.9 Refractive Indices n of Various Gaseous Compounds Their Maximum Workplace Concentration (MWC) and the Change in Refractive Index Caused by that Particular Concentration (for $T = 20^\circ\text{C}$, $P = 101.315$ hPa, $\lambda = 633$ nm)

The overall estimated relative uncertainty of such a stabilized laser is $\pm 10^{-9}$ (which results from an estimated relative standard deviation of 3.4×10^{-10} [1]), which makes it suitable for the practical realization of the definition of primary and secondary standards.

Refractive Index of Air

The length scale of a displacement interferometer that is operated in ambient air is given by $\lambda_A = \lambda_v/n_A$, where λ_A is the wavelength of the source in air, λ_v is the wavelength in vacuum and n_A is the refractive index of air. The vacuum wavelength λ_v is related to the speed of light by $\lambda_v = c/f_0$. The constant c , the speed of light in vacuum, was redefined in 1983 [1]. It is now defined to be exactly $c = 299,792,458$ m s $^{-1}$.

Thus, in order to measure distances interferometrically, it is essential to know the refractive index of air with an accuracy that is not less than the stability and the degree of certainty of the vacuum wavelength of the light source.

According to Edlén [7, 8] and Owens[9], the refractive index is a function of the atmospheric pressure P , the temperature T , the relative humidity H , or alternatively the partial pressure of the water vapor in air e_s , and the carbon dioxide concentration by volume D . The standard composition by volume of dry air is given by 78.03% N $_2$, 20.99% O $_2$, 0.933% Ar, 0.035% CO $_2$, and some other trace components, mainly noble gases [10]. The only component of the above list that might have a variability is CO $_2$, which follows a long-term increasing behavior presumably associated with the combustion of fossil fuel [11]. The current value is ≈ 350 ppm by volume and is increasing by ≈ 1.4 ppm per year. The CO $_2$ concentration in air can also change in an industrial environment due to CO $_2$ emitters and can therefore show significant local variations.

More recently, dependencies of the refractive index on nonnatural gaseous compounds like hydrocarbons in the air have been published [12] as well as corrections to Edlén's formulations [13–15]. Corrections to the refractive index due to those compounds may be necessary for very high-precision measurements in an industrial environment where chemical solvents or oils are in use. In Table 6.9, some nonnatural compounds, their maximum workplace concentrations, and their effect on the refractive index if present at the location of the interferometer are listed.

Jones [16] combined a precise determination of the density of moist air with Edlén's formulation to yield a somewhat simpler representation. For a typical iodine-stabilized He–Ne laser that has a vacuum wavelength of $\lambda_v = 632.9913$ nm, the Jones formulation is given by [17]:

$$n(P, T, H, D) = 1 + A - B \quad (6.72)$$

where

$$A = 78.603 \left[1 + 0.540(D - 0.0003) \right] \frac{P}{TZ} \times 10^{-8}$$

$$B = (0.00042066 f_E e_s H) \times 10^{-8} \quad (6.73)$$

In Equation 6.73, P is the atmospheric pressure in pascals, T is the absolute temperature in kelvin, H is the relative humidity in %, and D is the concentration of CO_2 in percent by volume. There are three additional factors in Jones' formulation that take the nonideal behavior of moist air as compared to an ideal gas into account. They are Z , a compressibility factor that reflects the nonideality of the air–water vapor mixture and which, for air containing reasonable amounts of CO_2 at a temperature between 15°C and 28°C and pressure of between 7×10^4 Pa and 11×10^4 Pa, lies in the range between 0.99949 and 0.99979. f_E is an enhancement factor that expresses the fact that the effective saturation vapor pressure of water in air is greater than the saturation vapor pressure e_s . For the pressure and temperature ranges given above, f_E is bounded between 1.0030 and 1.0046 [16]. e_s is the saturation vapor pressure over a plane surface of pure liquid water and according to Jones is about 1705 Pa at a temperature of 15.0°C and about 3779 Pa for 28.0°C . Tables of Z , f_E and e_s are included in the Appendix of Jones' paper [16].

Table 6.10 gives an overview of the changes in environmental parameters that would cause a relative index change of 10^{-7} .

Edlén [8] and Jones [16] estimate that their empirical expressions for the dependency of the refractive index of air on the listed parameters has an absolute uncertainty of 5×10^{-8} .

Besides this fundamental limitation, there are some practical considerations that must be taken into account regarding the precision with which the environmental parameters can be measured. Estler [17] states that atmospheric pressure P can currently be determined with an uncertainty of ≈ 2.7 Pa, which can be assumed to be constant for the entire optical path of the interferometer if it is oriented horizontally. Please note that at sea level, the pressure gradient is ≈ -13 Pa m^{-1} , resulting in a pressure-induced change in n_A of $3.4 \times 10^{-8} \text{ m}^{-1}$ if the measuring equipment is not kept level.

In an exceptionally well-controlled laboratory environment where special care is devoted to keep temperature gradients from affecting the refractive index along the optical path as much as possible, uncertainties of the temperature measurement can be as low as 0.01°C according to [17]. Humidity measured with high accuracy dew-point hygrometers can have uncertainties down to 0.5%. Changes in carbon dioxide concentrations have to be very significant (20% of the natural concentration) to cause a $\Delta n/n$ of 10^{-8} .

Michelson Interferometer

The basis for most interferometers used in interferometric dimensional gages is the classical Michelson interferometer [4] which is shown in Figure 6.49. The coherent monochromatic light of a wavelength-stabilized He–Ne laser is incident onto a beam splitter which splits the light into two equally intense beams (1) and (2).

TABLE 6.10 Parameters of Standard Air and Their Deviation to Cause a $\Delta n/n$ of 10^{-7}

Parameter	Standard value	Variation for $\Delta n/n = +1 \times 10^{-7}$
Pressure P	101.3 kPa	+37.3 Pa
Temperature T	20.0°C	-0.1°C
Humidity H	40%	-10.0%
CO_2 concentration	350 ppm	+670 ppm

FIGURE 6.49 Schematics of the basic Michelson interferometer.

They are reflected off of both the stationary and the translatable mirror whose displacement x is to be measured, and recombined at the splitter, where they are redirected toward a concave lens. Due to the coherence of the laser light, the wavefronts have a well-defined phase relation with respect to each other. This phase is determined by the difference between the optical path lengths of the two beams in arms 1 and 2. If this path difference is continuously changed by translating one of the mirrors, a sinusoidal intensity variation can be observed at a fixed location in space behind the lens used to introduce a beam divergence, resulting in an annular fringe pattern. The pinhole is used to define an exact location of observation and the photodetector picks up the varying intensity for further processing. In the most basic signal processing setup, the number of bright and dark cycles are fed into a counter, which then counts changes in optical path length in integer multiples of $\lambda_A/2$. More sophisticated signal processing not only counts cycles but also determines relative phase changes in the sinusoidal varying intensity so that resolutions of $\lambda_A/512$ can ultimately be achieved.

When moving the mirror, one must guarantee a smooth motion without backward jitter of the mirror carriage to avoid double counts of interference fringes. Very high-quality linear bearings (such as air bearings) are necessary to accomplish just that.

As can be seen in Figure 6.49, the light reflected off both mirrors essentially retraces its own path and is at least partially incident onto the active volume of the laser source (3), thereby forming an external laser resonator which is able to detune the laser, effectively modulating its output power as well as its wavelength. To avoid this effect, commercial versions of Michelson interferometers employ corner-cube reflectors instead of plane mirrors as well as optical isolators, as shown in Figures 6.50 and 6.51. Some authors, however, report using optical arrangements that utilize this effect in conjunction with laser diodes to realize low-cost, short-travel displacement sensors [18, 19]. These setups will not be discussed here, however.

Two-Frequency Heterodyne Interferometer

Figure 6.50 shows the commercially available two-frequency Michelson interferometer operating with a Zeeman-stabilized He-Ne laser source. This laser emits two longitudinal modes with frequencies f_1 and f_2 that are both circularly polarized in opposite directions. By passing the modes through a quarter-wave

FIGURE 6.50 Two-frequency heterodyne interferometer (Courtesy of Spindler & Hoyer Inc.).

plate, two orthogonal linearly polarized waves are generated. Both are split by a nonpolarizing beam splitter. There is a polarizer located in arm 1 of that splitter, which is rotated by 45° with respect to both polarized waves impinging on it, thus effectively allowing them to interfere behind it yielding a difference frequency of $f_2 - f_1$ that is picked up by a photodetector and counted by a reference counter (frequency difference typically 1.5 MHz).

The orthogonal polarized waves in 2 are further split by a polarizing splitter. Spectral component $f_1 < f_2$ is transmitted into measuring arm 3 and frequency component f_2 is reflected into reference arm 4 of the interferometer. Due to the velocity v of the reflector in arm 3 resulting in a displacement x , the frequency f_1 is Doppler-shifted by f_D (Equation 6.74). Movement of the reflector toward the interferometer results in a positive Doppler frequency $f_D > 0$. After recombining both waves from 3 and 4 in the beam splitter again, they are sent through a polarizer in arm 5 that also is rotated by 45° with respect to the direction of polarization of both recombined waves, thereby allowing them to interfere, yielding a difference frequency of $f_2 - f_1 - f_D$ at the location of the photodetector, which is counted by a second counter. By continuously forming the difference of both counts, the measurand (the displacement of x in multiples of $\lambda_A/2$) is calculated.

With this type of interferometer, the direction of motion is given by the sign of the resulting count. One disadvantage of the two-mode heterodyne interferometer is its limited dynamic range for the velocity v of the reflector moving toward the interferometer, since the Doppler frequency f_D , given by:

$$f_D = \frac{2}{\lambda_A} v \quad (6.74)$$

is bound to be less than the initial frequency difference between f_2 and f_1 for stationary reflectors. Given a typical Zeeman effect-induced frequency difference f_z of 1.5 MHz, the velocity v is therefore bound to be less than:

FIGURE 6.51 Single-mode homodyne interferometer (Courtesy of Spindler & Hoyer Inc.).

$$v < \frac{f}{2} \lambda_A = 0.474 \text{ m s}^{-1} \quad (6.75)$$

There is no such bound if the reflector is traveling away from the interferometer. By electronically interpolating the output signal of the photodetector, subwavelength resolution can be obtained [22].

Single-Mode Homodyne Interferometer

An interferometer setup that has no limitation on the maximum velocity in the above sense is the single-mode homodyne interferometer shown in Figure 6.51.

As in the two-frequency heterodyne interferometer, a Zeeman effect-stabilized laser source that emits two frequency-displaced circularly polarized axial modes is usually used. After passing through a quarter-wave plate, two orthogonal polarized waves are generated, only one of which (f_1) is further used. The other (f_2) is reflected out of the optical path by an appropriately oriented polarizing beam splitter. The plane of polarization in arm 1 of the interferometer is tilted by 45° with respect to the plane defined by the two arms 2 and 3. The second polarizing beam splitter will transmit one horizontally oriented component into the measuring arm 2 and reflect a vertically oriented component into the reference arm 3 of the interferometer. The two arms of the interferometer maintain their orthogonal polarizations. The frequency of the wavefront in arm 2 is shifted by the Doppler effect (Equation 6.74) due to the motion of the reflector. The light reflected by the two triple mirrors is recombined in the polarizing beam splitter and redirected by a mirror. Since in this particular optical setup, the polarization states of the two beams in the two arms of the interferometer are orthogonal, there is no interference after the redirecting mirror

in arm 4 as was the case with the basic Michelson interferometer setup (Figure 6.49). After passing a quarter-wave plate at 45° , two opposite circular polarized waves (one with frequency f_1 , the other with frequency $f_1 \pm f_D$) are generated and can be described by a rotating phasor (characterized by $\Phi(t)$) with constant amplitude whose rate of rotation is dependent on the Doppler frequency (in arm 5). Amplitude fluctuations can be observed at the photodetectors A–D after this phasor has passed polarizers, which it does after being split by a nonpolarizing beam splitter.

The output of an interferometer has the general form:

$$I(t) = I_o(t) \frac{1}{2} \left[1 + \cos(\Phi(t)) \right] \quad (6.76)$$

It is desired to infer $\Phi(t)$ from observation of $I(t)$. Note that $I_o(t)$, which is the intensity of the laser, can also fluctuate with time. The problems encountered with this are (1) the ambiguity in the sign of $\Phi(t)$ and (2) the dependence of the calculated phase on the intensity fluctuations due to the aging of the laser and optical components. The first problem stems from the fact that $\arccos(\dots)$ yields two solutions to Equation 6.76:

$$\Phi(t) = \pm \arccos \left[\frac{2I(t)}{I_o(t)} - 1 \right] \quad (6.77)$$

The sign ambiguity can be resolved by also generating a $\sin(\Phi(t))$ yielding quadrature signals. In order to do so, a second output of the interferometer of the form:

$$I_2(t) = I_o(t) \frac{1}{2} \left[1 + \sin(\Phi(t)) \right] \quad (6.78)$$

is sought. Equations 6.76 and 6.78 will determine $\Phi(t)$ unambiguously only in the region $[0, 2\pi)$, but there is still an ambiguity modulo 2π . The second problem can be dealt with by adding two more outputs of the form:

$$I_3(t) = I_o(t) \frac{1}{2} \left[1 - \cos(\Phi(t)) \right] \quad (6.79)$$

$$I_4(t) = I_o(t) \frac{1}{2} \left[1 - \sin(\Phi(t)) \right] \quad (6.80)$$

Taking Equations 6.76 to 6.79 and 6.78 to 6.80, it is possible to obtain a zero crossing at the linear most sensitive point of inflection of the fringe where the effect of intensity fluctuations on the phase measurement is minimal. The setup of Figure 6.51 attempts to obtain these four outputs. Signal A represents the intensity variations as given in Equation 6.76 and signal B due to the nature of the splitting action is shifted with respect to A by 180° (Equation 6.79). There is another arm to the right of the nonpolarizing beam splitter incorporating the polarizing beam splitter II, which is rotated by 45° with respect to beam splitter I so that the attached detectors C and D are generating the signals defined by Equations 6.78 and 6.80.

Since the Doppler frequency is time dependent according to the velocity v of the measuring reflector, the distance, x , traveled by the reflector up to time T is given by Equation 6.81.

$$x = \int_0^T v(t) dt = \int_0^T f_D(t) \frac{\lambda_A}{2} dt = \int_0^T \frac{\partial \Phi(t)}{\partial t} \frac{\lambda_A}{4\pi} dt \quad (6.81)$$

FIGURE 6.52 A simple signal conditioning circuit yielding quadrature signals E and F.

It should be noted that the resolution of this interferometer is limited to $\lambda_N/4$ if no special hardware is used to interpolate between [interference](#) fringes.

This particular interferometer is not limited with respect to a maximum unambiguous Doppler frequency.

Interferometer Signal Processing

At the photodetectors ends the optical path of the interferometers. Since the photodetectors are sensitive to light intensity values only the sinusoidal signal caused by motion of the reflector will be superimposed onto a pedestal signal proportional to the mean intensity over time or displacement, respectively. The electronics attached to the photodetectors is aimed to reliably detect zero-crossings of the sinusoidal component of the signals (A through D) even under low contrast conditions by subtracting out the pedestal signal component in the comparators. Low fringe contrast can be the result of small reflector tilt and/or vibration during periods of reflector movement, nonideal interferometer alignment, and imperfections in optical components like unequal splitting of the beam in beam splitters. [Figure 6.52](#) shows a simple conditioning unit.

The main purpose of that set up is to produce digital quadrature signals (E and F in [Figure 6.52](#)) that can most easily be used to perform signal interpolation digitally [20, 21] and also allow for the determination of the direction of movement by using, for example, signal E as count signal and F as an up/down indicator.

Both comparators compare sinusoidal components having a possibly slowly time-varying dc pedestal amplified by buffer amplifiers. All photodetector signals A through D will be affected by this dc pedestal so that forming their difference in the comparator will yield zero-crossing signals independent of the pedestal. The two comparator units are necessary to generate quadrature signals for direction detection. Furthermore, this electronics allows easily for a fringe interpolation by a factor of 4, bringing the least-count resolution of the interferometer down to ≈ 160 nm. This interpolation can be done if instead of feeding the signal E into the count input, the exored signal $E \oplus F$ is used. In this case, the up/down terminal of the counter circuit needs to be connected to the signal $E \& F$. If an even higher resolution is sought, digital interpolation of these quadrature signals can be performed [20–22].

Conclusions

Using laser interferometers operating with highly stabilized laser sources, relative uncertainties in length measurements as low as 5×10^{-8} can be realized, which makes these kinds of equipment suitable to convey

primary and secondary length standards into industrial measurement labs. Since, for practical purposes, these interferometers need to be operated in ambient air, the uncertainty in the refractive index of air gives the largest single factor limiting the overall precision. Decreasing the uncertainty stemming from that source necessitates the determination of environmental parameters such as relative humidity, temperature along the optical path, and atmospheric pressure with very little error. Laser refractometers able to determine the refractive index of air directly, on the other hand, allow for the direct measurement and compensation of the refractive index. Zeeman effect-stabilized laser sources can reach a relative uncertainty of less than 10^{-8} and thus contribute only a small portion of the overall error. The interferometer itself, depending on the signal processing involved, will have at least count resolution of $\lambda_A/4$ without any optical or electronic interpolation and can have an order of magnitude less uncertainty if high-performance phase meters are used to subdivide the wavelength λ_A . Very high-quality air bearings and a very well-controlled measurement environment are necessary to reach these goals.

Defining Terms

Heterodyne technique: The superposition of two harmonic signals with frequencies f_1 and f_2 in a nonlinear device results in a signal containing both sum and difference frequencies. For interferometric purposes where each individual frequency is in the 10^{14} Hz range, the frequency difference might be low enough to be registered by photodetectors. They also serve as nonlinear devices because their response is to light intensity only, which is proportional to the light amplitude squared.

Interference: A phenomenon that strikingly illustrates the wave nature of light. It occurs when radiation follows more than one path from its source to the point of detection. It may be described as the local departures of the resultant intensity from the law of addition as the point of detection is moved, for the intensity oscillates about the sum of the separate intensities.

Laser: The acronym of *Light Amplification by Stimulated Emission of Radiation*. It was originally used to describe light amplification, but has more recently come to mean an optical oscillator.

Refractive index: A number specifying the ratio of the propagation velocities of light in vacuum c to that in a medium. The refractive index for any medium is always somewhat larger than 1. Its value is dependent on the composition of the medium and the wavelength of the incident radiation.

Zeeman effect: An effect that is observed if excited atoms emit their radiation in the presence of a magnetic field. The longitudinal Zeeman effect causes a single emission line to split symmetrically into right and left circularly polarized lines.

Appendix to Section 6.5

In the appendix below some companies are listed that manufacture either complete interferometer systems or major components thereof, such as beam splitters, retroreflectors, refractometers, wavemeters, etc. This list is by no means exhaustive. Furthermore, no price information is included because the system cost is too much dependent on the particular choice of system components.

Companies that produce interferometers or significant components.

6.6 Bore Gaging Displacement Sensors

Viktor P. Astakhov

Dimensions are a part of the total specification assigned to parts designed by engineering. However, the engineer in industry is constantly faced with the fact that no two objects in the material world can ever be made exactly the same. The small variations that occur in repetitive production must be considered in the design. To inform the workman how much variation from exact size is permissible, the designer uses a tolerance or limit dimension technique. A **tolerance** is defined as the total permissible variation of size, or the difference between the limits of size. **Limit dimensions** are the maximum and minimum permissible dimensions. Proper tolerancing practice ensures that the finished product functions in its intended manner and operates for its expected life.

Bore Tolerancing

All bore dimensions applied to the drawing, except those specifically labeled as basic, gage, reference, maximum, or minimum, will have an exact tolerance, either applied directly to the dimension or indicated by means of general tolerance notes. For any directly tolerated decimal dimension, the tolerance has the same number of decimal places as the decimal portion of the dimension.

Engineering tolerances may broadly be divided into three groups: (1) **size tolerances** assigned to dimensions such as length, diameter, and angle; (2) **geometric tolerances** used to control a hole shape in the longitudinal and transverse directions; and (3) **positional tolerances** used to control the relative position of mating features. Interested readers may refer to [1, 2].

The **ISO system of limits and fits** (ISO Recommendation R 286) covers standard tolerances and deviations for sizes up to 3150 mm. The system is based on a series of tolerances graded to suit all classes of work from the finest to the most coarse, along with different types of fits that range from coarse clearance to heavy interference. Here, **fit** is the general term used to signify the range of tightness that may result from the application of a specific combination of tolerances in the design of mating parts.

There are 18 tolerance grades intended to meet the requirements of different classes of parts. These tolerance grades are referred to as ITs and range from IT 01, IT 02 (reserved for the future), and IT 1, to IT 16 (for today's use). In each grade, the tolerance values increase with size according to a formula that relates the value of a given constant to the mean diameter of a particular size range. The system provides 27 different fundamental deviations for sizes up to and including 500 mm, and 14 for larger sizes to give different type of fits ranging from coarse clearance to heavy interference. Interested readers may refer to [3].

Bore Gage Classification and Specification

To measure the above-listed tolerances, modern manufacturing requires the use of gages. A **gage** is defined as a device for investigating the dimensional fitness of a part for specific function. **Gaging** is defined by ANSI as a process of measuring manufactured materials to assure the specified uniformity of size and contour required by industries. Gaging thereby assures the proper functioning and interchangeability of parts; that is, one part will fit in the same place as any similar part and perform the same function, whether the part is for the original assembly or replacement in service.

Bore gages may be classified as follows:

1. Master gages
2. Inspection gages
3. Manufacturer's gages
4. Gages that control dimensions
5. Gages that control various parameters of bore geometry
6. Fixed limit working gages

7. Variable indicating gages
8. Post-process gages
9. In-process gages

Master gages are made to their basic dimensions as accurately as possible and are used for reference, such as for checking or setting inspection of manufacturer's gages. *Inspection gages* are used by inspectors to check the manufactured products. *Manufacturer's gages* are used for inspection of parts during production.

Post-process gages are used for inspecting parts after being manufactured. Basically, this kind of gage accomplishes two things: (1) it controls the dimensions of a product within the prescribed limitations, and (2) it segregates or rejects products that are outside these limits. Post-process gaging with feedback is a technique to improve part accuracy by using the results of part inspection to compensate for repeatable errors in the machine tool path. The process is normally applied to CNC (computer numerically controlled) machines using inspection data to modify the part program, and on tracer machines using the same data to modify the part template.

In-process gages are used for inspecting parts during the machining cycle. In today's manufacturing strategy, in-process gages and data-collection software provide faster feedback on quality. Indeed, the data-collection and distribution aspect of 100% inspection has become as important as the gaging technology itself. Software specifically designed to capture information from multiple gages, measure dozens of products types and sizes, and make it available to both roving inspectors and supervising quality personnel as needed, is quickly becoming part of quality control strategies. In conjunction with computer numerically controlled (CNC) units, in-process gaging can automatically compensate for workpiece misalignment, tool length variations, and errors due to tool wear.

Gages That Control Dimensions

Gages that control dimensions are used to control bore diameter. These gages can be either post-process or in-process gages. Further, these gages can be either *fixed limit gages* or *variable indicating gages*.

A *plug gage* is a fixed limit working bore gage. These inexpensive gages do not actually measure dimensions or geometry. They simply tell the operator whether the bore is oversized or undersized. The actual design of most plug gages is standard, being covered by American Gage Design (AGD) standards. However, there are many cases where a special plug gage must be designed.

A plug gage is usually made up of two members. One member is called the go end, and the other the no-go or not-go end. The gage commonly has two parts: the gaging member, and a handle with the sign, go or no-go, and the gagemaker's tolerance marked on it. There are generally three types of AGD standard plug gages. First is the single-end plug gage (Figure 6.53(a)); the second is the double-end (Figure 6.53(b)); and the third is the progressive gage (Figure 6.53(c)). Interested readers may refer to [4].

Fixed-limit gage tolerance is generally determined from the amount of workpiece tolerance. A 10% rule is generally used for determining the amount of gage tolerance for fixed, limit-type gages. Four classes of gagemakers' tolerances have been established by the American Gage Design Committee and are in general use [4]. These four classes establish maximum variation for any designed gage size. The degree of accuracy needed determines the class of gage to be used. Table 6.11 shows these four classes of gagemakers' tolerances. Referring to Table 6.11, class XX gages are used primarily as master gages and for final close tolerance inspection. Class X gages are used for some types of master gage work and as close tolerance inspection and working gages. Class Y gages are used as inspection and working gages. Class Z are used as working gages where part tolerances are large. Table 6.12 shows the diameter ranges and prices of the plug gages manufactured by the Flexbar Machine Corp.

Variable indicating gages allow the user to inspect some bore parameters and get numbers for charting and statistical process control (commonly abbreviated as SPC). These gages have one primary advantage over fixed gages: they show how much a hole is oversized or undersized. When using a variable indicating gage, a master ring gage to the nominal dimension to be checked must be used to preset the gage to zero. Then, in applying the gage, the variation from zero is read from the dial scale. Figure 6.54 shows industry's

FIGURE 6.53 AGD cylindrical plug gages to inspect the diameter of holes: (a) two separate gage members; (b) two gage members mounted on single handle with one gage member on each end; (c) progressive gage.

most popular dial and electronic bore gages. Figure 6.55 shows a set of dial bore gages for the range of 35 mm to 150 mm. Figure 6.56 shows the Intrinic[®] plus (Brown & Sharpe) internal micrometer. Intrinic[®] plus provides simple, accurate inside measurement capability. The micrometer features automatic shut-off, electronic memory mode, instantaneous inch/metric conversion, and a standard direct output for SPC applications. Tolerance classification at a glance allows quick, efficient sorting while inspecting. The display shows the inspector, in color, if any dimension is within tolerance (green), out-of-tolerance (red), or reworkable (yellow). Table 6.13 presents the basic ranges and prices for these micrometers.

Gages That Control Geometry

Gages that control various parameters of bore geometry are used for complex comparisons of part shape to an ideal shape. All these gages are post-process gages. Two major categories of geometry gages are in use: gages with manual probe head systems and form measuring machines.

Gages with Manual Probe Head Systems

Geometry gages with manual probe head systems are rapidly becoming common in many high-precision metalworking applications. The simplest form of manual probe head systems in common use is the air plug gage (spindle) (Figure 6.57). Compressed air from the air gage indicating unit is pressed to the plug gage and allowed to escape from two or more jets in the periphery. When the air plug gage is inserted into a hole, the air escaping from the jets is limited by the clearance between the jet faces and the hole. The small changes in clearance, arising when the air plug gage is inserted in successive holes of different sizes, produce changes in the flow rate or back pressure in the circuit. The magnification and datum setting of systems with variable control orifices and zero bleeds is carried out with master holes. Some errors of form that can be detected with air plug gages are: (1) taper, (2) bell mouthing, (3) barreling, (4) ovality, and (5) lobing. Dearborn (Dearborne Gage Company, MI) open-orifice air spindles are available as standard to use in measuring thru, blind, and counterbored holes ranging in diameter from 0.070 in. (2 mm) to 6.000 in. (154 mm).

FIGURE 6.54 Industry's most popular dial and electronic bore gages (Courtesy of The L.S. Starrett Co.).

Another type of geometry gage with manual probe head system is the electronic bore gage. These gages measure bores at various depths to determine conditions such as bellmouth, taper, convexity, or concavity. They are also able to determine out-of-roundness conditions when equipped with a 3-point measuring system. [Figure 6.58](#) shows a TRIOMATIC® electronic bore gage (Brown & Sharpe), and

FIGURE 6.54 (continued)

Table 6.14 presents the basic ranges and prices for these gages. TRIOMATIC® electronic bore gages feature automatic shut-off, electronic memory mode, instantaneous inch/metric conversion, and a standard direct output to a data handling system for SPC and statistical quality control. Mechanically, TRIOMATIC® electronic bore gages use the time-tested, three contact points interchangeable heads. The contact points are spaced 120° apart, ensuring proper centering and alignment that are especially essential for deep holes. The tips of the points are made of tungsten-carbide to resist wear, and extend to the surface of the heard for measuring at the bottom of blind holes or the surface of steps within a hole. Since the tips are connected to a cone-actuated electronic measuring system, these gages are referred to as *electronic gages*.

Form Measuring Instruments

Most modern form measuring instruments stage the workpiece on a turntable and provide a means to position a gage head against the part (Figure 6.59). As the turntable rotates, the gage head measures deviation from the true circle. Those gages where the gage head is supported by a simple, rigid, manual, or motorized stand that does not provide precise control over positioning are capable of performing the following measurements: roundness, concentricity, circular runout, circular flatness, perpendicularity, plane runout, top and bottom face runout, circular parallelism, and coaxiality. Modern fully automatic machines are the most sophisticated measuring instruments. Normally, they are equipped with a Windows™-based, PC-compatible graphical user interface to perform real-time data acquisition and processing. Mitutoyo/MTI Corp. produces a wide range of these machines (Table 6.15). The RA-600 series (Figure 6.60) features an innovative, fully automatic method that enables the machine to perform centering and leveling automatically if any deviation is detected during preliminary measurement. In addition, these machines can measure thickness, squareness, cylindricity, spiral cylindricity, straightness, total

FIGURE 6.54 (continued)

runout, vertical straightness, and vertical parallelism. The machines are supplied with MeasurLink® data acquisition software for Windows™, which allows immediate measurement data analysis and feedback for variable, attribute, and short inspection runs. The software gives the quality control/production manager the ability to create traceability lists of unlimited size. Information such as machine center, operator, materials used, assignable causes, and other relevant data can be stored and attached to measurement values. See [Table 6.16](#) for a list of companies that make bore gages.

GAGE R AND R Standards

Gage Repeatability and Reproducibility (GAGE R AND R) capability standards have direct implications for parts makers and for gage manufacturers. Repeatability is the ability of an operator using a single gage to obtain the same measurements during a series of tests. Reproducibility is the ability of different

operators to obtain similar results with the same gage. GAGE R AND R blends these two factors together to determine a measuring system's reliability and its suitability for a particular measuring application. For example, a gage design that meets the GAGE R AND R standards for 50 mm (2 in.) bores may be unsatisfactory on 250 mm (10 in.) bores. A gage that meets a tolerance of 2 μm , may not be satisfactory

at a tolerance of $1\ \mu\text{m}$. The GAGE R AND R standards will help parts makers identify the best gage for each application and at each tolerance.

The growing acceptance of ISO 9004 as an international quality philosophy is creating significant changes for manufacturers. The most important change that ISO 9004 will create is the need for international GAGE R AND R capability standards and the guarantee of a level playing field. Previously, gage manufacturers and parts makers had many different sets of measuring criteria. Now, in establishing GAGE R AND R capability standards along with ISO 9004 standards, there will be an international set of standards that applies to everyone. A set of measurements from Europe will mean the same as a set from North America or a set from Asia.

The factors that influence GAGE R AND R capability when gaging a bore include:

1. Variation resulting from the bore gage: This variation includes linearity, repeatability, stability, and calibration.
2. Variation resulting from the operation using a bore gage: This variation includes repeatability by an individual operator using the gage and reproducibility by different operators using the same gage.
3. Variation resulting from the production line: Part surface finish, application setup errors, and temperature changes cause this variation.

Dyer company (Dyer, Lancaster, PA 17604) reported the following ranges of these variations for its 830 and 230 series bore gages: linearity $\pm 0.001\ \text{mm}$ ($\pm 0.000040\ \text{in.}$); repeatability $< \pm 0.00025\ \text{mm}$ ($\pm 0.000010\ \text{in.}$); stability — bore gages are made from a special alloy steel that resists temperature changes

or “hand heat.” The sealed construction ensures performance reliability even under damp or oily conditions; repeatability by an individual operator — the gages are non-tipping and self-centering in both the axial and radial planes of the bore. The operator can keep his/her hands on or off the gage. The operator has no influence when measuring the bore. The automatic alignment of the bore gage results in a highly reproducible reading.

Defining Terms

Dimension: A numerical value expressed in appropriate units of measure and indicated on drawings with lines, symbols, and notes to define the geometrical characteristics of an object.

Tolerance: The total permissible variation of size, form, or location.

Fit: The general term used to signify the range of tightness which may result from the application of a specific combination of allowances and tolerances in the design of mating parts.

ISO System of Limits and Fits: A standardized system of limits and fits, a group of tolerances considered as corresponding to the same level of accuracy for all basic sizes.

Gage: A device for investigating the dimensional fitness of a part for specified function.

Gaging: A process of measuring manufacturing materials to assure the specified uniformity of size and contour required by industries.

6.7 Time-of-Flight Ultrasonic Displacement Sensors

Teklic Ole Pedersen and Nils Karlsson

Ultrasound is an acoustic wave with a frequency higher than the audible range of the human ear, which is 20 kHz. Ultrasound can be within the audible range for some animals, like dogs, bats, or dolphins. In the years around 1883, Sir Francis Galton performed the first known experiments with whistles generating ultrasound. Many decades later, people started to find ultrasound applications in engineering, medicine, and daily life. The basic principle for the use of ultrasound as a measurement tool is the *time-of-flight technique*. The pulse-echo method is one example. In the pulse-echo method, a pulse of ultrasound is transmitted in a medium. When the pulse reaches another medium, it is totally or partially reflected, and the elapsed time from emission to detection of the reflected pulse is measured. This time depends on the distance and the velocity of the sound. When sound travels with a known velocity c , the time t elapsed between the outgoing signal and its incoming echo is a measure of the distance d to the object causing the echo.

$$d = \frac{ct}{2} \quad (6.82)$$

Figure 6.61 shows a simple pulse-echo system. The transmitter and the receiver could be the same device, but they are separated for clarity in this figure.

The oscillator generates an electric signal with a typical frequency of 40 kHz. This electric signal is transformed into mechanical vibrations of the same frequency in the transmitter. These vibrations generate sound waves that are reflected by the object. The reflected sound echo causes an electric signal in the receiver. For precise measurements, the speed of sound is a crucial parameter. A typical value in air at 1 atm pressure and room temperature is 343 m s^{-1} , but the speed of sound is influenced by air pressure, air temperature, and the chemical composition of air (water, CO_2 , etc.). For example, the speed of sound is proportional to the square root of absolute temperature. Measuring distances in an environment with large temperature gradients can result in erroneously calculated distances. As an advantage, ultrasound waves are robust against other disturbances such as light, smoke, and electromagnetic interference [1–4].

Physical Characteristics of Sound Waves

Sound is a vibration in matter. It propagates as a longitudinal wave, i.e., the displacement in the material is in the direction of the sound wave propagation. A plane wave that propagates in the x direction can be described by

$$\Delta x = A \sin \omega \left(t - \frac{x}{c} \right) \quad (6.83)$$

where A is the amplitude, $\omega = 2\pi f$, f being the frequency of the wave and Δx is the displacement of a particle at time t at the position x .

The velocity of sound depends on the medium in which it propagates. In a homogeneous and isotropic solid, the velocity depends on the density ρ and the modulus of elasticity E according to Equation 6.84.

$$c = \sqrt{\frac{E}{\rho}} \quad (6.84)$$

In a liquid, the velocity depends on the density and the adiabatic compressibility K , Equation 6.85.

FIGURE 6.61 Principle of a pulse-echo ultrasound system for distance measurements (Tr = transmitter, Re = receiver).

$$c = \sqrt{\frac{1}{K\rho}} \quad (6.85)$$

In gases, the velocity of sound is described by Equation 6.86. Here g represents the ratio of the specific heat at constant pressure (c_p) to the specific heat at constant volume (c_v), p is pressure, R is the universal gas constant, T is the absolute temperature, and M is the molecular weight.

$$c = \sqrt{\frac{gRT}{M}} = \sqrt{\frac{c_p}{c_v} \frac{p}{\rho}} \quad (6.86)$$

An important quantity is the *specific acoustic impedance*. It is, in general, a complex quantity but in the far field (Figure 6.63), the imaginary component disappears, leaving a real quantity. This real quantity is the product of the density ρ and the sound speed c in the medium. This product is called the characteristic impedance R_a (Equation 6.87).

$$R_a = \rho c \quad (6.87)$$

The characteristic impedance is thus independent of the sound frequency.

An acoustic wave has an intensity I (rate of flow of energy per unit area), which can be expressed in watts per square meter (W m^{-2}). A usually unwanted phenomenon arises when the sound wave has to pass from one medium with characteristic impedance R_1 to another medium with characteristic impedance R_2 . If R_1 and R_2 have different values, a part of the wave intensity will reflect at the boundary between the two media (see Figure 6.61 and 6.62). The two media are said to be mismatched, or poorly coupled, if a major part of the wave intensity is reflected and a minor part is transmitted. The relative amounts of reflected and transmitted wave intensities can be defined by:

$$\text{Reflection coefficient} = \frac{I_{\text{refl}}}{I_{\text{incident}}} \quad (6.88a)$$

$$\text{Transmission coefficient} = \frac{I_{\text{trans}}}{I_{\text{incident}}} \quad (6.88b)$$

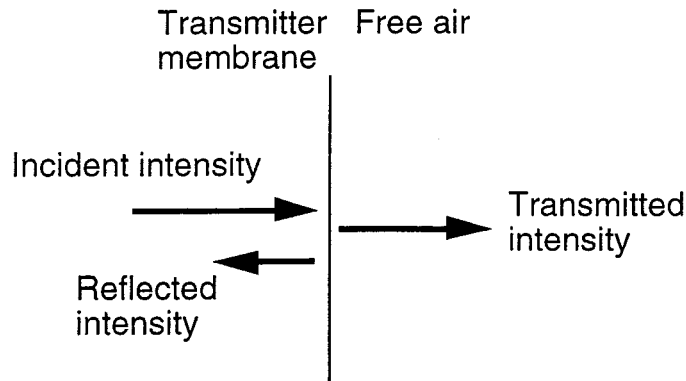

FIGURE 6.62 Reflection and transmission of a sound wave at the interface between media of different characteristic impedances.

It can be shown [1] that these coefficients have simple relations to the previously mentioned characteristic impedances.

$$\text{Reflection coefficient} = \frac{(R_1 - R_2)^2}{(R_1 + R_2)^2} \quad (6.89a)$$

$$\text{Transmission coefficient} = \frac{4R_1R_2}{(R_1 + R_2)^2} \quad (6.89b)$$

The practical importance of the acoustic impedance is realized when the ultrasonic pulse-echo system shown in Figure 6.61 is considered. First, the electric energy is converted into mechanical vibrations of a membrane in the transmitter. Second, the vibrations (the sound wave) have to pass through the boundary between the membrane (usually a solid material) and free air. Because the transmitter membrane and the free air have different characteristic impedances, much of the acoustic intensity is reflected (Figure 6.62).

The transmitted ultrasound in free air will first propagate in a parallel beam (near field of the transducer); but after a distance L , the beam diverges (the far field of the transducer). See Equation 6.90 and Figure 6.63.

$$L \approx \frac{D^2}{4\lambda} \quad (6.90)$$

D is the diameter of the circular transmitter and λ is the wavelength of the ultrasound.

The sound intensity in the near field is complicated due to interference effects of sound originating from different parts of the transducer membrane. In the far field, the intensity is approximately uniform and the beam spread follows:

$$\sin\beta = 1.22 \frac{\lambda}{D} \quad (6.91)$$

where β is the half lobe angle.

FIGURE 6.63 Illustration of the ultrasound beam in the near field and the far field of the transducer.

To get a narrow beam, the transmitter membrane diameter must be large with respect to the wavelength. High-frequency ultrasound cannot be the general solution as ultrasound of a high frequency is absorbed faster than ultrasound of a low frequency [1–4].

Ultrasound Transducers

Most ultrasound transducers convert electric energy to mechanical energy and vice versa. The most common types of in-air transducers are [5–7]:

1. Mechanical
2. Electromagnetic
3. Piezoelectric
4. Electrostatic
5. Magnetostrictive

The simplest type, mechanical transducers such as whistles and sirens, are used up to approximately 50 kHz. This type works only as a transmitter.

Electromagnetic transducers such as loudspeakers and microphones can be used for ultrasonic wave generation, but they are mainly suited for lower frequencies.

The piezoelectric transducer (Figure 6.64) is more suitable for use in ultrasonics and is quite common. It uses a property of piezoelectric crystals: they change dimensions when they are exposed to an electric field. When an alternating voltage is applied over the piezoelectric material, it changes its dimensions with the frequency of the voltage. The transducer is mainly suited for use at frequencies near the mechanical resonance frequency of the crystal. The piezoelectric transducer can be both a transmitter and a receiver: when a piezoelectric material is forced to vibrate by a sound pulse, it generates a voltage. Some natural crystals, such as quartz, are piezoelectric. Ceramics can be polarized to become piezoelectric; so can some polymers like PVDF (polyvinylidene fluoride). Polymers are suitable as transducers in air since their acoustic impedance is low [8–10] compared with other standard piezoelectric materials.

The electrostatic transducer (Figure 6.64) is a plate capacitor with one plate fixed and the other free to vibrate as a membrane. When a voltage is applied between the plates, the electrostatic forces tend to attract or repel the plates relative to each other depending on the polarity of the voltage. This transducer can be used both as a transmitter and a receiver [11].

The magnetostrictive transducer is based on the phenomenon of magnetostriction, which means that the dimensions of a ferromagnetic rod change due to the changes of an externally applied magnetic field. This transducer can also act as both a receiver and a transmitter.

FIGURE 6.64 Ultrasonic transducers piezoelectric (left) and electrostatic (right).

Principles of Time-of-Flight Systems

There are several techniques for ultrasonic range measurements [12–15].

The previously described *pulse echo method* is the simplest one. Usually, this method has a low signal-to-noise ratio (SNR) because of the low transmitted energy due to the short duration of the pulse. Multireflections are detectable.

In the *phase angle method*, the phase angle is measured between the continuous transmitted signal and the continuous received signal and is used as a measure of the distance. The method is relatively insensitive to disturbances. Multireflections are not detectable in a meaningful way. When the distance is longer than one wavelength, another method must be used to monitor the distance.

The *frequency modulation method* uses transmitted signals that are linearly frequency modulated. Thus, detected signals are a delayed replica of the transmitted signal at an earlier frequency. The frequency shift is proportional to the time-of-flight. The method is robust against disturbing signals, and multireflections are detectable.

The *correlation method* (Figure 6.65) determines the cross-correlation function between transmitted and received signals. When the transmitted signal is a random sequence, i.e., white Gaussian noise, the cross-correlation function estimates the impulse response of the system, which, in turn, is a good indicator of all possible time delays. The method is robust against disturbances, and multireflections are detectable.

Industrial acoustic noise can affect the received signals in an ultrasound time-of-flight system. The noise can be generated from leaking compressed air pipes, noisy machines, or other ultrasonic systems. This external noise is not correlated with the relevant echo signals of the transmitted noise and can therefore be eliminated by the use of correlation methods. Disturbances correlated with the relevant echo signal (e.g., unwanted reflections) will not be eliminated by the use of correlation methods.

The impulse response $h(t, t_0)$ is used as a sensitive indicator of time delay between transmitted signal at time t_0 and received signal at time t . The impulse response is given by [14]:

$$h(t, t_0) = F^{-1} \begin{bmatrix} S_{xy} \\ S_{xx} \end{bmatrix} \quad (6.92)$$

FIGURE 6.65 Diagram of a correlation-based time-of-flight system.

where F^{-1} is the inverse Fourier transform, x is the transmitted signal, y is the received signal, $S_{xy}(f)$ is the cross-spectral density function [the Fourier transform of the cross-correlation function of the transmitted signal $x(t)$ and the received signal $y(t)$] and S_{xx} is the power density function (the Fourier transform of the auto-correlation function of the transmitted signal).

To analyze the transfer channel by data acquisition requires a high sampling rate, theoretically at least two times the highest frequency component in the received signal (and in practice as high as 10 times the highest frequency). One way to reduce the sampling rate is to first convert the signal from its bandpass characteristics around a center frequency f_0 (approx. 50 kHz) to lowpass characteristics from dc to $B/2$, where B is the appropriate bandwidth. The accuracy of the range estimate, and hence the time interval $t - t_0$, can be improved by processing the estimate of the impulse response $h(t - t_0)$ with a curve-fitting (least square) method and digital filtering in a computer. A block diagram of a correlation-based time-of-flight system is shown in Figure 6.65. Further details and complete design examples can be found in the literature [12–15].

Table 6.17 lists some advantages and drawbacks of the described time-of-flight methods.

TABLE 6.17 Advantages and Disadvantages of Time-of-Flight Methods

Method	Main advantage	Main disadvantage
Pulse echo method	Simple	Low signal-to-noise ratio
Phase angle method	Rather insensitive to disturbances	Cannot be used directly at distances longer than the wavelength of the ultrasound
Frequency modulation method	Robust against disturbances; multireflections detectable	Can give ambiguous results measurements on long and short distances can give the same result (compare with phase angle method)
Correlation method	Very robust against disturbances	Make relatively high demands on hardware and/or computations

6.8 Optical Encoder Displacement Sensors

J. R. René Mayer

The detection of angular and linear motion is a key function in a multitude of systems such as machine tools, industrial robots, a variety of instruments, computer mice, etc. Although they are one of many techniques capable of such measurements, the ease with which they are interfaced to digital systems has made them very popular.

Optical encoders are used to measure either angular or linear positions. Those used for angular detection are commonly called rotary or shaft encoders, since they usually detect the rotation of a shaft. Optical encoders encompass a variety of devices, all of which use light as the means to transform movement into electrical signals. All devices have two basic building blocks: a main grating and a detection system. It is the position of one with respect to the other that is detected. The main grating represents the measurement standard. For linear measurements, the main grating, commonly called the scale, is one or more sets of parallel lines of constant or specially coded pitch supported by a substrate. Similarly, a rotary encoder has a grating with radial lines on a disk.

Both linear and rotary encoders can, in principle, be absolute or incremental, although in practice, linear absolute encoders employing optical principles are quite uncommon and have drastically limited

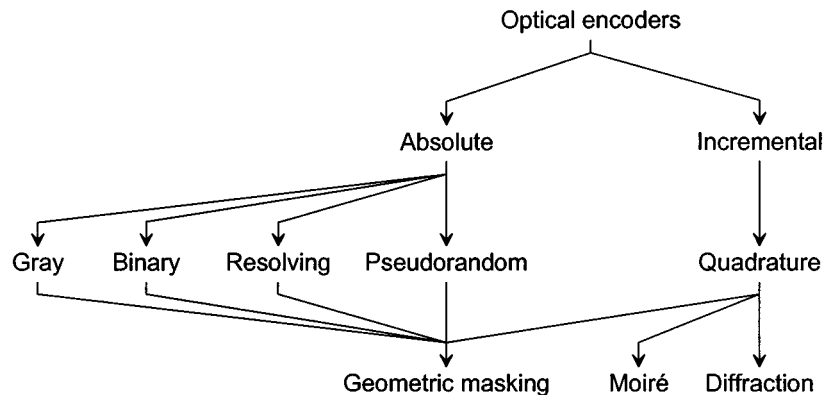

FIGURE 6.66 Classifications of optical encoders based on (1) the nature of the final information provided, (2) the type of signals generated, and (3) the technology used to generate the signals.

performance characteristics (accuracy, resolution, and/or maximum operating speed). Figure 6.66 shows a simplified classification of optical encoders. This classification refers to the nature of the information generated. The incremental encoder detects movement relative to a reference point. As a result, some form of reference signal is usually supplied by the encoder at a fixed position in order to define a reference position. The current position is then incremented (or decremented) as appropriate. Multiple reference marks can also be used, where the distance between successive marks is unique so that as soon as two successive marks have been detected, it becomes possible to establish absolute position from then on. The reference point can also be mechanical. Should power be lost or a signal transmission error occur, then the absolute position is lost and the encoder must return to one or more reference points in order to reset its counters. Unfortunately, a loss of count may not be detected until a reference point is reaccessed. Furthermore, reading errors may accumulate. On the other hand, absolute encoders produce a set of binary signals from which the absolute position can be deduced without the knowledge of the previous motion history. The current position is known right from powering-on. In the case of absolute rotary encoders, single and multiturn devices are available. Multiturn devices use an internal mechanical transmission system to drive a second grating that serves as turn counter.

Most incremental encoders use quadrature signals as output to carry the motion information. Some encoders use one square-wave signal, which is used for position in one direction only. Also, this single square wave can be fed into either a PLC (programmable logic controller) or another electronic interface that converts this signal to a rate or RPM (revolution per minute) for speed indication. However, whenever bidirectional operation is required, quadrature signals are necessary. Quadrature signals come in analog or digital form. The analog form consists simply of a sine and a cosine signal. The number of sinusoidal cycles per unit change of the measured variable (a revolution or 360° for a rotary encoder) determines the basic resolution of the encoder prior to interpolation. The digital form consists of two square-wave trains, 90° (often called electrical degree) out of phase. The 90° phase lag is indispensable in order to detect the motion direction and hence increment or decrement the position counter accordingly. The main optical techniques to generate the quadrature signals are geometric masking, Moiré fringes, and diffraction based. For linear encoders, the basic resolution is related to the distance traveled by the grating in order for the encoder to produce one full quadrature cycle. For rotary encoders, the basic resolution is usually described as the number of quadrature cycles per turn. The resolution of an encoder system can be increased by electronic means. With analog quadrature signals, it is possible to interpolate within each quadrature cycle. The limit of the interpolation factor depends on the quality (mark space, quadrature separation, and jitter) of the basic signals. With square-wave signals, multiplication by a factor of two or four is easily achieved. Increasing the resolution in this manner does not, however, improve the trueness, often called accuracy (or linearity) of the measurement.

FIGURE 6.67 (a) Absolute encoders using a natural binary code of four digits. Four tracks are required. The moving read head has four apertures and is shown in position 7 along the scale. (b) The output of the read head aperture corresponding to the least significant track. It represents the proportion of light area covering the aperture. (c) The binary digit obtained after squaring the raw output signal.

Absolute encoders are classified according to the type of code used. The main four codes are Gray, binary (usually read by vee-scan detection), optical resolving, and pseudorandom. All absolute encoders use geometric masking to generate the code.

Encoder Signals and Processing Circuitry

Absolute Encoders

Direct Binary

Figure 6.67(a) illustrates the concept of an absolute linear optical encoder using a direct binary encoded scale. The fixed scale has n tracks (here n is 4), each providing one bit of a direct binary number. The lowest track (first track from the center of the disk for a rotary encoder) is the most significant digit and has a weight, 2^{n-1} (here 2^3), while the upper track is the least significant digit with a weight 2^0 . The track providing the least significant digit has 2^{n-1} cycles of light and dark records, while the most significant track has 2^0 or 1 such cycle. For each track, the moving read head has a readout unit consisting of a light source, a mask, and a photodetector. Figure 6.67(b) shows the output from the photodetector, which represents the total intensity of light reaching its surface. As the mask passes over a clear region of the grating, the photodetector output increases, and then decreases. In theory, a truncated triangular wave is obtained, which can easily be converted to a square wave (Figure 6.67(c)) by a suitably chosen thresholding level. The result is a high or 1 for a light record and a low or 0 for a dark one. The position, in base 10, corresponding to the reading head position in Figure 6.67 is

$$1 \times 2^0 + 1 \times 2^1 + 1 \times 2^2 + 0 \times 2^3 = 7 \quad (6.93)$$

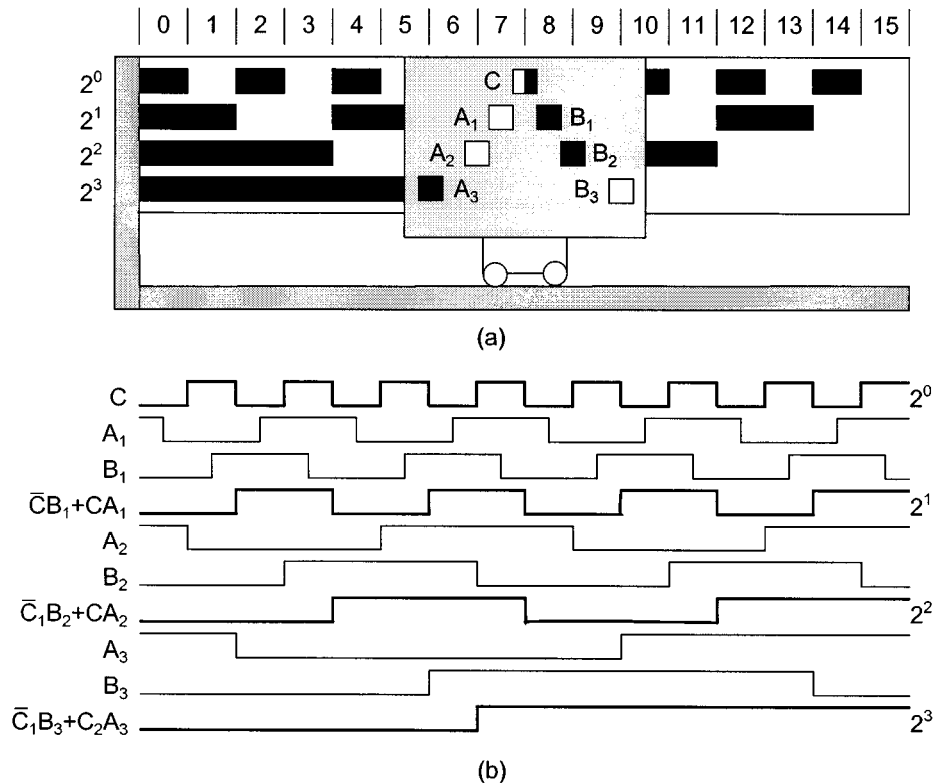

FIGURE 6.68 The vee-scan configuration of reading units in (a) removes the ambiguity associated with a natural binary scale. Simple combinational logic is then used to generate the natural binary readout in (b).

The code configuration just described is not suitable for practical use because some transitions require that two or more bit values change simultaneously. For example, from position 7 to position 8, all bits change values. Unless the change is simultaneous, an incorrect position readout results at some position. This would require that the scale is geometrically perfect, that the read head be perfectly aligned with the scale, and that the electronics are perfectly adjusted and stable over time. This problem is solved either by the use of a vee-scan detection method or the use of a unit-distance code such as the Gray code.

Vee-scan

The vee-scan method uses a V-shape pattern of readout units that removes the potential reading ambiguity of direct binary scales. Stephens et al. [1] indicate the read points at which transitions are detected in [Figure 6.68\(a\)](#). They also describe the conversion of the thresholded output signals to binary code using combinational logic. The primary advantage is that the location tolerance of the transition point of each reading unit need only be $\pm 1/8$ of the cycle length for that particular track. For example, $\pm 45^\circ$ for the most significant track of a rotary encoder disk. [Figure 6.68\(b\)](#) shows a direct binary word obtained through logic combinations of the vee-scan readings.

Gray Code

The use of vee-scan requires additional reading heads as well as processing electronics. The Gray code is a unit-distance code and so only one bit of data changes between representations of two consecutive numbers or successive positions. This removes the possibility of ambiguous readout. It has the following advantages: (1) it is easily converted to direct binary code, and (2) the finest tracks are twice the width of equivalent direct binary code tracks. [Figure 6.69\(a\)](#) shows a Gray code linear scale. [Figure 6.69\(b\)](#) shows a scheme for the conversion from Gray code to binary code and proceeds as follows: (1) the most significant bit (msb) of the binary code equals the msb of the Gray-coded number; (2) add (modulo-2)

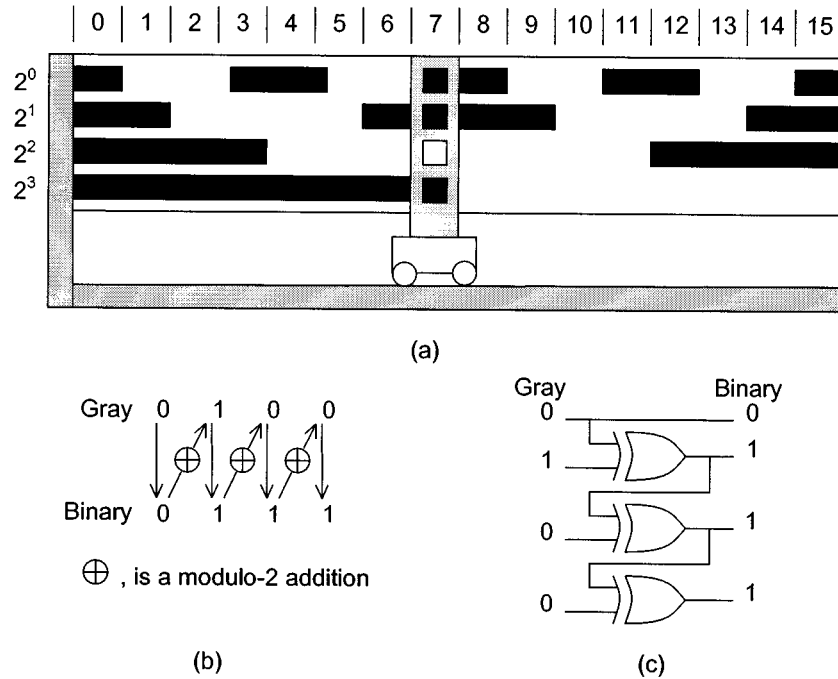

FIGURE 6.69 (a) Gray code allows a transition on only one track between each successive position so that no ambiguity arises. A scheme based on modulo-2 additions converts the Gray code to natural binary code in (b). Exclusive-ORs implement the conversion in (c).

the msb of the binary number to the next significant bit of the Gray-coded number to obtain the next binary bit; and (3) repeat step (2) until all bits of the Gray-coded number have been added modulo-2. The resultant number is the binary equivalent of the Gray-coded number. The modulo-2 addition is equivalent to the action of an exclusive-OR. Figure 6.69(c) shows a simple circuit using combinational logic to perform Gray to binary conversion. Sente et al. [2] suggest the use of an external ROM to convert the code where the input coded word is the address and the data is the output coded word. Using a 16-bit ROM for a 12-bit code, Sente et al. [2] suggest using the remaining 4 bits to implement a direction signal. Stephens et al. [1] describe the use of vee-scan with a gray code scale for even better robustness.

Pseudorandom Code

Pseudorandom encoding allows the use of only two tracks to produce an absolute encoder. One track contains the pattern used to identify the current position, while the other is used to synchronize the reading of the encoded track and remove ambiguity problems. A pseudorandom binary sequence (PRBS) is a series of binary records or numbers, generated in such a way that any consecutive series of n digits is unique. Such code is called chain code, and it has the property that the first $n-1$ digits of an n -bit word are identical to the last $n-1$ digits of the previous code word. This allows their partial overlapping on a single track. A PRBS of length $2^n - 1$ is defined by:

$$XN(j) \mid j=0, 1, \dots, 2^n-1 \quad (6.94)$$

The code can be generated by reading the n th stage of a feedback shift register after j shifts. The register must be initialized so that at least one of the registers is nonzero and the feedback connection implements the formula

$$X(0) = X(n) \oplus c(n-1) X(n-1) \oplus \dots \oplus c(1) X(1) \quad (6.95)$$

TABLE 6.18 Shift-Register Feedback Connections for Generating Pseudorandom Binary Sequences

n	Length	Direct sequence	Reverse sequence
4	15	1, 4	3, 4
5	31	2, 5	3, 5
6	63	1, 6	5, 6
7	127	3, 7	4, 7
8	255	2, 3, 4, 8	4, 5, 6, 8
9	511	4, 9	5, 9
10	1023	3, 10	7, 10
11	2047	2, 11	9, 11
12	4095	1, 4, 6, 12	6, 8, 11, 12
13	8191	1, 3, 4, 13	9, 10, 12, 13
14	16,383	1, 6, 10, 14	4, 8, 13, 14

where the c coefficients are 0 or 1. The feedback registers for which c is 1 are listed in Table 6.18 for values of n from 4 to 14. The following is a PRBS for $n = 4$ with the pseudocode obtained using all registers set to 1 initially, 111101011001000. For a rotary encoder disk, the 15 sectors would have a 24° width.

Petriu [3, 4] describes a possible configuration of a PRBS disk that uses a PRBS track and a synchronization track (Figure 6.70), together with the processing method to reconstitute the position in natural binary. Table 6.18 gives the reverse feedback configuration. The shift register is initially loaded with the current n -tuple. Then the reverse logic is applied recurrently until the initial sequence of the PRBS is reached. At this point, the n -bit counter represents the value of j . For a rotary encoder $(j * 360)/(2^n - 1)$ is the current angular position; whereas for a linear encoder, the position is $j * P$ where P is the scale record length or pitch. Petriu [4] suggests that in order to allow nonambiguous bidirectional reading, $n + 1$ heads are used on the PRBS track. The synchronization track has a series of 0s and 1s in records of the same width as the PRBS track and in phase. There is a $P/2$ shift, where P is the record's length between the A head on the synchronization track and the $n + 1$ read heads on the PRBS track. The $n + 1$ records are updated on a trigger from the A signal. This ensures that the $n + 1$ heads are closely aligned with the PRBS record mid-position. A second read head called B on the synchronization track is shifted by $P/2$ relative to A. A and B are in quadrature, which allows their simultaneous use to generate a motion direction signal. The correct n -tuple, i.e., the lower or upper subset, is selected on the basis of the moving direction and is then converted to natural binary by reverse feedback. Petriu [4] also suggests a simple means of increasing the resolution by a factor of 2 using some additional electronics. He also proposes a scheme to use an arbitrary (not $2^n - 1$) number of sectors, but this requires a third track and some additional correction electronics to handle the last $n - 1$ records of a disk, since these are no longer PRBS patterns. Tomlinson [5] proposes another method for truncation of the PRBS sequence that does not require a third track. Instead, particular codes were removed by applying additional logic in the direct and reverse feedback logic.

Ross and Taylor [6] and Arsic and Denic [7] suggest ways of reducing the number of reading heads by accumulating readings into a shift register so that a minimum of two heads are sufficient to read the PRBS track. However, on start-up, the correct position is not known until the encoder has moved so that all registers have been updated. This type of encoder is therefore not completely absolute because it does not indicate its correct position on start-up. Finally, Arazi [8] mentions the use of a ROM that stores the translation table, as an alternative to a logic circuit.

Optical Resolving

This method has similarities with its electromagnetic counterpart and depends on the generation of a sine and a cosine signal pair per encoder shaft revolution. The resolution and accuracy of this encoder depend on its ability to generate signals that conform to their ideal waveforms and the resolving power of the electronic circuit responsible for performing the rectangular to polar conversion to produce angular

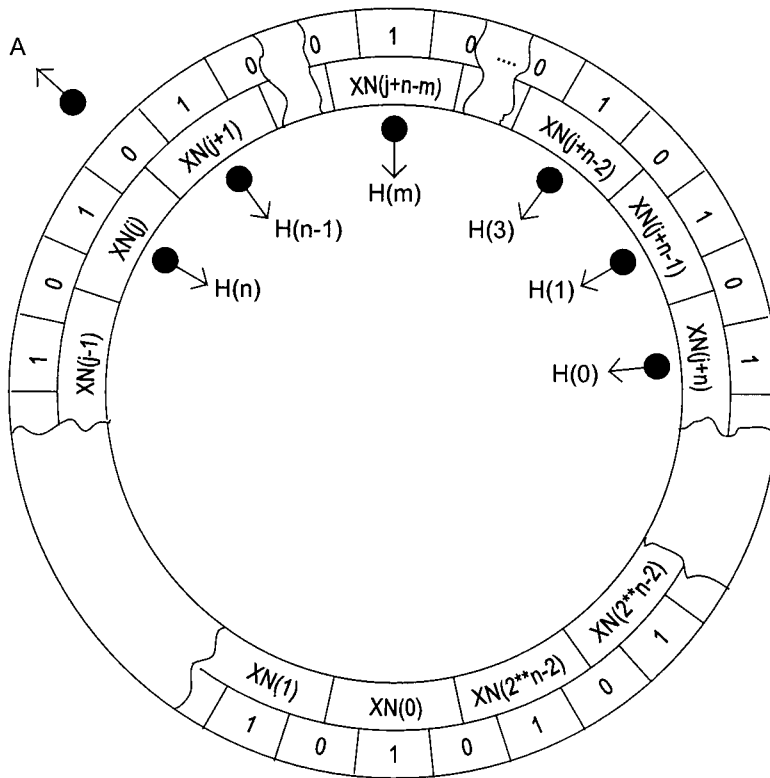

FIGURE 6.70 Pseudorandom shaft encoder with a simple synchronization track to validate the readout from the n -tuple read by the reading heads $H(i)$, $i = n, \dots, 1$. The circuit is a simplified code conversion to binary based on the reverse feedback logic. The counter counts the number of steps required to return to the initial sequence.

FIGURE 6.71 The lowest possible resolution for a rotary incremental encoder. The outer track provides $n = 2$ cycles of the alternating black and clear records. Two heads A and B displaced by 90° give, after squaring, two square waves in quadrature.

output data. The methods for accomplishing this conversion are similar to those described in the sections on analog quadrature signal interpolation. The code disk of such a device does not incorporate a series of parallel lines of constant pitch, but rather depends on special code tracks having analog profile signal outputs. These can be effected by changing the code tracks' cross-sections or by graduating their optical density around the revolution. In the latter case, a masking reticle need not be employed.

Incremental Encoders Quadrature Signals

Digital Quadrature Signals

Figure 6.71 illustrates the concept of an incremental rotary optical encoder. The shaft-mounted disk has a series of alternating dark and light sectors of equal length and in equal numbers. The dark and light code is detected by a stationary mask with two apertures, A and B, displaced one quarter of a cycle from each other. When a light sector covers a window, a 1 signal is produced, and a 0 results from a dark sector. At a transition, a rising or falling signal occurs. These signals require some pretreatment to square the signals and avoid problems associated with slow movement at the transition positions, resulting in slow rise time and fall time, in the presence of low noise. The resulting cleaned A and B signals are two square waves 90° out of phase and are called quadrature signals. Since the A and B signals have only four possible states, they clearly do not provide a means of distinguishing more than four different locations. As a result, absolute position discrimination is only possible within one quadrature cycle. Instead, the quadrature signals are used to increment or decrement a counter that gives the actual position. The counter is initialized (usually reset) on a z-phase signal produced on a separate track; the innermost track in Figure 6.71. It is also possible to have a number of z-phase signals over the encoder range with a distance coded variation between the z-phase markers. The code can be used to initialize the counter at nonzero positions.

Figure 6.72(a) shows a simple circuit from Conner [9] to provide one count per cycle of the quadrature signal. The direction information necessary to decide whether to increment or decrement the counters is also produced. Note that Schmitt triggers provide some amount of hysteresis and redress the falling and rising edges from the encoder. Further circuitry is required to increase the amount of hysteresis in very noisy environments. Additional treatment may be required before feeding these signals to counters. The reason is that if, following a count, there is a small movement in the opposite direction without a reverse count signal being issued followed by a forward motion, then the forward motion produces a second count at the same position. Kuzdrall [10] proposes a more reliable circuit in Figure 6.72(b). The

FIGURE 6.72 Circuit producing a direction and a count signal as described by Conner [9] in (a). Caution must be exercised when using this circuit for counting purposes since multiple counts are possible when the encoder oscillates around the A = 0, B = 0 and the A = 0, B = 1 states. Kuzdrall's circuit [10] in (b), counts up and down at the same states transition but depending on the direction of movement.

FIGURE 6.73 Divide-by-four circuit producing four counts per cycle of the quadrature signals. Based on Butler's design [14], except for the LS138 demultiplexer that replaces the suggested 4051 multiplexer because of the latter's unequal fall time and rise time. The clocked shift registers generate a 4-bit code to the demultiplexer for each clock cycle. The clock frequency should be 8 times the maximum frequency of the quadrature signals.

circuit drives a 74HC193 counter with a down clock and an up clock. Both flip-flops are normally in the high state. Whenever one of them switches to a low state, it is soon reset by the use of that output as a Set signal. That low output is only possible when phase B is low and there is a transition on A. Depending on the direction of that transition, one of the flip-flops produces the brief low state, causing an appropriate up or down count. The problem associated with small oscillations around a position is reduced since the up and down counts occur at the same encoder position. Venugopal [11] proposes a circuit, in Figure 6.72(c), that produces a similar effect. A count can only occur when B is low and there is a transition on A. Depending on the transition direction, one of two monostables triggers and effectively allows the count at the appropriate input of the 74LS193 counter.

In cases where a noisy environment is present, Holle [12] describes a digital filter to clean the A and B signals further, a filter that uses a small number of logic gates to form a 4-bit delay filter. Wigmore [13] proposes other circuits for count and direction detection.

Tables 6.23 and 6.24 list commercial chips and their suppliers' details. Some chips produce count and direction signals or up and down clocking signals. Others also include counters.

The above circuits do not fully exploit the information contained in the quadrature signals since only one of the four edges (or states) within one quadrature cycle is used to count. Figure 6.73 shows a slightly modified version of a divide-by-four counter circuit proposed by Butler [14]. Two 4-bit shift registers, three exclusive-OR gates, and an eight channel demultiplexer derive the up and down count signals. The clocked shift registers generate a 4-bit code to the demultiplexer for each clock cycle. To ensure that no encoder transitions are missed, the clock frequency should be at least $8NS$, where N is the number of cycles produced by the encoder for each shaft revolutions and S is the maximum speed in revolutions per second. The up and down signals can be fed to cascaded 74ALS193 counters. This circuit analyzes the current and previous states of the A and B channels to either count up, count down, or issue an error flag when an improper sequence occurs.

Kuzdrall [10] proposes to view a quadrature signal cycle as a Gray code so that the two least significant bits of the count are obtained by a Gray code to binary code conversion as in Figure 6.72(b). Phase A generates bit 1 of the natural binary position, and phase B is exclusive-ORed with phase A to produce the least significant bit. The counter provides the remaining bits of the natural binary position. Marty [15] proposes a state machine that stores both the actual A and B values and the previous values using D-type flip-flops (in a similar way to Butler) to form a hexadecimal number. In all, eight different hex-digits are generated, four for each direction of motion. A 4-line to 16-line decoder then feeds into two 4-input NAND gates to produce an up or down count signal. As for Butler, this last circuit is not dependent on propagation delays as with Kuzdrall's circuit.

Analog Quadrature Signals

Interpolation by resistor network

Some optical encoders deliver analog quadrature signals in the form of a $\sin(\theta)$ signal, A, and a $\cos(\theta)$ signal, B, where θ is the phase (electrical degree) within one cycle of the quadrature signal. θ does not equal shaft angle but is related to it: 360 electrical degrees of θ corresponds to $360/N$ mechanical degrees, where N is the number of analog quadrature signal cycles per shaft revolution. Indeed, θ still exists for linear encoders of this type. Although these signals can be squared and fed to a divide-by-four counter, they can also be processed directly to generate a finer resolution. The main techniques are (1) multiple phase shifted signals, (2) lookup table, and (3) arctangent processor.

The multiple phase-shifted signals method relies solely on electronics to increase the frequency of the final digital quadrature signals by an integer amount. Benzaid et al. [16] propose the circuit of Figure 6.74(a), which has been designed in this particular case for a fourfold frequency increase. This can then be followed by a digital divide-by-four circuit (not shown). The A and B signals are combined to produce an additional six phase-shifted signals, three of which are shifted by $\pi/8$, $\pi/4$, and $3\pi/8$, respectively, from the A signal, and three others that are shifted similarly from the B signal. The result is a total of 8 available sinusoidal signals, phase-shifted by $\alpha = i \pi/8$ with $i = 0, 1, \dots, 7$. This can be generalized, saying that for an m -fold increase in resolution, $2m$ signals that are phase-shifted by $\alpha i \pi/2m$ with $i = 0, 1, \dots, 2m - 1$ are required. The phase-shifted sinusoidal signals are then squared using TTL converters. Figure 6.74(b) shows the resulting square waves. The addition, modulo-2, of the signals for even values of i gives A' , and similarly for the signals with odd values of i gives B' . The modulo-2 sum is performed via exclusive-ORs.

The vector additions of the initial A and B signals result in phase-shifted signals. The weights of A and B are calculated from the trigonometric relations:

$$\sin(\theta + \alpha) = \cos(\alpha) \sin(\theta) + \sin(\alpha) \cos(\theta) \quad (6.96)$$

and

$$\cos(\theta + \alpha) = -\sin(\alpha) \sin(\theta) + \cos(\alpha) \cos(\theta) \quad (6.97)$$

where $\sin(\theta) = A$ and $\cos(\theta) = B$.

Thus,

$$\sin(\theta + \alpha) = \cos(\alpha) A + \sin(\alpha) B \quad (6.98)$$

and

$$\cos(\theta + \alpha) = -\sin(\alpha) A + \cos(\alpha) B \quad (6.99)$$

Note that the amplitudes of the phase-shifted signals are not critical, since it is their zero-crossing points that produce the square-wave transition. Also, in the circuit of Figure 6.74(a), the weights were slightly modified to simplify the implementation, which results in a small variation of the duty cycle of A' and B' .

The phase-shifted signals can alternatively be produced using voltage dividers and Schmitt triggers, where the divider resistors are in the ratio $\tan(\alpha)$ [17]. As m increases, the precision of the weights become more stringent and the speed of the electronics processing the high-frequency square signals might limit the upper value of m possible with this method.

Interpolation by Sampling and Numerical Processing

A number of methods digitize the analog quadrature signals in order to perform a digital interpolation within one cycle of the quadrature signals. These techniques permit an even higher interpolation. The signals are periodically sampled in sample-and-hold circuitry and digitized by an analog to digital converter (ADC). One technique uses an interpolation table, while the other performs arctangent calculations.

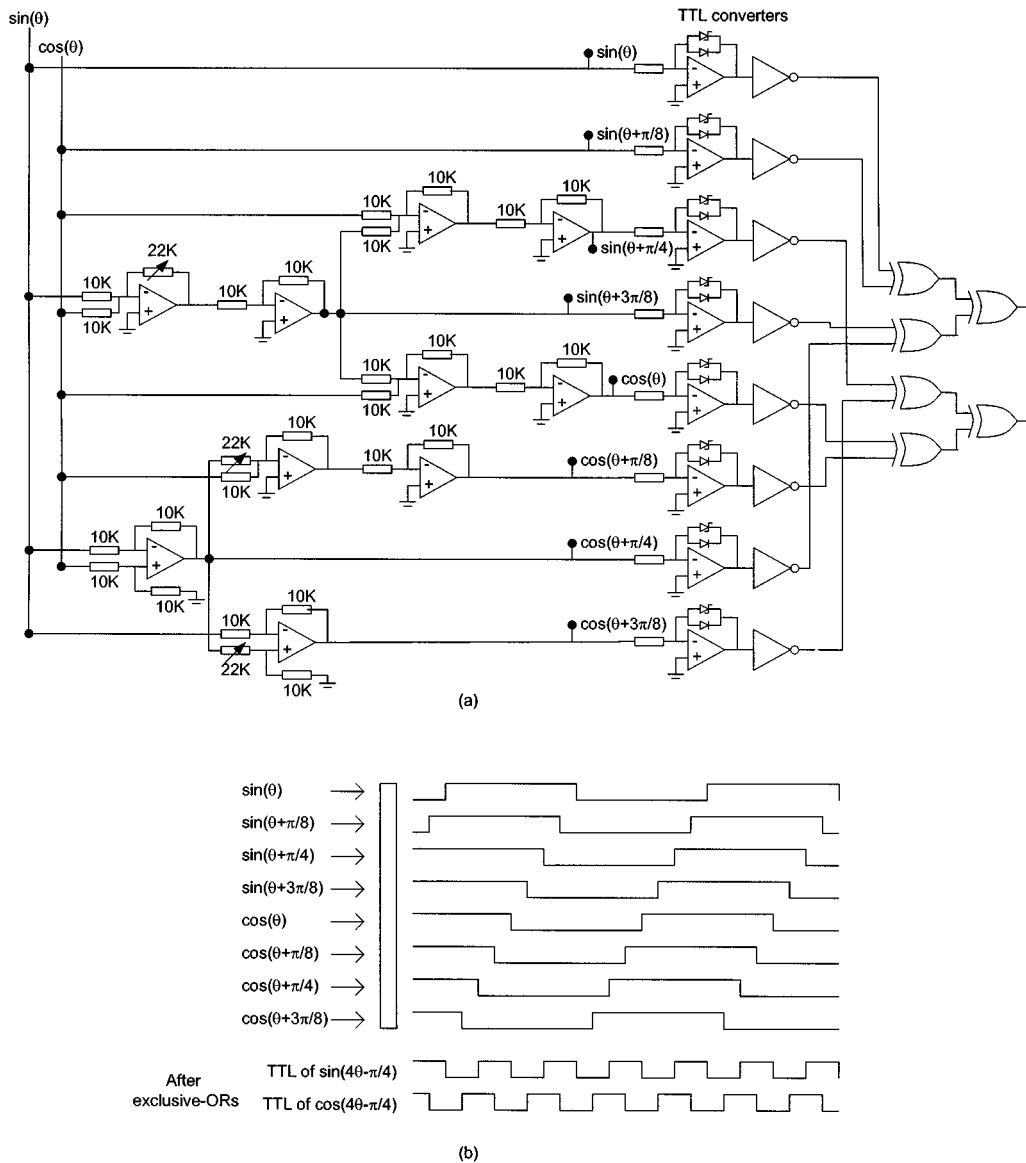

FIGURE 6.74 Interpolation circuit by Benzaid et al. [16]. The sine and cosine signals from the encoder are vector-combined in (a) to produce various phase-shifted signals. Following TTL conversion, they are exclusive-ORed. The squared phase-shifted signals and the final result are in (b).

Hagiwara [18] uses an m -bit ADC to digitize the analog A and B signals into the binary numbers D_a and D_b . Figure 6.75(a) shows how these binary numbers are used as the addresses of a grid, here built for $m = 3$ as a 2^m by 2^m grid. Hagiwara then associates a phase angle with the center of each cell of the matrix using simple arctangent calculations. The angle is calculated with respect to the center of the grid. This phase angle is then associated with one of $2^n - 1$ phase codes using:

$$\text{Phase code} = \text{integer part of } \left(2^n \theta / 2\pi \right) \tag{6.100}$$

as shown in Figure 6.75(b).

FIGURE 6.75 Hagiwara [18] proposes a two-dimensional look-up table that associates a quantized phase value to a set of digitized values of the quadrature signals. The phase code associated with a grid address may be adjusted to compensate for known errors in the quadrature signals.

The proposed circuit includes the means of performing the accumulation of interpolated values to deliver the encoder absolute position. A modification to this circuit is also proposed that can compensate the phase code for known inaccuracies in the encoder signals with respect to the actual encoder position.

For the highest possible level of interpolation, Mayer [19] describes an arctangent calculator method. It uses a microprocessor to perform high-level trigonometric calculations on the digitized analog signals. As this process is performed, the analog signals are continuously squared and fed to a divide-by-four counter. The two information sources are combined to produce the encoder's position with a very high level of resolution. Note, however, that although the resulting theoretical resolution is limited only by the ADC, in practice it is the quality of the analog signals in relation to the physical position being measured that will limit the precision obtained.

Encoding Principles

Optical encoders use one of three techniques to generate the electrical signals from the relative movement of the grating and the reading heads. They are (1) geometric masking, (2) Moiré effects, and (3) laser interference. Note that absolute encoders mainly use geometric masking. Geometric masking relies on geometric optics theory and considers light as traveling in a straight line. However, as the grating period reduces and the resolution of the encoder increases, Moiré fringe effects are observed and used to produce the signals. Although diffraction effects then become nonnegligible, their influence can be controlled by careful design. Finally, for very high resolution, diffraction effects are directly exploited to perform the measurements.

Geometric Masking

Geometric masking is applied to absolute and incremental encoders. The electromagnetic field associated with the propagation of visible light is characterized by very rapid oscillations (frequencies of the order of 10^{14} s^{-1}). It may therefore be expected that a good first-order approximation to the propagation laws of light is obtained by neglecting the wavelength of light. In this case, diffraction phenomena may be ignored and light may be thought to propagate in a straight line. Geometry can then be used to analyze

FIGURE 6.76 The reading head contains a light source that can be an incandescent bulb or a light emitting diode. The light may require a condenser in order to collimate it. This redirects the light rays from the source so that they travel perpendicular to the gratings. The stationary index grating structures the light beam into bands that then cross the moving grating. Depending on the relative position of the fixed and the moving gratings, more or less light reaches the photodetector. The detector produces a signal proportional to the total amount of light on its sensitive surface.

the behavior of light. The approximation is valid whenever light rays propagate through an encoder grating with fairly coarse pitch (say, more than $10\ \mu\text{m}$). Figure 6.76 shows a portion of an encoder scale being scanned by a reading head with multiple slits in order to send more light onto the photosensitive area. The light source is collimated (rays are made parallel to each other after having been emitted in multiple directions from a small source), passes through the stationary grating or index grating, and propagates through the moving grating. In the case of an incremental encoder, a second head would read from the same moving grating but be displaced by $n + 1/4$ pitch in order to produce a second signal with a phase of 90° . When the slits of the two gratings are aligned, a maximum amount of light reaches the detector. Similarly, a minimum amount of light is transmitted when the gratings are out of phase by 180° . Depending on the design of the grating, such as the duty cycle of the transmitting and opaque sectors, various cyclic signal patterns are obtained. Generally, it is noteworthy that optical encoders can also be used as a reflective as opposed to transmissive design. Also, in some absolute optical encoders, the encoding principle does not rely on a primary grating, per se, or the detection system does not necessarily incorporate any masking element.

Moiré Fringes

Moiré fringe methods are primarily associated with incremental encoders. Moiré fringes are observed when light passes through two similar periodic patterns brought close to each other and with their line pattern nearly parallel. Figure 6.77 shows linear and radial gratings producing Moiré fringes. Take a linear grating with sinusoidal amplitude transmittance as proposed by Gasvik [20]:

$$f(x, y) = a + a \cos(2\pi x/P) \quad (6.101)$$

where P is the grating period, a is the amplitude, and x is measured perpendicularly to the grating lines. It is also possible to represent a square wave type grating using a Fourier series in the case of a radial grating and a Fourier integral for a linear grating. When two linear gratings, a and b , are laid in contact, the resulting transmittance, f_c , is the product of their individual transmittances f_a and f_b :

$$f_c = f_a \times f_b \quad (6.102)$$

FIGURE 6.77 Moiré fringes produced when two gratings of equal pitch are overimposed. In (a), two radial gratings with 180 cycles have their centers displaced horizontally by approximately half of the grating pitch (as measured on the perimeter). This could be due to encoder assembly errors. Ditchburn [21] explains that the fringes are always circular and pass by the two centers. In (b), the same displacement was followed by a rotation of half a pitch as a result of the normal movement of the encoder disk. This causes a phase change of 180° of the fringe pattern at any fixed observation point, as represented by the rectangular observation region. The width of the fringes depends on the offset displacement between the two grating centers. If they coincide, the whole pattern changes from a dark to a relatively bright fringe. In (c), two linear gratings are rotated by one tenth (in radian) of their grating pitch. This could be due to encoder assembly or mounting errors. As a result, Moiré fringes occur at 90° to the grating and with a period 10 times larger. The normal displacement of one grating by half of the grating pitch causes a phase change of 180° of the Moiré fringe pattern at any fixed observation point, as represented by the rectangular observation region.

In the case when a misalignment γ exists between the two gratings, the separation of the Moiré fringe is d with:

$$d = P / \left[2 \sin(\gamma/2) \right] \quad (6.103)$$

and for small γ ,

$$d = P / \gamma \quad (6.104)$$

It follows that when the two gratings are moved relative to each other by a distance x' in the direction perpendicular to their lines, then the phase $\varphi(x')$ of the Moiré fringes at a stationary location changes by:

$$\varphi(x') = 2\pi x' / P \quad (6.105)$$

In effect, every time x' equals P , the entire Moiré fringe pattern undergoes one complete cycle of fluctuation. If the two gratings are adjusted to near parallelism, then the fringes are “fluffed out” (see Burch [22]) to an infinite width. Under such conditions, there is no fringe motion to be observed and the entire region simply goes from brightness to darkness. These effects are mathematically predicted using a convolution integral.

$$f_c(x') = \int_{x_1}^{x_2} f_a(x) f_b(x - x') / dx \quad (6.106)$$

with x_1 to x_2 representing the region covered by the photodetector. If $g_a(k)$ and $g_b(k)$ are the exponential Fourier transforms of f_a and f_b , then the photodetector response f_c will have the Fourier transform $g_c(k)$,

$$g_c(k) = g_a(k) g_b(-k) \quad (6.107)$$

Moiré effects can be obtained by transmission or by reflection at the grating.

It must be kept in mind, however, that as the grating pitch reduces, diffraction effects become significant; careful design and adjustment of the gap between the stationary and moving grating and also lighting and detection arrangements become critical. Since a large number of lines of the gratings are used to generate the photodetector response, small local imperfections of the grating pitch are averaged out, resulting in an improved measurement accuracy.

Diffraction-Based Encoders

Diffraction-based encoders are used for the highest levels of precision. They successfully exploit diffraction effects and are referred to as physical optics encoders as opposed to geometrical optics encoders. [Figure 6.78](#) shows diffraction effects observed when coherent light encounters a pattern of slits [20]. The slit is a few wavelengths wide, so strong diffraction effects are observed. Each slit may be thought of as acting as a coherent light source producing circular wavefronts. Along certain directions, portions of these wavefronts are in phase with each other. These directions are given by:

$$\sin \theta_m = m\lambda / P \quad (6.108)$$

FIGURE 6.78 The grating diffracts the coherent planar wavefront coming from the left into a series of circular wavefronts. The coherent circular wavefronts are in phase along certain directions resulting in diffracted planar wavefronts. These planar wavefronts correspond to the common tangents of the circles. For example, the third innermost circle of the uppermost slit is in phase with the fourth innermost circle of the middle slit and also with the fifth innermost circle of the lowest slit. This diffracted wavefront corresponds to the first order diffraction ($m = 1$) and makes an angle θ_1 with the initial planar wavefront direction. A similar order wavefront ($m = -1$) has a direction $-\theta_1$. These two wavefronts are initially in phase. A displacement of the grating downward by x causes the $m = 1$ wavefront to move by a distance $x\lambda/P$ and the $m = -1$ wavefront by $-x\lambda/P$, thus causing a phase shift between the two wavefronts of $2x\lambda/P$. This relative phase shift produces a movement of interference fringes at the photodetector.

where m is a positive or negative integer and is the order of diffraction, and P is the diffraction grating period. Suppose now that the slits are moving by a distance x as shown in Figure 6.78. Then the phase of the wavefront at a stationary location will increase for m positive and decrease for m negative by $2\pi mx/P$. When the slit pattern has moved by one pattern cycle, then the two wavefronts will have developed a relative phase change of $2m$ cycles. The two phase-shifted wavefronts may be recombined to produce interference fringes.

Rotary Encoders

The Canon laser rotary encoder uses an optical configuration that generates four cycles of interference fringes per cycle of the diffraction grating. This is achieved by splitting the original wavefront in two and interrogating the grating at two diametrically opposed locations. Reflecting both diffracted beams back through the grating results in a further doubling of the resolution. The two beams are finally recombined for interference fringe counting. Furthermore, as explained by Nishimura and Ishizuka [23], using diametrically opposed portions of the disk attenuates the effect of eccentricity. An encoder with an external diameter of 36 mm produces 81,000 analog quadrature cycles per revolution. The grating has a pitch of approximately $5 \mu\text{m}$ and the laser light has a wavelength of 780 nm.

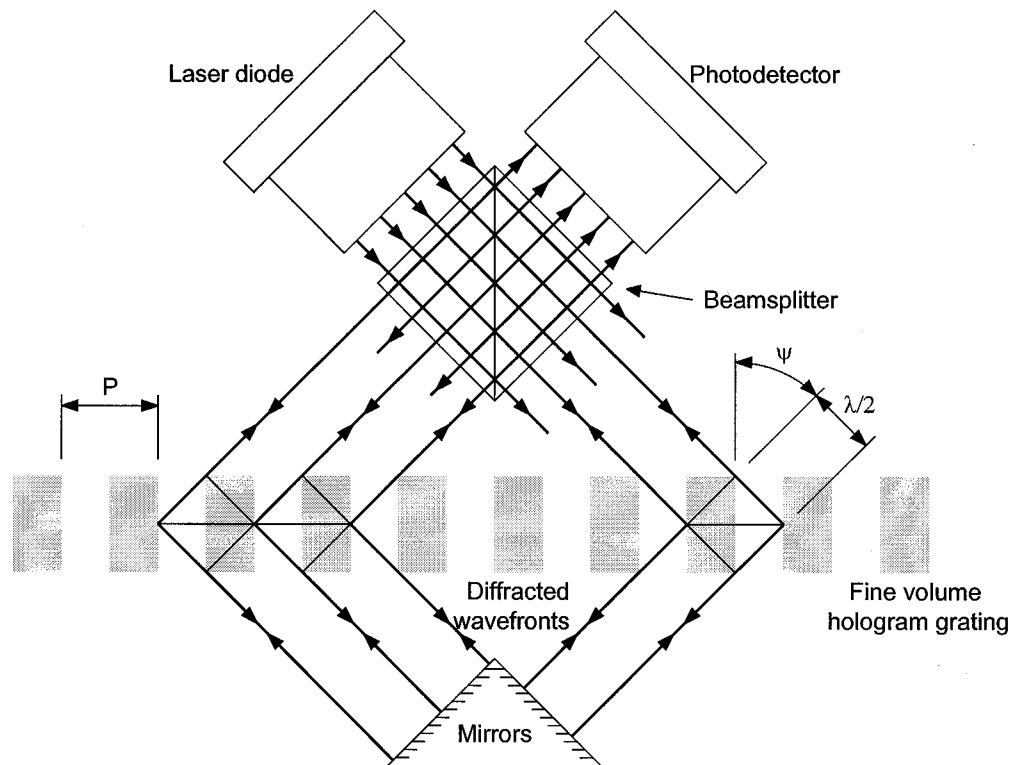

FIGURE 6.79 The coherent planar wavefront of the laser diode is split into two at the beam splitter. Both beams can be regarded as being partially reflected at the grating by minute mirrors separated by a pitch, P . Maximum reflection is achieved when $2P \sin \psi = \lambda$. Each reflected portion of the incident beam is phase shifted by one λ with respect to that reflected by an adjacent mirror so that the reflected wavefront remains coherent. The reflected wavefronts are truly reflected at the orthogonal mirrors for a second pass through the grating, after which they are recombined by the splitter to interfere at the photodetector. A displacement of the grating by x along its axis causes one beam path to be shortened by $2x\lambda/P$, while the other is lengthened by the same amount. A grating motion by P causes four fringe cycles.

Linear Encoders

Sony markets a laser linear encoder with a volume hologram grating of $0.55 \mu\text{m}$ pitch [24]. Figure 6.79 gives some insight into the principle of operation of this type of encoder. In theory, for maximum intensity of the reflected light beam through the hologram grating, the path length difference from successive plane mirrors must be equal to λ [20]. The Sony Laserscale encoder uses a semiconductor laser as the coherent light source. The beam splitter produces two beams to interrogate the grating at two separate locations. The beams are then diffracted by the hologram grating, followed by a reflection at the mirrors and pass a second time through the grating. They are finally recombined at the photodetector to produce interference fringes. Because the two beams are diffracted by the grating in opposite directions, and because they pass twice through the grating, four signal cycles are obtained when the grating moves by one pitch.

The Heidenhain company produces both linear and rotary encoders of very high resolution, also using the principles of diffraction. Their approach, unlike those previously mentioned, uses an index grating and a reflecting scale grating [17, 25].

The Renishaw company uses a fine reflective grating of $20 \mu\text{m}$ pitch that diffuses the light from an infrared light-emitting diode. In order to avoid the problems caused by diffraction effects, the index

grating of a conventional Moiré approach would require a very small gap between the index and main gratings. Instead, the index grating is located at a distance of 2.5 mm. The index grating is then able to diffract the diffused light from the main grating and to image it 2.5 mm further. There, a fringe pattern of the Moiré type is produced and photoelectrically analyzed [26].

Components and Technology

The choice of an encoder demands careful consideration of a number of factors, such as: (1) the required resolution, repeatability, and accuracy (linearity); (2) the maximum and minimum operating speeds; (3) the environmental conditions: temperature range, relative humidity (condensing or not condensing), contaminants such as dust, water, oil, etc.; (4) minimum friction torque (or force) acceptable; (5) maximum inertia acceptable; (6) available space; (7) position to be known immediately after a power loss; (8) range in degrees (or mm); (9) mounting and shaft loading; and (10) price.

Rotary encoders also sometimes employ reflective tapes attached to, or markings directly etched into, the surface of a drum or spindle to be read from the side. In special cases, tapes or engravings of this type can be made to conform to the surface of an elliptical cross-section cam or other irregular contour. Cylindrical primary gratings employing transmissive readout have also been produced.

The main gratings (scale) come in a wide variety of materials, both for the substrate and for the marking. Flexible scales based on a metal tape substrate are also available from Renishaw, allowing very long (tens of meters) continuous reading of linear motion. [Tables 6.19 through 6.21](#) list a number of encoders currently available on the market. The list is not exhaustive in terms of suppliers and does not cover all the models of the suppliers listed. [Table 6.22](#) gives the address and telephone numbers of the suppliers. [Tables 6.23 and 6.24](#) list some suppliers of quadrature decoding circuits.

6.9 Magnetic Displacement Sensors

David S. Nyce

Several types of linear and angular displacement measuring devices rely on electromagnetic fields, and the magnetic properties of materials, in the operation of their basic sensing elements. Some may not commonly be referred to as magnetic sensors, but are instead named according to their specific sensing technique. Magnetic sensors presented here use a permanent magnet, or an ac or dc powered electromagnet. Together with various materials used to sense the magnetic field, the combination is arranged to obtain a response indicating angular or linear displacement. The sensor is either caused to operate by a magnetic field, or the properties of the sensor are derived from the use of a magnetic field. Types of magnetic sensors presented in this section include magnetostrictive, magnetoresistive, Hall effect, and magnetic encoders. Some versions of synchro/resolvers and related sensors meet those requirements, but are included in Section 6.10 and thus will not be included in this section. Inductive proximity sensors measure displacement over a very limited range, and are covered in Section 6.2. LVDTs meet these requirements, but are also in Section 6.2.

An important aspect of magnetic sensors is that they utilize a noncontact sensing element. There is no mechanical connection or linkage between the stationary members and the movable members of the sensor. In some devices that sense a position magnet or core, the sensor can even be designed to allow removal of the magnet or core from the sensitive element, when readings are not required. Noncontact implies that the lifetime of the sensing element is not limited to a finite number of cycles by friction-induced wear. This is important in some industrial machinery. Sensors presented here utilize noncontact sensing techniques.

Displacement refers to a change in position, rather than an absolute position. In common industrial practice, however, displacement sensors are typically labeled as either incremental or absolute. An incremental sensor indicates the amount of change between the present location and a previous location. If the information that describes the current location is lost, due to power loss or other disturbance, the system must be reset. During the reset, the sensor must be in a reference position. Magnetic encoders can be designed as either incremental or absolute reading. Optical encoders, inductosyns, and synchro/resolvers are types of displacement sensors that can be designed as either incremental or absolute reading, but are covered in other chapters.

Most displacement position sensors described in this section are absolute reading. They supply a reading of distance or angle from a fixed datum, rather than from a previous position. Consecutive readings can be subtracted to give an incremental indication. An absolute sensor indicates the current position without the need for knowledge of the previous position. It never needs to be reset to a reference location in order to derive the measured location. Absolute reading displacement sensors are also commonly called *position sensors*.

Magnetic sensor types will be described here based on the technology employed, rather than the application. Relative usefulness for making linear or angular measurements will be indicated for each type of sensor.

Noncontact magnetic sensor technology for displacement measurement includes magnetostrictive, magnetoresistive, Hall effect, and magnetic encoders.

Magnetic Field Terminology: Defining Terms

Magnetic field intensity (H), or magnetizing force: The force that drives the generation of magnetic flux in a material. H is measured in $A\ m^{-1}$.

Magnetic flux density (B): The amount of magnetic flux resulting from the applied magnetizing force. B is measured in $N/(A\cdot m)$.

Magnetic permeability (μ): The ability of a material to support magnetic lines of flux. The μ of a material is the product of the relative permeability of that material and the permeability of free space. The relative permeability of most nonferrous materials is near unity. In free space, magnetic flux density is related to magnetic field intensity by the formula:

$$B = \mu_0 H$$

where μ_0 is the permeability of free space, having the value $4\pi \times 10^{-7}\ H\ m^{-1}$. In other materials, the magnetic flux density at a point is related to the magnetic intensity at the same point by:

$$B = \mu H$$

where

$$\mu = \mu_0 \mu_r$$

and μ_r is the relative permeability [1].

Hysteresis: A phenomenon in which the state of a system does not reversibly follow changes in an external parameter [2]. In a displacement sensor, it is the difference in output readings obtained at a given point when approaching that point from upscale and downscale readings. [Figure 6.80](#) is a typical output vs. input graph.

Magnetic hysteresis: Depicted in the hysteresis loop, [Figure 6.81](#). When a ferromagnetic material is placed in an alternating magnetic field, the flux density (B) lags behind the magnetizing force (H) that causes it. The area under the hysteresis loop is the hysteresis loss per cycle, and is high for permanent magnets and low for high permeability, low-loss magnetic materials [3].

Magnetic saturation: The upper limit to the ability of ferromagnetic materials to carry flux.

Magnetization curve: Shows the amount of magnetizing force needed for a ferromagnetic material to become saturated. It is a graph with B as the ordinate and H as the abscissa (also known as the B - H curve). A magnetization curve for a specific material would look the same as [Figure 6.81](#), with the addition of calibration marks and the curve adjusted to describe the characteristic of that material.

Magnetostrictive Sensors

A magnetostrictive displacement sensor uses a ferromagnetic element to detect the location of a position magnet that is displaced along its length. The position magnet is attached to a member whose position

FIGURE 6.80 Hysteresis: output vs. input.

FIGURE 6.81 Magnetic hysteresis.

FIGURE 6.82 Magnetostrictive sensor with position magnet.

is to be sensed, and the sensor body remains stationary, see Figure 6.82. The position magnet moves along the measuring area without contacting the sensing element.

Ferromagnetic materials such as iron and nickel display the property called *magnetostriction*. Application of a magnetic field to these materials causes a strain in the crystal structure, resulting in a change in the size and shape of the material. A material exhibiting positive magnetostriction will expand when magnetized. Conversely, with negative magnetostriction, the material contracts when magnetized [4].

The ferromagnetic materials used in magnetostrictive displacement sensors are transition metals, such as iron, nickel, and cobalt. In these metals, the $3d$ electron shell is not completely filled, which allows the formation of a magnetic moment (i.e., the shells closer to the nucleus are complete, and they do not contribute to the magnetic moment). As electron spins are rotated by a magnetic field, coupling between the electron spin and the electron orbit causes electron energies to change. The crystal strains so that electrons at the surface can relax to states of lower energy [5].

This physical response of a ferromagnetic material is due to the presence of magnetic moments, and can be understood by considering the material as a collection of tiny permanent magnets, called *domains*. Each domain consists of many atoms. When a material is not magnetized, the domains are randomly arranged. However, when the material is magnetized, the domains are oriented with their axes approximately parallel to each other. Interaction of an external magnetic field with the domains causes the magnetostrictive effect. See Figure 6.83. This effect can be optimized by controlling the ordering of domains through alloy selection, thermal annealing, cold working, and magnetic field strength.

While application of a magnetic field causes the physical strain, as described above, the reverse is also true: exerting stress causes the magnetic properties (permeability, susceptibility) to change. This is called the *Villari effect*.

In magnetostrictive sensors, uniform distortions of length, as shown in Figure 6.83, offer limited usefulness. Usually, the magnetization is rotated with a small field to induce a local distortion, using the

FIGURE 6.83 Magnetic domains: alignment with magnetic field, “ H ”, causes dimensional changes.

FIGURE 6.84 Operation of magnetostrictive position sensor.

Wiedemann effect. This is a mechanical torsion that occurs at a point along a magnetostrictive wire when an electric current is passed through the wire while it is subjected to an axial magnetic field. The torsion occurs at the location of the axial magnetic field, which is usually provided by a small permanent magnet called the position magnet.

In a displacement sensor, a ferromagnetic wire or tube called the waveguide is used as the sensing element, see Figure 6.84. The sensor measures the distance between the position magnet and the pickup. To start a measurement, a current pulse I (called the interrogation pulse), is applied to the waveguide. This causes a magnetic field to instantly surround it along its full length.

In a magnetostrictive position sensor, the current is a pulse of approximately 1 to 2 μs duration. A torsional mechanical wave is launched at the location of the position magnet due to the Wiedemann effect. Portions of this wave travel both toward and away from the pickup. The wave traveling along the waveguide toward the pickup is detected when it arrives at the pickup. The time measurement between application of the current pulse (launching of the torsion wave at the position magnet) until its detection by the pickup represents the location of the position magnet. The speed of the wave is typically about 3000 m s^{-1} . The portion of the wave traveling away from the pickup could act as an interfering signal after it is reflected from the waveguide tip. So instead, it is damped by a damping element when it reaches the end of the waveguide opposite the pickup. Damping is usually accomplished by attaching one of various configurations of elastomeric materials to the end of the waveguide. The end of the waveguide within the damping element is unusable for position determination, and therefore called the “dead zone.”

The time measurement can be buffered and used directly as the sensor output, or it can be conditioned inside the sensor to provide various output types, including analog voltage or current, pulse width modulation, CANbus, SSI, HART, Profibus, etc. Magnetostrictive position sensors can be made as short as 1 cm long or up to more than 30 m long. Resolution of those produced by MTS Systems Corp. is as fine as $1 \mu\text{m}$. Temperature coefficients of 2 to 5 $\text{ppm } ^\circ\text{C}^{-1}$ can be achieved. The sensors are inherently stable, since the measurement relies on the physical properties of the waveguide material. Longer sensors become very cost effective because the same electronics package can drive sensors of varying length; only the waveguide and its packaging are increased in length to make the sensor longer.

The magnetostrictive wire can be straight for a linear sensor, or shaped to provide curved or rotary measurements. Curved sensors are often used to measure angular or nonlinear motion in industrial applications, although rotary magnetostrictive sensors are not yet very popular.

FIGURE 6.85 Magnetoresistance.

Magnetoresistive Sensors

In most magnetic materials, electrical resistance decreases when a magnetic field is applied and the magnetization is *perpendicular* to the current flow (a current will be flowing any time electrical resistance is measured) (see Figure 6.85). The resistance decreases as the **magnetic flux density** increases, until the material reaches magnetic saturation. The rate of resistance decrease is less as the material nears saturation. The amount of resistance change is on the order of about 1% at room temperature (0.3% in iron, 2% in nickel). When the magnetic field is *parallel* to the current, the resistance increases with increasing magnetic field strength. Sensitivity is greatest when the magnetic field is perpendicular to the current flow. These are properties of the phenomenon called *magnetoresistance* (MR). The MR effect is due to the combination of two component parts. These are: a reduction in forward carrier velocity as a result of the carriers being forced to move sideways as well as forward, and a reduction in the effective cross-sectional area of the conductor as a result of the carriers being crowded to one side [6].

When a position magnet is brought close to a single MR sensing element, the resistance change is maximum as the magnet passes over the approximate center of the element and then reduces until the magnet is past the element. The resistance changes according to:

$$\text{Resistivity} = \text{Voltage} / (\text{carrier density} \times \text{carrier velocity}) \quad (6.111)$$

By using multiple MR elements arranged along a line, a longer displacement measuring device can be fashioned. The signals from the string of sensors are decoded to find which elements are being affected by the magnet. Then the individual readings are used to determine the magnet position more precisely. Relatively high-performance sensors can be manufactured. Temperature sensitivity of the MR elements needs to be compensated, and longer sensors contain many individual sensing elements. Because of this, longer sensors become more difficult to manufacture, and are expensive.

Anisotropic MR materials are capable of resistance changes in the range of 1% or 2%. The MR of a conductor body can be increased by making it a composite of two or more layers of materials having different levels of magnetoresistance. Multilayered structures of exotic materials (sometimes more than 10 layers) have enabled development of materials that exhibit much greater magnetoresistive effect, and saturate at larger applied fields. This has been named Giant MagnetoResistance (GMR). Some commercial sensors based on GMR are currently available. The GMR elements can be arranged in a four-element bridge connection for greater sensitivity. In this arrangement, two of the elements are shielded from the applied magnetic field. The other two elements are sensitive to the applied field. Sensitivity can also be increased by incorporating flux concentrators on the sensitive elements. In a bridge connection, the output voltage can vary by more than 5% of the supply voltage [7]. Rotary sensors can be constructed by attaching a pole piece to a rotating shaft. One or more permanent magnets and the pole piece are arranged to cause the magnetic field around the MR element to change with angular displacement.

FIGURE 6.86 Hall effect.

Further research is being conducted on MR materials to improve the sensitivity by lowering the strength of magnetic field needed, and increasing the amount of resistance change. The next higher level of MR performance is being called Colossal MagnetoResistance (CMR). CMR is not yet practical for industrial sensors because of severe limitations on the operating temperature range.

Although MR, GMR, and CMR are limited for use in displacement sensors at this time by cost, temperature, and fabrication constraints, much research is in progress. Maybe Humongous Magneto-Resistance (HMR) is next?

Hall Effect Sensors

The Hall effect is a property exhibited in a conductor affected by a magnetic field. A voltage potential V_H , called the Hall voltage, appears across the conductor when a magnetic field is applied at right angles to the current flow. Its direction is perpendicular to both the magnetic field and current. The magnitude of the Hall voltage is proportional to both the magnetic flux density and the current. The magnetic field causes a gradient of carrier concentration across the conductor. The larger number of carriers on one side of the conductor, compared to the other side, causes the voltage potential V_H . A pictorial representation is shown in Figure 6.86. The amplitude of the voltage varies with the current and magnetic field according to: [8]

$$V_H = K_H \beta I / z \quad (6.112)$$

- where V_H = Hall voltage
 K_H = Hall constant
 β = magnetic flux density
 I = current flowing through the conductor
 z = thickness of the conductor

Sensors utilizing the Hall effect typically are constructed of semiconductor material, giving the advantage of allowing conditioning electronics to be deposited right on the same material. Either *p*- or *n*-type semiconductor material can be used, with the associated polarity of current flow. The greatest output is achieved with a large Hall constant, which requires high carrier mobility. Low resistivity will limit thermal noise voltage, for a more useful signal-to-noise ratio (SNR). These conditions are optimized using an *n*-type semiconductor [6].

A displacement sensor can be made with a Hall sensing element and a movable magnet, with an output proportional to the distance between the two. Two magnets can be arranged with one Hall sensor as in Figure 6.87 to yield a near-zero field intensity when the sensor is equidistant between the magnets. These

FIGURE 6.87 Two magnet hall sensor.

single Hall effect device configurations have a very limited linear range. Longer range displacement sensors can be built using multiple Hall sensors spaced along a carrier substrate. A magnet is moved along in close proximity to the carrier. As the magnet approaches and then moves away from each Hall element, the respective sensors will have increasing or decreasing outputs. The output from the battery of sensors is derived by reading the individual outputs of the sensors closest to the magnet, and also decoding those particular sensors being read. This method can produce relatively high-performance displacement sensors of up to several meters long. Longer sensors become increasingly more difficult to produce and are expensive because of the large number of sensors being multiplexed. Rotary, as well as linear displacement, sensors can be produced by mechanical arrangement of the sensing elements to cause magnetic field variation with the desired angular or linear input.

Magnetic Encoders

Magnetic encoders use a strip or disk of magnetic media onto which digital information is stored. This information is recorded at the location it describes, and is in the form of a collection of magnetized and nonmagnetized areas. A magnetic encoder includes this sensing element, as well as one or more read heads, electronics, and a mechanical enclosure with input shaft and bushings. The input shaft moves in and out for a linear sensor. It has wipers to prevent ingestion of foreign material, and bushings designed to accept side-loading. An angular sensor has a shaft that rotates, and includes bushings to withstand thrust and side-loading. The encoded media is implemented as either a strip in a linear sensor, or as a disk in an angular sensor.

As a read head passes above the encoded area, it picks up the magnetic variations and reads the position information. The information, digital ones and zeroes, will usually be encoded in several parallel tracks to represent the binary digits of the position information. A standard binary code presents a problem for encoders in that some numbers require the changing of several of the bits at one time to indicate a single increment of the number represented. If all the changing bits are not perfectly aligned with each other, instantaneous erroneous readings will result. To avoid this problem, a special adaptation of the binary code called “Gray code” is used. See [Table 6.25](#). A single increment of the number represented causes a change of only 1 bit in the Gray code.

The read head incorporates a ferromagnetic core wound with input and output windings. A read pulse is applied to the input winding, and information is read on the output winding. If the core is above a magnetized area of the magnetic media, the core becomes saturated, no output pulse is generated, and a logic 0 results [9]. If the core is above a nonmagnetized area when the read pulse is applied, an output pulse occurs and produces a logic 1. Another arrangement that is practical for angular, but not linear encoders, uses a ring-shaped multipole permanent magnet. The magnet is rotated past a pair of sensors

TABLE 6.25 Gray Code

10	1010	1111	0001	0000

**FIGURE 6.88** Quadrature output.

to yield an incremental reading with sine and cosine outputs (called “quadrature” output. See [Figure 6.88](#)). The waveforms can be square, sinusoidal, or triangular. A and B outputs are used to indicate the displacement and the direction of the displacement. The number of transitions or “counts” is proportional to the displacement magnitude. The direction of displacement (i.e., + or –) can be found by comparing the two phases. For example, in [Figure 6.88](#), at the time the A phase changes from a logic 0 to a 1, the status of the B phase will indicate the direction of travel. A logic 0 on the B phase could equal the positive direction; a logic 1 could equal the negative direction.

Magnetic encoders can be incremental or absolute. In an incremental configuration, equally spaced pulses encoded on the magnetic media are read from one or more tracks. The pulses are collected by an up/down counter, and the counter output represents the position. Quadrature outputs can be coded to tell the direction of displacement, as described above. The zero position is set by resetting the counter.

Absolute magnetic encoders have the digital code representing the position encoded directly at that position. No counter is needed. The Gray code can be interpreted to yield the position in engineering units. Nonlinear coding, such as sine or cosine, is sometimes used. [Table 6.26](#) provides a list of sensors and manufacturers.

6.10 Synchro/Resolver Displacement Sensors

Robert M. Hyatt, Jr. and David Dayton

Most electromagnetic position transducers are based on transformer technology. Transformers work by exciting the primary winding with a continuously changing voltage and inducing a voltage in the secondary winding by subjecting it to the changing magnetic field set up by the primary. They are ac-only devices, which make all electromagnetically coupled position sensors ac transformer coupled. They are inductive by nature, consisting of wound coils. By varying the amount of coupling from the primary (excited) winding of a transformer to the secondary (coupled) winding with respect to either linear or rotary displacement, an analog signal can be generated that represents the displacement. This coupling variation is accomplished by moving either one of the windings or a core element that provides a flux path between the two windings.

FIGURE 6.89 The induction potentiometer has windings on the rotor and the stator.

One of the simplest forms of electromagnetic position transducers is the LVDT, which is described in Section 6.2 on inductive sensors. If the displacement of the core in an LVDT-type unit is changed from linear to rotary, the device becomes an RVDT (rotary variable differential transformer).

Induction Potentiometers

The component designer can “boost” the output, increase accuracy, and achieve a slightly greater angular range if windings are placed on the rotor as shown in Figure 6.89. The disadvantages to this method are (1) additional windings, (2) more physical space required, (3) greater variation over temperature, and (4) greater phase shift due to the additional windings.

The advantage of the induction pot design is greater sensitivity (more volts per degree), resulting in better signal to noise and higher accuracy in most cases.

Resolvers

If the two-slot lamination in the stator stack shown in Figure 6.89 is replaced by a multislot lamination (see Figure 6.90), and two sets of windings are designed in concentric coil sets and distributed in each quadrant of the laminated stack; a close approximation to a sine wave can be generated on one of the secondary windings and a close approximation to a cosine wave can be generated on the other set of windings. Rotary transformers of this design are called *resolvers*. Using a multislot rotor lamination and distributing the windings in the rotor, the sine-cosine waveforms can be improved even further.

A resolver effectively amplitude modulates the ac excitation signal placed on the rotor windings in proportion to the sine and the cosine of the angle of mechanical rotation. This sine-cosine electrical output information measured across the stator windings may be used for position and velocity data. In this manner, the resolver is an analog trigonometric function generator. Most resolvers have two primary windings that are located at right angles to each other in the stator, and two secondary windings also at right angles to each other, located on the rotor (see Figure 6.91).

FIGURE 6.90 The resolver stator has distributed coil windings on a 16-slot lamination to generate a sine wave.

FIGURE 6.91 A brushless resolver modulates the ac excitation on the rotor by the rotation angle.

If the rotor winding (R1-R3) is excited with the rated input voltage (see [Figure 6.92](#)), the amplitude of the output winding of the stator (S2-S4) will be proportional to the sine of the rotor angle θ , and the amplitude of the output of the second stator winding (S1-S3) will be proportional to cosine θ . (See [Figure 6.93](#).) This is commonly called the “control transmitter” mode and is used with most “state-of-the-art” resolver to digital converters.

In the control transmitter mode, electrical zero may be defined as the position of the rotor with respect to the stator at which there is minimum voltage across S2-S4 when the rotor winding R1-R3 is excited

FIGURE 6.92 The resolver rotor winding is excited with the rated input voltage.

with rated voltage. Nulls will occur across S2-S4 at the 0° and 180° positions, and will occur across S1-S3 at the 90° and 270° positions.

If the stator winding S1-S3 is excited with the rated input voltage and stator winding S2-S4 is excited with the rated input voltage electrically shifted by exactly 90° , then the output sensed on the rotor winding R1-R3 does not vary with rotor rotation in amplitude or frequency from the input reference signal. It is the sum of both inputs. It does, however, vary in time phase from the rated input by the angle of the shaft from a referenced “zero” point (see Figure 6.94). This is a “phase analog” output and the device is termed a “control transformer.” By measuring the time difference between the zero crossing of the reference voltage waveform and the output voltage waveform, the phase angle (which is the physical angular displacement of the output shaft) can be calculated.

Because the resolver is an analog device and the outputs are continuous through 360° , the theoretical resolution of a resolver is infinite. There are, however, ambiguities in output voltages caused by inherent variations in the transformation of the voltage from primary to secondary through 360° of rotation. These ambiguities result in inaccuracy when determining the true angular position. The types of error signals that are found in resolvers are shown in Figure 6.95.

As a rule, the larger the diameter of the stator laminations, the better the accuracy and the higher the absolute resolution of the device. This is a function of the number of magnetic poles that can be fit into the device, which is a direct function of the number of slots in the stator and rotor laminations. With multispeed units (see the section on multispeeds below), the resolution increases as a multiple of the speeds. For most angular excursions, the multispeed resolver can exceed the positioning accuracy capability of any other component in its size, weight, and price range.

Operating Parameters and Specifications for Resolvers

There are seven functional parameters that define the operation of a resolver in the analog mode. These are (1) accuracy, (2) operating voltage amplitude, (3) operating frequency, (4) phase shift of the output voltage from the referenced input voltage, (5) maximum allowable current draw, (6) the transformation ratio of output voltage over input voltage, and (7) the null voltage. Although impedance controls the functional parameters, it is transparent to the user. The lamination and coil design are usually developed to minimize null voltage and input current, and the impedance is a direct fallout of the inherent design of the resolver. The following procedure can be used to measure the seven values for most resolvers.

Equipment Needed for Testing Resolvers

- A mechanical index stand that can position the shaft of the resolver to an angular accuracy that is an order of magnitude greater than the specified accuracy of the resolver.
- An ac signal generator capable of up to 24 Vrms at 10 kHz.
- A phase angle voltmeter (PAV) capable of measuring “in phase” and “quadrature” voltage components for determining the transformation ratio and the null voltage as well as the phase angle between the output voltage and the reference input voltage.
- A $1\ \Omega$ resistor used to measure input current with the PAV.

FIGURE 6.93 The single-speed resolver stator output is the sine or cosine of the angle.

FIGURE 6.94 Resolver stator windings excited at 0° and 90° yield a phase shift with rotor rotation. Phase analog output at 225° vs. input voltage.

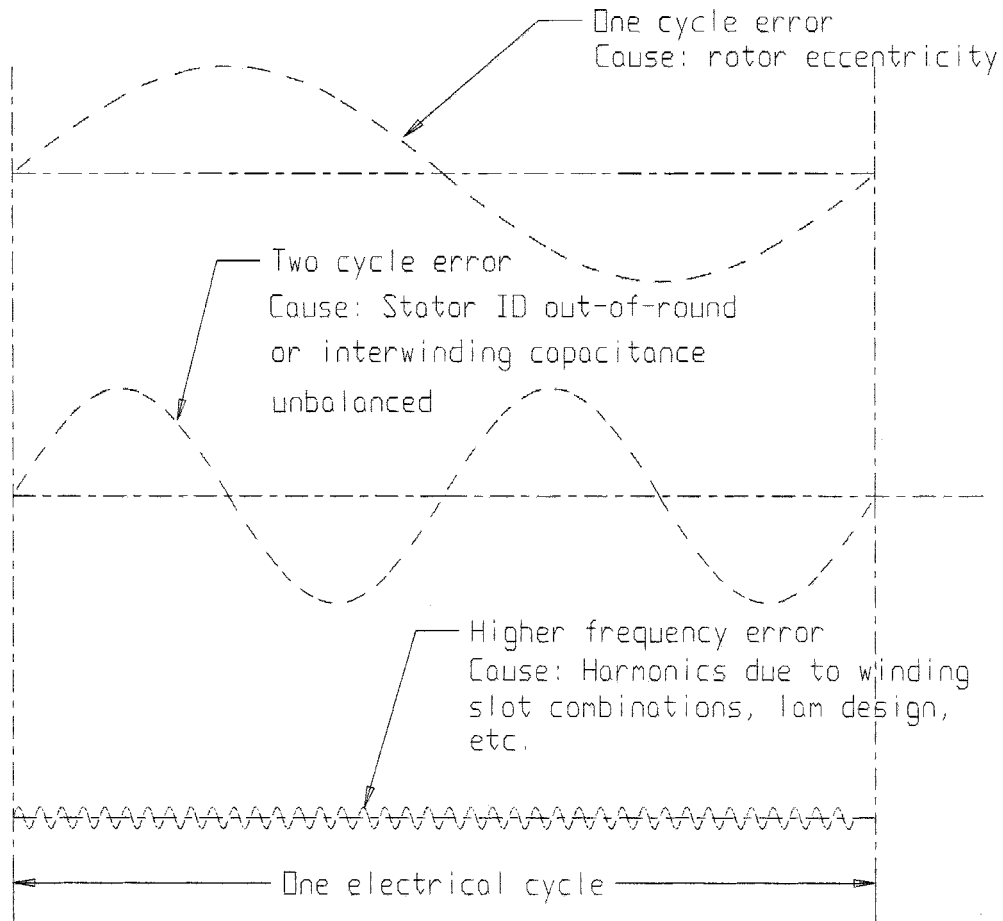

FIGURE 6.95 There are several causes of errors in resolvers and synchros.

An angle position indicator (API) used in conjunction with the index stand to measure the accuracy of the resolver.

1. Using the above equipment with the index stand in the 0° position, mount the resolver on the index stand and lock the resolver shaft in place.
2. Place the $1\ \Omega$ resistor in series with the R1 (red/wht) lead of the resolver.
3. Connect the resolver rotor leads, R1 (red/wht) & R3 (yel/wht) (see Figure 6.91) to the sine wave signal generator and set the voltage and frequency to the designed values for the resolver.
4. Connect the terminals from the sine wave signal generator to the reference input of the phase angle voltmeter (PAV).
5. Connect the resolver output leads S2 (yel) and S4 (blu) to the PAV input terminals and place the PAV in the total output voltage mode.
6. Rotate the index stand to the 0° position.
7. Turn the resolver housing while monitoring the total output voltage on the PAV until a minimum voltage reading is obtained on the PAV. Record this value. This is the *null voltage* of the resolver.
8. Turn the index stand to the 90° position.
9. Change the output display on the PAV to show the *phase angle* between the reference voltage and the voltage on leads S2-S4. Record this phase angle reading.
10. Change the output display on the PAV to show the *total output voltage* of the resolver.
11. Record this voltage.
12. Calculate the *transformation ratio* by dividing the reading in step 11 by the input reference voltage amplitude.
13. Connect the input leads of the PAV across the $1\ \Omega$ resistor and record the total voltage on the PAV display. Since this reading is across a $1\ \Omega$ resistor, it is also the *total current*.
14. Disconnect the resolver and the signal generator from the PAV.
15. Connect the terminals from the sine wave signal generator to the reference input of the angle position indicator (API).
16. Connect the stator leads S1 (red), S3 (blk), S2 (yel), and S4 (blu) to the API S1, S3, S2, and S4 inputs, respectively.
17. Check the *accuracy* of the resolver by recording the display on the API every 20° through 360° of mechanical rotation on the index stand. Record all values.

Resolver Benefits

Designers of motion control systems today have a variety of technologies from which to choose feedback devices. The popularity of brushless dc motors has emphasized the need for rotor position information to commutate windings as a key application in sensor products. Encoders are widely used due to the ease of interface with today's drivers but have some inherent performance limitations in temperature range, shock and vibration handling, and contamination resistance. The resolver is a much more rugged device due to its construction and materials, and can be mated with modular R to D converters that will meet all performance requirements and work reliably in the roughest of industrial and aerospace environments.

The excitation signal E_x into the resolver is converted by transformer coupling into sine and cosine (quadrature) outputs which equal $E_x \sin \theta$ and $E_x \cos \theta$. The resolver-to-digital converter (shown in Figure 6.98) calculates the angle:

$$\Theta = \arctan \left(\frac{E_x \sin \Theta}{E_x \cos \Theta} \right) \quad (6.113)$$

In this ratiometric format, the output of the sine winding is divided by the output of the cosine winding, and any injected noise whose magnitude is approximately equivalent on both windings is canceled. This provides an inherent noise rejection feature that is beneficial to the resolver user. This feature also results in a large degree of temperature compensation.

FIGURE 6.96 A two-speed resolver yields two electrical cycles for one rotation.

Multispeed Units

The relationship for multispeeds is that the speed ($2\times$, $3\times$, etc.) designates how many full sinusoidal cycles the resolver output electrically completes in 360° of mechanical rotation. The $2\times$ electrical output is such that the full sinusoidal cycle for a $2\times$ resolver occurs in 180° instead of 360° . A $2\times$ resolver output is shown in Figure 6.96. A full $3\times$ cycle is completed in 120° . The number of speeds selected for use is a function of the system requirements. Increasing the number of magnetic poles in the rotor and stator creates multispeed units. Each speed has several winding and slot combinations. The optimum combination is selected by the resolver designer based on system demands.

Applications

Resolvers are often used in conjunction with motors, and because of their inherent similarity of design (copper windings on iron lamination stacks), their environmental resistance is quite similar. They are ideal to design into industrial applications where dust and airborne liquids can obscure optical encoder signals. NC machines, coil winders, presses, and positioning tables are uses where resolvers excel. The resolver's inherent resistance to shock and vibration makes it uniquely suited to moving platforms, and their reliability under these conditions lends a welcome hand to the designers of robots, gantries, and automotive transfer lines.

Heat sensitivity is always a problem for motion control systems designers. Resolvers used for sensing the position of valves in high-temperature applications such as aircraft engines, petrochemical refining, and chemical processing have continually proven their reliability.

Moving devices to precise positions with smooth and accurate control can be a real challenge in the electromagnetic noise environment of the modern industrial facility. Emitted and conducted EMI from adjacent equipment, and input voltage variations with unwanted current spikes on input power lines can rob digital systems of their signal integrity. The analog resolver continues to function without information loss or signal interruption. Digitizing the signal can be done at a remote interface under more controlled conditions than on the factory floor. Only robust materials can perform well in harsh environments.

Synchros

As long ago as World War II, synchros were used in analog positioning systems to provide data and to control the physical position of mechanical devices such as radar antennae, indicator needles on instrumentation, and fire control mechanisms in military equipment. The term "synchro" defines an electromagnetic position transducer that has a set of three phase output windings that are electrically and mechanically spaced by 120° instead of the 90° spacing found in a resolver. In the rotor primary mode, the synchro is excited by a single-phase ac signal on the rotor. As the rotor moves 360° , the three amplitude modulated sine waves on the three phases of the output have a discrete set of amplitudes for each angular position. By interpreting these amplitudes, a table can be established to decode the exact rotary position.

In most applications, resolvers have replaced synchros because of the sophistication of the resolver-to-digital converters that are commercially available. Working with a sine and cosine is simpler and requires less conversion and decoding than using three 120° spaced signals. If conversion of a synchro output is desired in resolver format, a device known as a Scott “T” transformer can be used for conversion. In most synchro-to-digital processors, the first step is to convert the signal to a resolver format with a Scott “T” device.

A Modular Solution

The brushless resolver is a self-contained feedback device that, unlike optical encoders, provides an analog signal with infinite resolution. Not only can the output signal be converted to precise digital position information, but it also provides an accurate velocity signal, thus eliminating the need for using a separate tachometer. Reliability is enhanced using the same resolver for speed feedback and commutation. Piece part count can be reduced and the complexity of using Hall-effect devices for timing signals for commutation can be eliminated.

A modular approach allows the designer to easily select a single or multispeed resolver and appropriate electronics that will meet almost any desired level of resolution and accuracy. The resolvers are designed in the most commonly used frame sizes: 8, 11, 15, and 21. Housed models feature high-quality, motor-grade ball bearings. Heavy-duty industrial grade units are enclosed in rugged black painted aluminum housings with either flange, face, or servo-type mounting, and utilize MS-style connectors.

The Sensible Design Alternative for Shaft Angle Encoding

The requirement for velocity and position feedback plays an important role in today’s motion control systems. With the development of low-cost monolithic resolver-to-digital converters, a resolver-based system provides design engineers with the building blocks to handle a wide variety of applications. A resolver’s small size, rugged design, and the ability to provide a very high degree of accuracy under severe conditions, make this the ideal transducer for absolute position sensing. These devices are also well suited for use in extremely hostile environments such as continuous mechanical shock and vibration, humidity, oil mist, coolants, and solvents. Absolute position sensing vs. incremental position sensing is a necessity when working in an environment where there is the possibility of power loss. Whenever power is supplied to an absolute system, it is capable of reading its position immediately; this eliminates the need for a “go home” or reference starting point.

Resolver-to-Digital Converters

A monolithic resolver-to-digital converter requires only six external passive components to set the bandwidth and maximum tracking rate. The bandwidth controls how quickly the converter will react to a large change in position on the resolver output. The converter can also be programmed to provide either 10, 12, 14, or 16 bits of parallel data. A resolver-based system can provide high dynamic capability and high resolution for today’s motion control systems where precision feedback for both position and velocity is required.

Closed Loop Feedback

In a typical closed loop servo model as in [Figure 6.97](#), the position sensor plays an important role by constantly updating the position and velocity information. Selection of a machine control strategy will often be based on performance, total application cost, and technology comfort. The accuracy of the system is determined by the smallest resolution of the position-sensing device. A resolver-to-digital converter in the 16-bit mode has 2^{16} (65,536) counts per revolution, which is equivalent to a resolution of 20 arc seconds. The overall accuracy of the resolver-to-digital converter is ± 2.3 arc minutes. An accuracy specification defines the maximum error in achieving a desired position. System accuracy must be smaller than the tolerance on the desired measurement. An important feature of the resolver-to-digital converter

FIGURE 6.97 A closed-loop servo model uses a resolver-to-digital converter.

is repeatability. With a repeatability specification of ± 1 LSB (least significant bit) in the 16-bit mode, this provides an accurate measurement when determining position from point to point. For example, moving from point A to point B and back to point A, the converter in the 16-bit mode will be accurate within 20 arc seconds of the original position. The error curve of a resolver-to-digital converter is repeatable within ± 1 LSB. The combination of high precision resolvers (± 20 arc seconds) with a resolver-to-digital converter provides accurate absolute position information for precision feedback for motion control.

Type II Servo Loop

The motor speed is monitored using the velocity output signal generated by the resolver-to-digital converter. This signal is a dc voltage proportional to the rate of speed, positive for increasing angles and negative for decreasing angles, with a typical linearity specification of 0.25% and a typical reversal error of 0.75%. The error processing is performed using the industry standard technique for type II tracking, resolver-to-digital converters (see Figure 6.98).

The dc error is integrated, yielding a velocity voltage that drives a voltage-controlled oscillator (VCO). This VCO is an incremental integrator (constant voltage input to position rate output) that together with the velocity integrator, forms a type II critically damped, servo feedback loop. This information allows the motor to maintain constant speeds under varying loads when it is interfaced with a programmable logic controller (PLC). The PLC-based architecture is used for I/O intensive control applications. The PLC provides a low-cost option for those developers familiar with its ladder logic programming language. Integration of the motion, I/O, operator's interface, and communication are usually supported through additional cards that are plugged into the backplane.

Applications

Specific applications require unique profiles to control the speed and acceleration of the motor to perform the task at hand. By reducing the accelerations and decelerations that occur during each operation, it is possible to lower the cost and use more efficient motors. Industrial applications include the following:

- Ballscrew positioning
- Motor commutation
- Robotics positioning

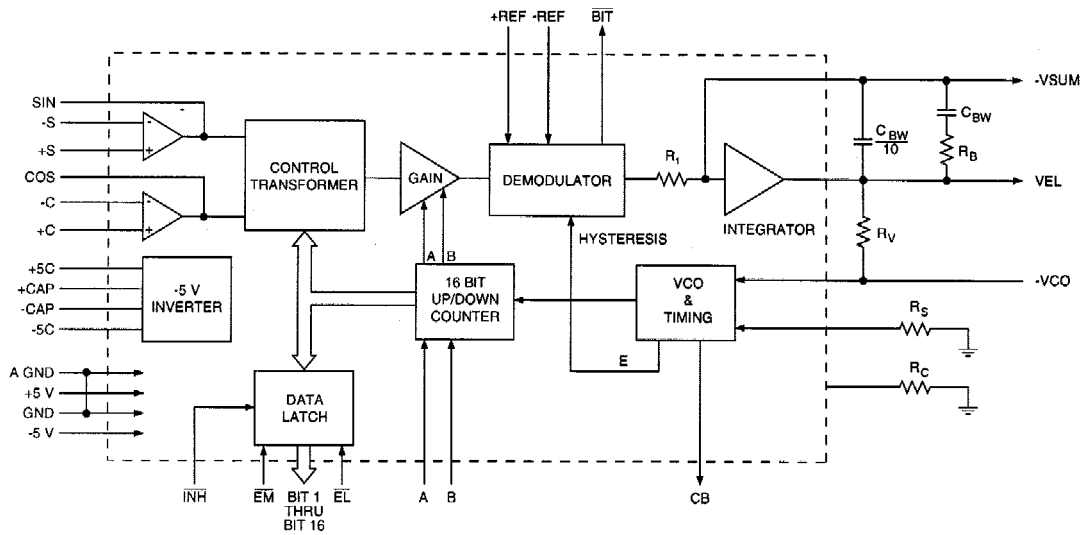

FIGURE 6.98 Error processing uses type II tracking resolver-to-digital converters.

- Machine vision systems
- X-Y tables
- Component insertion
- Remote video controls
- Web guides
- Pick and place machines

Resolver-to-Digital Conversion

For a resolver-to-digital converter, the resolver information is presented to a solid-state resolver conditioner that reduces the signal amplitude to 2 V rms sine and cosine; the amplitude of one being proportional to the sine of θ (the angle to be digitized), and the amplitude of the other being proportional to the cosine of θ . (The amplitudes referred to are, of course, the carrier amplitudes at the reference frequency, i.e., the cosine wave is actually $\cos \theta \cos \omega t$; but the carrier term, $\cos \omega t$, will be ignored in this discussion because it will be removed in the demodulator, and at any rate contains no data). A quadrant selector circuit in the control transformer enables selection of the quadrant in which θ lies, and automatically sets the polarities of the sine θ and $\cos \theta$ appropriately, for computational significance. The $\sin \theta$, $\cos \theta$ outputs of the quadrant selector are then fed to the sine and cosine multipliers, also contained in the control transformer. These multipliers are digitally programmed resistive networks. The transfer function of each of these networks is determined by a digital input (which switches in proportioned resistors), so that the instantaneous value of the output is the product of the instantaneous value of the analog input and the sine (or cosine) of the digitally encoded angle. If the instantaneous value of the analog input of the sine multiplier is $\cos \theta$, and the digitally encoded "word" presented to the sine multiplier is ϕ , then the output code is $\cos \theta \sin \phi$. Thus, the two outputs of the multipliers are

$$\text{From the sine multiplier: } \cos \theta \sin \phi$$

$$\text{From the cosine multiplier: } \sin \theta \cos \phi$$

These outputs are fed to an operational subtractor, at the differencing junction shown, so that the input fed to the demodulator is

$$\sin \theta \cos \phi - \cos \theta \sin \phi = \sin (\theta - \phi) \quad (6.114)$$

The right-hand side of this trigonometric identity indicates that the differencing-junction output represents a carrier-frequency sine wave with an amplitude proportional to the sine of the difference between θ (the angle to be digitized) and ϕ (the angle stored in digital form in the up/down counter). This point is the ac error signal brought out as (e). The demodulator is also presented with the reference voltage, which has been isolated from the reference source, and appropriately scaled, by the reference conditioner. The output of the demodulator is then, an analog dc level, proportional to $\sin(\theta - \phi)$, in other words, to the sine of the “error” between the actual angular position of the resolver and the digitally encoded angle, ϕ , which is the output of the counter. This point dc error is sometimes brought out as (D) while an addition of a threshold detector will give a built-in-test (BIT) flag. When the ac error signal exceeds 100 LSBs, the BIT flag will indicate a tracking error. This angular error signal is then fed into the error processor and VCO. This circuit consists essentially of an analog integrator whose output (the time integral to the error) controls the frequency of a voltage-controlled oscillator (VCO). The VCO produces clock pulses that are counted by the up/down counter. The “sense” of the error (ϕ too high or ϕ too low) is determined by the polarity of (ϕ), and is used to generate a control counter signal (U), which determines whether the counter increments upward or downward. Finally, note that the up/down counter, like any counter, is functionally an incremental integrator; therefore, the tracking converter constitutes in itself a closed-loop servomechanism (continuously attempting to null the error to zero) with two integrators in series. This called a “Type II” servo loop, which has decided advantages over Type 1 or Type 0 loops. In order to appreciate the value of a Type II servo behavior of this tracking converter, consider first the shaft is not moving. Ignoring inaccuracies, drifts, and the inevitable quantizing error, the error should be zero ($\theta = \phi$), and the digital output represents the true shaft angle of the resolver. Now, start the resolver shaft moving, and allow it to accelerate uniformly, from $d\theta/dt = 0$ to $d\theta/dt = V$. During the acceleration, an error will develop because the converter cannot instantaneously respond to the change of angular velocity. However, since the VCO is controlled by an integrator, the output of which is the integral of the error, the greater the lag (between θ and ϕ), the faster the counter will be called on to catch up. When the velocity becomes constant at V , the VCO will have settled to a rate of counting that exactly corresponds to the rate of change in θ per unit time and instantaneously $\theta = \phi$. Therefore, $d\phi/dt$ will always track $d\theta/dt$ without a velocity or position error. the only error will be momentary (transient) error, during acceleration or deceleration. Furthermore, the information produced by the tracking converter is always “fresh,” being continually updated, and always available at the output of the counter. Since $d\theta/dt$ tracks the input velocity it can be brought out as velocity, a dc voltage proportional to the rate of rotation, which is of sufficient linearity in modern converters to eliminate the need for a tachometer in many systems.

Bandwidth Optimization

When using a low-cost monolithic converter for position and velocity feedback, it is important to understand the dynamic response for a changing input. When considering what bandwidth to set the converter, several parameters must be taken into consideration. The ability to track step responses and accelerations will determine what bandwidth to select. The lower the bandwidth of the resolver-to-digital converter, the greater the noise immunity; high frequency noise will be rejected. The relationship between the maximum tracking rate and bandwidth determines the settling time for small and large steps. For a small step input, the bandwidth determines the converter settling time. When one has a large step, the maximum velocity slew rate and bandwidth together, determine the settling time.

Encoder Emulation

Today’s resolver-to-digital converters also have the ability to emulate the output of an optical incremental encoder. By providing the outputs A, B, and Zero Index, the encoder can be replaced with a resolver and resolver-to-digital converter without changing the existing interface hardware.

Determining Position Lag Error Due to Acceleration

As the bandwidth and the maximum tracking rate are varied, one can determine the acceleration constant (K_a) and large step settling time.

EXAMPLE:

Resolution: 16 bit
 Bandwidth: 100 Hz
 Reference: 1000 Hz
 Max tracking: 10 rps

$$BW = \frac{\sqrt{2}A}{\pi} \quad (6.115)$$

If the bandwidth = 100 Hz

$$A = 222$$

$$K_a = A^2$$

$$K_a = 49,284^\circ \text{ s}^{-2}$$

The lag in degrees during an acceleration is:

$$\frac{\text{Acceleration}}{K_a} \quad (6.116)$$

EXAMPLE:

$$\text{Acceleration} = 19,000^\circ \text{ s}^{-2}$$

$$K_a = 49,284^\circ \text{ s}^{-2}$$

$$LAG = 19,000/49,284 = 0.38^\circ$$

$$\text{In 16 bit 1 LSB} = 0.0055^\circ$$

$$\text{Acceleration (1 LSB lag)} = K_a \times 0.0055 \text{ (16 bit)}$$

$$49,284 \times 0.0055 = 270^\circ \text{ s}^{-2}$$

Large Step Settling Time

To determine the settling time for a large step response (179°), one must take into account the maximum tracking rate and bandwidth.

EXAMPLE:

$$\text{A } 179^\circ \text{ step with 100 Hz BW and 10 rps max tracking}$$

$$\text{Max tracking at 10 rps} = 3600^\circ \text{ s}^{-1}$$

$$179/3600 = 49 \text{ ms}$$

Then one must add the settling time due to bandwidth limitations; this is approximately 11 time constants (16-bit mode).

Time Constants

Resolution	# of counts/rotation	# of time constants
10	1024	7
12	4096	8
14	16384	10
16	65536	11

$$\text{Time constant} = 1/A$$

$$A = 222$$

$$1/A = 4.5 \text{ ms}$$

$$11 \text{ time constants} = 45 \text{ ms}$$

TABLE 6.27 List of Resolver and Synchro Suppliers

Company	Location	Phone number	Types of resolvers
API Harowe	West Chester, PA	(800) 566-5274	Brushless frameless, housed, & heavy-duty units
Admotec, Inc.	Norwich, VT	(802) 649-5800	Rotasyn solid rotor resolvers
Neotech, Inc.	Hatfield, PA	(215) 822-5520	Housed brush & brushless units
Vernitron Corp.	San Diego, CA	(800) 777-3393	Brushless, segment, brushed, & housed units
Servo Systems	Montville, NJ	(973) 335-1007	Brushed & brushless units
American Electronics	Fullerton, CA	(714) 871-3020	Housed units
Computer Conversions	East Northport, NY	(516) 261-3300	Explosion proof & specialty units
Poltron Corp.	Gaithersburg, MD	(301) 208-6597	Resolvers
Tamagawa Trading Co.	Tokyo, Japan	011-81-37-383-175	Brushless frameless & housed units
MPC Products	Skokie, IL	(800) 323-4302	Housed resolvers
Transicoil, Inc.	Trooper, PA	(800) 323-7115	Housed brushless & brushed resolvers
Litton Poly-Scientific	Blacksburg, VA	(800) 336-2112	Brushed and brushless resolvers
Kearfott Guidance & Navigation Corp.	Wayne, NJ	(973) 785-6000	Brushed & brushless resolvers
Novatronics, Inc.	Stratford, Ontario, Canada	(519) 271-3880	Resolvers
Muirhead Vactric	Lake Zurich, IL	(847) 726-0270	Resolvers

Therefore, the approximate settling time for a large step would be 94 ms. This is an approximation. Synchros and resolvers are used in a wide variety of dynamic conditions. Understanding how the converter reacts to these input changes will allow one to optimize the bandwidth and maximum tracking rate for each application. Table 6.27 provides a list of resolver and synchro suppliers.

6.11 Optical Fiber Displacement Sensors

Richard O. Claus, Vikram Bhatia, and Anbo Wang

The objective of this section is to present a rigorous theoretical and experimental analysis of short gage length optical fiber sensors for measurement of cyclical strain on or in materials. Four different types of sensors are evaluated systematically on the basis of various performance criteria such as strain resolution, dynamic range, cross-sensitivity to other ambient perturbations, simplicity of fabrication, and complexity of demodulation process. The sensing methods that would be investigated include well-established technologies, (e.g., fiber Bragg gratings), and rapidly evolving measurement techniques such as long-period gratings. Other than the grating-based sensors, two popular versions of Fabry–Perot interferometric sensors (intrinsic and extrinsic) will be evaluated for their suitability. A theoretical study of the cross-sensitivities of these sensors to an arbitrary combination of strain vectors and temperature, similar to that proposed by Sirkis in his SPIE paper in 1991 [1], will be developed.

The outline of this section is as follows. The principle of operation and fabrication process of each of the four sensors are discussed separately. Sensitivity to strain and other simultaneous perturbations such as temperature are analyzed. The overall cost and performance of a sensing technique depend heavily on the signal demodulation process. The detection schemes for all four sensors are discussed and compared

on the basis of their complexity. Finally, a theoretical analysis of the cross-sensitivities of the four sensing schemes is presented and their performances are compared.

Strain measurements using optical fiber sensors in both embedded and surface-mounted configurations have been reported by researchers in the past [2]. Fiber optic sensors are small in size, immune to electromagnetic interference, and can be easily integrated with existing optical fiber communication links. Such sensors can typically be easily multiplexed, resulting in distributed networks that can be used for health monitoring of integrated, high-performance materials and structures. Optical fiber sensors for strain measurements should possess certain important characteristics. These sensors should either be insensitive to ambient fluctuations in temperature and pressure, or should have demodulation techniques that compensate for changes in the output signal due to the undesired perturbations. In the embedded configuration, the sensors for axial strain measurements should have minimum cross-sensitivity to other strain states. The sensor signal should itself be simple and easy to demodulate. Nonlinearities in the output demand expensive decoding procedures or require precalibrating the sensor. The sensor should ideally provide an absolute and real-time strain measurement in a form that can be easily processed. For environments where large strain magnitudes are expected, the sensor should have a large dynamic range while at the same time maintaining the desired sensitivity. A discussion of each of the four sensing schemes individually, along with their relative merits and demerits, follows.

Extrinsic Fabry–Perot Interferometric Sensor

The extrinsic Fabry–Perot interferometric (EFPI) sensor, proposed by Murphy et al., is one of the most popular fiber optic sensors used for applications in health monitoring of smart materials and structures [3]. As the name suggests, the EFPI is an interferometric sensor in which the detected intensity is modulated by the parameter under measurement. The simplest configuration of an EFPI is shown in [Figure 6.99](#).

The EFPI system consists of a single-mode laser diode that illuminates a Fabry–Perot cavity through a fused biconical tapered coupler. The cavity is formed between an input single-mode fiber and a reflecting single-mode or multimode fiber. Since the cavity is external to the lead-in/lead-out fiber, the EFPI sensor is independent of transverse strain and small ambient temperature fluctuations. The input fiber and the reflecting fiber are aligned using a hollow-core silica fiber. For uncoated fiber ends, a 4% Fresnel reflection results at both ends. The first reflection, R_1 , called the reference reflection, is independent of the applied perturbation. The second reflection, R_2 , termed the sensing reflection, is dependent on the length of the cavity, d , which in turn is modulated by the applied perturbation. These two reflections interfere (provided $2d < L_c$, the laser diode's coherence length), and the intensity I at the detector varies as a function of the cavity length:

$$I = I_0 \cos\left(\frac{4\pi}{\lambda} d\right) \quad (6.117)$$

where, I_0 is the maximum value of the output intensity and λ is the laser diode center wavelength.

The typical EFPI transfer function curve is shown in [Figure 6.100](#). Small perturbations that result in operation around the quiescent-point or Q-point of the sensor lead to a linear variation in output intensity. A fringe in the output signal is defined as the change in intensity from a maximum to a maximum or from a minimum to a minimum. Each fringe corresponds to a change in the cavity length by one half of the operating wavelength, λ . The change in the cavity length, Δd , is then employed to calculate the strain ε using the expression:

$$\varepsilon = \frac{\Delta d}{L} \quad (6.118)$$

FIGURE 6.99 A simple configuration of an extrinsic Fabry-Perot interferometric (EFPI) sensing system.

where, L is defined as the gage length of the sensor and is typically the distance between two points where the input and reflecting fibers are bonded to the hollow-core fiber. Matching of the two reflection signal amplitudes allows good fringe visibility in the output signal.

The EFPI sensor has been extensively used for measuring fatigue loading on F-15 aircraft wings, detection of crack formation and propagation in civil structures, and cure and lifetime monitoring in concrete and composite specimens [2, 4]. The temperature insensitivity of this sensor makes it attractive for a large number of applications. The EFPI sensor is capable of measuring sub-Angstrom displacements with strain resolution better than 1 microstrain and a dynamic range greater than $10,000 \mu\epsilon$. Although the change in output intensity of the EFPI is nonlinear corresponding to the magnitude of the parameter being measured, for small perturbations its operation can be limited to that around the Q-point of the transfer function curve. Moreover, the large bandwidth available with this sensor simplifies the measurement of highly cyclical strain. The EFPI sensor is capable of providing single-ended operation and is hence suitable for applications where access to the test area is limited. The sensor requires simple and inexpensive fabrication equipment and an assembly time of less than 10 min. Additionally, since the cavity is external to the fibers, transverse strain components that tend to influence intrinsic sensors through the Poisson's effect have negligible effect on the EFPI sensor output. The sensitivity to only axial strain and insensitivity to input polarization state have made the EFPI sensor the most preferred fiber optic sensor for embedded applications [1]. Thus, overall, the EFPI sensing system is very well suited to measurement of small magnitudes of cyclical strain.

FIGURE 6.100 A typical EFPI transfer function curve.

FIGURE 6.101 An intrinsic Fabry-Perot interferometric sensor (IFPI).

Although a version of the EFPI sensor that provides absolute output has been demonstrated, it lacks the bandwidth typically desired during the measurement of cyclical strain [5]. We have also recently proposed a small cavity length/high finesse EFPI sensor for measurement of small perturbations [6]. This configuration has a simple output that can be demodulated using an optical filter/photodetector combination.

Intrinsic Fabry-Perot Interferometric Sensor

The intrinsic Fabry-Perot interferometric (IFPI) sensor is similar in operation to its extrinsic counterpart but significant differences exist in the configurations of the two sensors [7]. The basic IFPI sensor is shown in Figure 6.101. An optically isolated laser diode is used as the optical source to one of the input arms of a bidirectional 2×2 coupler. The Fabry-Perot cavity is formed by fusing a small length of a single-mode fiber to one of the output legs of the coupler. As shown in Figure 6.101, the reference (R) and sensing (S) reflections interfere at the detector face to provide a sinusoidal intensity variation. The cavity can also be obtained by introducing two Fresnel reflectors — discontinuities in refractive index — along the length of a single fiber. Photosensitivity in germanosilicate fibers has been used in the past to fabricate broadband reflectors that enclose an IFPI cavity [8]. Since the cavity is formed within an optical

fiber, changes in the refractive index of the fiber due to the applied perturbation can significantly alter the phase of the sensing signal, S . Thus, the intrinsic cavity results in the sensor being sensitive to ambient temperature fluctuations and all states of strain.

The IFPI sensor, like all other interferometric signals, has a nonlinear output that complicates the measurement of large magnitude strain. This can again be overcome by operating the sensor in the linear regime around the Q-point of the sinusoidal transfer function curve. The main limitation of the IFPI strain sensor is that the photoelastic effect-induced change in index of refraction results in a nonlinear relationship between the applied perturbation and the change in cavity length. In fact, for most IFPI sensors, the change in propagation constant of the fundamental mode dominates the change in cavity length. Thus, IFPIs are highly susceptible to temperature changes and transverse strain components [1]. In embedded applications, the sensitivity to all the strain components can result in erroneous outputs. The fabrication process of an IFPI strain sensor is more complicated than that of the EFPI sensor since the sensing cavity must be formed within the optical fiber by some special procedure. The strain resolution of the IFPIs is also expected to be around $1 \mu\epsilon$ with an operating range greater than $10,000 \mu\epsilon$. IFPI sensors also suffer from drift in the output signal due to variations in the polarization state of the input light.

Thus, the preliminary analysis shows that the extrinsic version of the Fabry–Perot optical fiber sensor seems to have an overall advantage over its intrinsic version. The extrinsic sensor has negligible cross-sensitivity to temperature and transverse strain. Although the strain sensitivity, dynamic range, and bandwidth of the two sensors are comparable, the IFPIs can be expensive and cumbersome to fabricate due to the intrinsic nature of the sensing cavity.

The extrinsic and intrinsic Fabry–Perot interferometric sensors possess nonlinear sinusoidal outputs that complicate the signal processing at the detection end. Although intensity-based sensors have a simple output variation, they suffer from limited sensitivity to strain or other perturbations of interest. Grating-based sensors have recently become popular as transducers that provide wavelength-encoded output signals that can typically be easily demodulated to derive information about the perturbation under investigation. The advantages and drawbacks of Bragg grating sensing technology are discussed first. The basic operating mechanism of the Bragg grating-based strain sensor is elucidated and the expressions for strain resolution is obtained. These sensors are then compared to the recently developed long-period gratings in terms of fabrication process, cross-sensitivity to other parameters, and simplicity of signal demodulation.

Fiber Bragg Grating Sensor

The phenomenon of photosensitivity in optical fibers was discovered by Hill and co-workers in 1978 [9]. It was found that permanent refractive index changes could be induced in fibers by exposing the germanium-doped core to intense light at 488 or 514 nm. The sinusoidal modulation of index of refraction in the core due to the spatial variation in the writing beam gives rise to a refractive index grating that can be used to couple the energy in the fundamental guided mode to various guided and lossy modes. Later Meltz et al. proposed that photosensitivity is more efficient if the fiber is side-exposed to fringe pattern at wavelengths close to the absorption wavelength (242 nm) of the germanium defects in the fiber [10]. The side-writing process simplified the fabrication of Bragg gratings, and these devices have recently emerged as highly versatile components for communication and sensing systems. Recently, loading the fibers with hydrogen has been reported to result in two orders of magnitude higher index change in germanosilicate fibers [11].

Principle of Operation

Bragg gratings are based on the phase-matching condition between spatial modes propagating in optical fibers. This phase-matching condition is given by:

$$k_g + k_c = k_B \quad (6.119)$$

where, k_g , k_c , and k_B are, respectively, the wave-vectors of the coupled guided mode, the resulting coupling mode, and the grating. For a first-order interaction, $k_B = 2\pi/\Lambda$, where Λ is the grating periodicity. Since it is customary to use propagation constants while dealing with optical fiber modes, this condition reduces to the widely used equation for mode coupling due to a periodic perturbation:

$$\Delta\beta = \frac{2\pi}{\Lambda} \quad (6.120)$$

where, $\Delta\beta$ is the difference in the propagation constants of the two modes involved in mode coupling (both assumed to travel in the same direction).

Fiber Bragg gratings (FBGs) involve the coupling of the forward-propagating fundamental LP_{01} optical fiber waveguide propagation mode to the reverse-propagating LP_{01} mode [12]. Consider a single mode fiber with β_{01} and $-\beta_{01}$ as the propagation constant of the forward- and reverse-propagating fundamental LP_{01} modes. To satisfy the phase-matching condition,

$$\Delta\beta = \beta_{01} - (-\beta_{01}) = \frac{2\pi}{\Lambda} \quad (6.121)$$

where, $\beta_{01} = 2\pi n_{\text{eff}}/\lambda$ (n_{eff} is the effective index of the fundamental mode and λ is the free-space wavelength). Equation 6.121 reduces to [12]:

$$\lambda_B = 2\Lambda n_{\text{eff}} \quad (6.122)$$

where λ_B is termed the Bragg wavelength. The Bragg wavelength is the wavelength at which the forward-propagating LP_{01} mode couples to the reverse-propagating LP_{01} mode. This coupling is wavelength dependent since the propagation constants of the two modes are a function of the wavelength. Hence, if an FBG is interrogated by a broadband optical source, the wavelength at which phase-matching occurs is found to be reflected back. This wavelength is a function of the grating periodicity (Λ) and the effective index (n_{eff}) of the fundamental mode (Equation 6.122). Since strain and temperature effects can modulate both these parameters, the Bragg wavelength shifts with these external perturbations. This spectral shift is utilized to fabricate FBGs for sensing applications.

Figure 6.102 shows the mode coupling mechanism in fiber Bragg gratings using the β -plot. Since the difference in propagation constants ($\Delta\beta$) between the modes involved in coupling is large, Equation 6.120 reveals that only a small value of periodicity, Λ , is needed to induce this mode coupling. Typically for telecommunication applications, the value of λ_B is around 1.5 μm . From Equation 6.122, Λ is determined to be 0.5 μm (for $n_{\text{eff}} = 1.5$). Due to the small periodicities (of the order of 1 μm), FBGs are classified as short-period gratings.

Fabrication Techniques

Fiber Bragg gratings have commonly been manufactured using two side-exposure techniques: the interferometric method and the phase mask method. The interferometric method, depicted in Figure 6.103

FIGURE 6.102 Mode coupling mechanism in a fiber Bragg grating.

FIGURE 6.103 The interferometric fiber Bragg grating.

FIGURE 6.104 The novel interferometer technique.

comprises a UV beam at 244 or 248 nm split in two equal parts by a beam splitter [10]. The two beams are then focused on a portion of Ge-doped fiber (whose protective coating has been removed) using cylindrical lenses, and the periodicity of the resulting interference pattern and, hence, the Bragg wavelength are varied by altering the mutual angle, θ . The limitation of this method is that any relative vibration of the pairs of mirrors and lenses can lead to the degradation of the quality of the final grating and, hence, the entire system has a stringent stability requirement. To overcome this drawback, Kashyap et al. have proposed the novel interferometer technique where the path difference between the interfering UV beams is produced by the propagation through a right-angled prism (Figure 6.104) [12]. This technique is inherently stable because both beams are perturbed similarly by any prism vibration.

The phase mask technique has recently gained popularity as an efficient holographic side-writing procedure for grating fabrication [13]. In this method, as shown in Figure 6.105, an incident UV beam is diffracted into -1 , 0 , and $+1$ orders by a relief grating generated on a silica plate by e-beam exposure and plasma etching. The two first diffraction orders undergo total internal reflection at the glass/air interface of a rectangular prism and interfere on the bare fiber surface placed directly behind the mask. This technique is wavelength specific since the periodicity of the resulting two-beam interference pattern is uniquely determined by the diffraction angle of -1 and $+1$ orders and, thus, the properties of the phase

FIGURE 6.105 The phase mask technique for grating fabrication.

FIGURE 6.106 Diagram of the setup for monitoring the growth of the grating in transmission during fabrication.

mask. Obviously, different phase masks are required for fabrication of gratings at different Bragg wavelengths. The setup for actively monitoring the growth of the grating in transmission during fabrication is shown in Figure 6.106.

Bragg Grating Sensors

From Equation 6.122 we see that a change in the value of n_{eff} and/or Λ can cause the Bragg wavelength, λ , to shift. This fractional change in the resonance wavelength, $\Delta\lambda/\lambda$, is given by the expression:

$$\frac{\Delta\lambda}{\lambda} = \frac{\Delta\Lambda}{\Lambda} + \frac{\Delta n_{\text{eff}}}{n_{\text{eff}}} \quad (6.123)$$

where, $\Delta\Lambda/\Lambda$ and $\Delta n_{\text{eff}}/n_{\text{eff}}$ are the fractional changes in the periodicity and the effective index, respectively. The relative magnitudes of the two changes depend on the type of perturbation the grating is subjected to; for most applications, the effect due to change in effective index is the dominating mechanism.

Any axial strain, ϵ , applied to the grating changes the periodicity and the effective index and results in a shift in the Bragg wavelength, given by:

$$\frac{1}{\lambda} \frac{\Delta\lambda}{\epsilon} = \frac{1}{\Lambda} \frac{\Delta\Lambda}{\epsilon} + \frac{1}{n_{\text{eff}}} \frac{\Delta n_{\text{eff}}}{\epsilon} \quad (6.124)$$

The first term on the right-hand side is unity, while the second term has its origin in the photoelastic effect. An axial strain on the fiber serves to change the refractive index of both the core and the cladding. This results in the variation in the value of the effective index of glass. The photoelastic or strain-optic coefficient that relates the change in index of refraction due to mechanical displacement is about -0.27 . Thus, the variation in n_{eff} and Λ due to strain have contrasting effects on the Bragg peak. The fractional change in the Bragg wavelength due to axial strain is 0.73ϵ or 73% of the applied strain. At 1550 and 1300 nm, the shifts in the resonance wavelength are 11 nm/% ϵ and 9 nm/% ϵ , respectively. With temperature, a FBG at 1500 nm shifts by 1.6 nm for every 100°C rise in temperature [9].

Limitations of Bragg Grating Strain Sensors

The major limitation of Bragg grating sensors is the complex and expensive fabrication technique. Although side-writing is commonly used to manufacture these gratings, the requirement of expensive phase masks increases the cost of the sensing system. In the interferometric technique, stability of the setup is a critical factor in obtaining high-quality gratings. Since index changes of the order of 10^{-3} are required to fabricate these gratings, laser pulses of high energy levels are necessary. This might reduce laser operating lifetime and lead to increased maintenance expense. Additionally, introducing hydrogen or deuterium into the fiber allows increased index modulation as a result of the irradiation process.

The second major limitation of Bragg gratings is their limited bandwidth. The typical value of the full-width at half maximum (FWHM) is between 0.1 and 1 nm. Although higher bandwidths potentially can be obtained by chirping the index or periodicity along the grating length, this adds to the cost of the grating fabrication. The limited bandwidth requires high-resolution spectrum analyzers to monitor the grating spectrum. Kersey et al. have proposed an unbalanced Mach–Zender interferometer to detect the perturbation-induced wavelength shift [14]. Two unequal arms of the Mach–Zender interferometer are excited by the backreflection from a Bragg grating sensor element. Any change in the input optical wavelength modulates the phase difference between the two arms and results in a time-varying sinusoidal intensity at the output. This interference signal can be related to the shift in the Bragg peak and, hence, the magnitude of the perturbation can be obtained. Recently, modal interferometers have also been proposed to demodulate the output of a Bragg grating sensor [15]. The unbalanced interferometers are also susceptible to external perturbations and hence need to be isolated from the parameter under investigation. Moreover, the nonlinear output might require fringe counting equipment, which can be complex and expensive. Additionally, a change in the perturbation polarity at the maxima or minima of the transfer function curve will not be detected by this demodulation scheme. To overcome this limitation, two unbalanced interferometers can be employed for dynamic measurements.

The cross-sensitivity to temperature fluctuations leads to erroneous strain measurements in applications where the ambient temperature has a temporal variation. Thus, a reference grating that measures the temperature change must be utilized to compensate for the output of the strain sensor. Recently, temperature-independent sensing has been demonstrated using chirped gratings written in tapered optical fibers [16].

Last, the sensitivity of fiber Bragg grating strain sensors might not be adequate for certain applications. This sensitivity of the sensor depends on the minimum detectable wavelength shift at the detection end. Although excellent wavelength resolution can be obtained with unbalanced interferometric detection

techniques, standard spectrum analyzers typically provide a resolution of 0.1 nm. At 1300 nm, this minimum detectable change in wavelength corresponds to a strain resolution of 111 $\mu\epsilon$. Hence, in applications where strain smaller than 100 $\mu\epsilon$ is anticipated, Bragg grating sensors might not be practical. The dynamic range of strain measurement can be as much as 15,000 $\mu\epsilon$.

Long-Period Grating Sensor

This section discusses the use of novel long-period gratings as strain sensing devices. The principle of operation of these gratings, their fabrication process, preliminary strain tests, demodulation process, and cross-sensitivity to ambient temperature are analyzed.

Principle of Operation

Long-period gratings that couple the fundamental guided mode to different guided modes have been demonstrated in the past [17, 18]. Gratings with longer periodicities that involve coupling of a guided mode to forward-propagating cladding modes were recently proposed by Vengsarkar et al. [19, 20]. As stated previously, fiber gratings satisfy the Bragg phase-matching condition between the guided and cladding or radiation modes or, another guided mode. This wavelength-dependent phase-matching condition is given by:

$$\beta_{01} - \beta = \Delta\beta = \frac{2\pi}{\Lambda} \quad (6.125)$$

where Λ is the periodicity of the grating, β_{01} and β are the propagation constants of the fundamental guided mode and the mode to which coupling occurs, respectively.

For conventional fiber Bragg gratings, the coupling of the forward propagating LP₀₁ mode occurs to the reverse propagating LP₀₁ mode ($\beta = -\beta_{01}$). Since $\Delta\beta$ is large in this case (Figure 6.107(a)), the grating periodicity is small, typically of the order of 1 μm . Unblazed long-period gratings having index variations parallel to the long axis of the fiber couple the fundamental mode to the discrete and circularly-symmetric, forward-propagating cladding modes ($\beta = \beta^n$), resulting in smaller values of $\Delta\beta$ (Figure 6.107(b)) and

FIGURE 6.107

FIGURE 6.108 Setup used to fabricate long-period gratings.

hence periodicities ranging in hundreds of micrometers [19]. The cladding modes attenuate rapidly as they propagate along the length of the fiber due to the lossy cladding-coating interface and bends in the fiber. Since $\Delta\beta$ is discrete and a function of the wavelength, this coupling to the cladding modes is highly selective, leading to a wavelength-dependent loss. As a result, any modulation of the core and cladding guiding properties modifies the spectral response of long-period gratings, and this phenomenon can be utilized for sensing purposes. Moreover, since the cladding modes interact with the fiber jacket or any other material surrounding the cladding, changes in the properties of these ambient materials can also be detected.

Fabrication Procedure

To fabricate long-period gratings, hydrogen-loaded (3.4 mol%) germanosilicate fibers are exposed to 248 nm UV radiation from a KrF excimer laser, through a chrome-plated amplitude mask possessing a periodic rectangular transmittance function. Figure 6.108 shows the setup used to fabricate the gratings. The laser was pulsed at 20 Hz with a 8 ns pulse duration. The typical writing times for an energy of $100 \text{ mJ cm}^{-2} \text{ pulse}^{-1}$ and a 2.5 cm exposed length vary between 6 to 15 min for different fibers. The coupling wavelength, λ_p , shifts to higher values during exposure, due to the photoinduced enhancement of the refractive index of the fiber core and the resulting increase in β_{01} . After writing, the gratings are annealed at 150°C for 10 h to remove the unreacted hydrogen. This high-temperature annealing causes λ_p to move to shorter wavelengths due to the decay of UV-induced defects and diffusion of molecular hydrogen from the fiber. Figure 6.109 depicts the typical transmittance of a grating. Various attenuation bands correspond to coupling to discrete cladding modes of different orders. A number of gratings can be fabricated at the same time by placing more than one fiber behind the amplitude mask. Moreover, the stability requirements during the writing process are not as severe as those for short-period Bragg gratings.

For coupling to the highest-order cladding-mode, the maximum isolation (loss in transmission intensity) is typically in the 5 to 20 dB range on wavelengths, depending on fiber parameters, duration of UV exposure, and mask periodicity. The desired fundamental coupling wavelength can easily be varied using inexpensive amplitude masks of different periodicities. The insertion loss, polarization-mode dispersion, backreflection, and polarization-dependent loss of a typical grating are 0.2 dB, 0.01 ps, -80 dB, and 0.02 dB, respectively. The negligible polarization sensitivity and backreflection of these devices eliminate the need for expensive polarizers and isolators.

Preliminary experiments were performed to examine the strain sensitivity of long-period gratings written in different fibers [21, 22]. Gratings were fabricated in four different types of fibers: standard dispersion-shifted fiber (DSF), standard 1550 nm fiber, and conventional 980 and 1050 nm single-mode fibers, which for the sake of brevity are referred to as fibers A, B, C, and D, respectively. The strain sensitivity of gratings written in different fibers was determined by axially straining the gratings between

FIGURE 6.109 Typical transmission of a grating.

two longitudinally separated translation stages. The shift in the peak loss wavelength of the grating in fiber D as a function of the applied strain is depicted in Figure 6.110, along with that for a Bragg grating (about $9 \text{ nm } \% \epsilon^{-1}$, at 1300 nm) [9]. The strain coefficients of wavelength shift (β) for fibers A, B, C, and D are shown in Table 6.28. Fiber D has a coefficient $15.2 \text{ nm } \% \epsilon^{-1}$, which gives it a strain-induced shift that is 50% larger than that for a conventional Bragg grating. The strain resolution of this fiber for a 0.1 nm detectable wavelength shift is $65.75 \mu \epsilon$.

The demodulation scheme of a sensor determines the overall simplicity and sensitivity of the sensing system. Short-period Bragg grating sensors were shown to possess signal processing techniques that are complex and expensive to implement. A simple demodulation method to extract information from long-period gratings is possible. The wide bandwidth of the resonance bands enables the wavelength shift due to the external perturbation to be converted into an intensity variation that can be easily detected.

Figure 6.111 shows the shift induced by strain in a grating written in fiber C. The increase in the loss at 1317 nm is about 1.6 dB . A laser diode centered at 1317 nm was used as the optical source, and the change in transmitted intensity was monitored as a function of applied strain. The transmitted intensity is plotted in Figure 6.112 for three different trials. The repeatability of the experiment demonstrates the feasibility of using this simple scheme to utilize the high sensitivity of long-period gratings. The transmission of a laser diode centered on the slope of the grating spectrum on either side of the resonance wavelength can be used as a measure of the applied perturbation. A simple detector and amplifier combination at the output can be used to determine the transmission through the detector. On the other hand, a broadband source can also be used to interrogate the grating. At the output, an optical bandpass filter can be used to transmit only a fixed bandwidth of the signal to the detector. The bandpass filter should again be centered on either side of the peak loss band of the resonance band. These schemes are easy to implement, and unlike conventional Bragg gratings, the requirement of complex and expensive interferometric demodulation schemes is not necessary [22].

FIGURE 6.110 Shift in peak loss wavelength as a function of the applied strain.

TABLE 6.28 Strain Sensitivity of Long-Period Gratings Written in Four Different Types of Fibers

Type of fiber	Strain sensitivity (nm %ε ⁻¹)
A — Standard dispersion-shifted fiber (DSF)	-7.27
B — Standard 1550 nm communication fiber	4.73
C — Conventional 980 nm single-mode fiber	4.29
D — Conventional 1060 nm single-mode fiber	15.21

Note: The values correspond to the shift in the highest order resonance wavelength.

Temperature Sensitivity of Long-Period Gratings

Gratings written in different fibers were also tested for their cross-sensitivity to temperature [22]. The temperature coefficients of wavelength shift for different fibers are shown in Table 6.29. The temperature sensitivity of a fiber Bragg grating is 0.014 nm °C⁻¹. Hence, the temperature sensitivity of a long-period grating is typically an order of magnitude higher than that of a Bragg grating. This large cross-sensitivity to ambient temperature can degrade the strain sensing performance of the system unless the output signal is adequately compensated. Multiparameter sensing using long-period gratings has been proposed to obtain precise strain measurements in environments with temperature fluctuations [21].

In summary, long-period grating sensors are highly versatile. These sensors can easily be used in conjunction with simple and inexpensive detection techniques. Experimental results prove that these methods can be used effectively without sacrificing the enhanced resolution of the sensors. Long-period grating sensors are insensitive to the input polarization and do not require coherent optical sources. The cross-sensitivity to temperature is a major concern while using these gratings for strain measurements.

FIGURE 6.112 Plot of the change in transmitted intensity as a function of strain, for three different trials.

Table 6.29 Temperature Sensitivity of Long-Period Gratings Written in Four Different Types of Fibers

Type of fiber	Temperature sensitivity (nm °C ⁻¹)
A — Standard dispersion-shifted fiber (DSF)	0.062
B — Standard 1550 nm communication fiber	0.058
C — Conventional 980 nm single-mode fiber	0.154
D — Conventional 1060 nm single-mode fiber	0.111

Note: The values correspond to the shift in the highest order resonance wavelength.

Comparison of Sensing Schemes

Based on the above results, the interferometric sensors have a high sensitivity and bandwidth, but are limited by the nonlinearity in their output signals. Conversely, intrinsic sensors are susceptible to ambient temperature changes while the grating-based sensors are simpler to multiplex. Each may be used in specific applications.

Conclusion

We have investigated the performance of four different interferometric and grating-based sensors. This analysis was based on the sensor head fabrication and cost, signal processing, cross-sensitivity to temperature, resolution, and operating range. The relative merits and demerits of the various sensing schemes were also discussed.

6.12 Optical Beam Deflection Sensing

Grover C. Wetsel

Measurements of the intensity of the light reflected and transmitted by a sample have been sources of information concerning the structure of matter for over a century. In recent decades, it has been found that measurement of the position of an optical beam that has scattered from a sample is an important and versatile means of characterizing materials and the motion of devices. Surely, the availability of a well-collimated beam from a laser has been crucial in the development of techniques and applications of *optical beam deflection (OBD)* sensing; however, the development and ready availability of various types of *position sensing detectors (PSDs)* have also been important factors. Optical beam deflection may be caused, for example, by propagation of a laser beam through a refractive-index gradient or by reflection from a displaced surface. A PSD provides an electronic signal that is a function of the laser beam position on the detector.

In this section, applications of optical beam deflection sensing are reviewed, the theories of operation of the three most common types of OBD sensors are developed, and typical operational characteristics of the devices are presented. The advantages and disadvantages of the various PSDs are also discussed.

FIGURE 6.113 A schematic diagram of the basic optical-beam-deflection (OBD) sensing configuration.

A schematic diagram of the basic OBD sensing configuration is illustrated in [Figure 6.113](#). In this case, the displacement, u , of the surface causes the position of the reflected beam on the PSD to move from point P to point P' ; the positional change produces a change in the output voltage of the PSD. The output voltage, V , of the PSD electronics can be calibrated in terms of the actual displacement, u , by measuring V versus u for known displacements.

OBD sensing has been used in a variety of applications, including photothermal optical beam deflection (PTOBD) spectroscopy [1], absolute measurement of optical attenuation [2], PTOBD imaging of surface and subsurface structure [3], photothermal displacement spectroscopy [4], atomic-force microscopy [5], and materials characterization [6]. It has also been used as an uncomplicated, sensitive, and accurate method of measurement of surface motion for scanning tunneling microscope scanner transducers [7] and ultrasonic transducer imaging [8].

Theory

The three basic types of devices for OBD sensing are (1) a photodetector behind a sharply edged screen (a knife edge); (2) a small array of photodetectors separated by relatively small, insensitive areas (bicell, quadcell); and (3) a continuous solid-state position sensor (one or two dimensional). Sensing characteristics of a device are determined by the effect of optical beam displacement on the photodetector power distribution. Since laser beams are commonly used in OBD sensing, the analysis involves the assumption that the spatial distribution of the intensity (I) in the plane perpendicular to the direction of wave propagation is axially symmetric with a Gaussian radial variation.

Knife-Edge Photodetector

The essential features of a PSD are represented by a photodetector shadowed by a semi-infinite knife edge, $y < 0$, as illustrated in [Figure 6.114](#). As can be anticipated from the symmetry of the arrangement and proved mathematically, the maximal deflection sensitivity occurs when the undeflected beam is centered on the knife edge. The intensity of the light reaching the photodetector due to the displacement (u) of the center of the beam is given in the reference frame of the displaced beam by:

$$I(r') = \frac{aP}{\pi} e^{-ar'^2} \quad (6.126)$$

FIGURE 6.114 Essential features of a position-sending detector (PSD), as represented by a photodetector shadowed by a semiinfinite knife edge.

where P is the total incident beam power, $a = 2/r_1^2$, r_1 is the Gaussian beam radius, and $r'^2 = x'^2 + y'^2$. In terms of the coordinates (x,y) of the undeflected beam, the rectangular coordinates of the deflected beam are $x' = x$ and $y' = y - u$. The power (P_d) on the detector is thus given by:

$$P_d = \frac{aP}{\pi} \int_0^{\infty} e^{-a(y-u)^2} dy \int_{-\infty}^{\infty} e^{-ax^2} dx = \frac{P}{2} \left[1 + \operatorname{erf} \left(\sqrt{2} \frac{u}{r_1} \right) \right] \quad (6.127)$$

where erf is the error function. One can see by inspection of Equation 6.127 that the essential characteristics of this position sensor are determined by u/r_1 . The normalized response, P_d/P is shown in [Figure 6.115](#) as a function of u/r_1 . When $u = r_1$, then $P_d = 97.7\% P$.

The deflection sensitivity is given by the slope of Equation 6.127,

$$\frac{dP_d}{du} = \sqrt{\frac{2}{\pi}} \frac{P}{r_1} e^{-2\left(\frac{u}{r_1}\right)^2}, \quad \text{with} \quad \left(\frac{dP_d}{du} \right)_{\max} = \left(\frac{dP_d}{du} \right)_{u=0} = \sqrt{\frac{2}{\pi}} \frac{P}{r_1} \quad (6.128)$$

Define the small-signal position sensor sensitivity (units of m^{-1}):

$$\alpha_{\text{KE}} \equiv \frac{1}{P} \left(\frac{dP_d}{du} \right)_{u=0} = \frac{1}{r_1} \sqrt{\frac{2}{\pi}} \quad (6.129)$$

FIGURE 6.115 The normalized response P_d/P as a function of u/r_1 (u = displacement of center of beam; r_1 = Gaussian beam radius; P_d = power on the detector; P = total incident beam power).

The optical power reaching the photodetector for small signals is then given by:

$$P_d \cong \frac{P}{2} + \left(\frac{dP_d}{du} \right)_{u=0} u = \frac{P}{2} + \alpha u P = \frac{P}{2} [1 + 2\alpha u] \quad (6.130)$$

The photodetector signal will be linear in displacement if $u \leq 0.387r_1$.

The photocurrent is:

$$I = KP_d \cong \frac{KP}{2} [1 + 2\alpha u] \quad (6.131)$$

where K is the photodetector responsivity in A/W. The position sensor voltage is obtained using a transimpedance amplifier with gain Z :

$$V = KZP_d \cong \frac{KZP}{2} [1 + 2\alpha u] \quad (6.132)$$

Bicell Detector

The deflection of a Gaussian beam initially centered in the insensitive gap of a bicell detector is illustrated in [Figure 6.116](#). The power incident on the upper half of the bicell is given by:

$$P_2 = \frac{aP}{\pi} \int_{y_2}^{\infty} e^{-a(y-u)^2} dy \int_{-\infty}^{\infty} e^{-ax^2} dx = \frac{P}{2} \left[1 - \operatorname{erf} \left(\frac{\sqrt{2}}{r_1} (y_2 - u) \right) \right] \quad (6.133)$$

FIGURE 6.116 Deflection of a Gaussian beam initially centered in the insensitive gap of a bicell detector.

The power incident on the lower half of the bicell is given by:

$$P_1 = \frac{aP}{\pi} \int_{-\infty}^{-y_1} e^{-a(y-u)^2} dy \int_{-\infty}^{\infty} e^{-ax^2} dx = \frac{P}{2} \left[1 - \operatorname{erf} \left(\frac{\sqrt{2}}{r_1} (y_1 + u) \right) \right] \quad (6.134)$$

The photocurrent from each detector of the bicell is converted to voltage by identical transimpedance amplifiers: $V_2 = KZP_2$ and $V_1 = KZP_1$; a difference amplifier is then used to obtain the bicell signal voltage:

$$V = V_2 - V_1 = KZ(P_2 - P_1) = \frac{KZP}{2} \left[\operatorname{erf} \left(\frac{\sqrt{2}}{r_1} (y_1 + u) \right) - \operatorname{erf} \left(\frac{\sqrt{2}}{r_1} (y_2 - u) \right) \right] \quad (6.135)$$

The normalized response, $2V/(KZP)$, is shown in Figure 6.117 as a function of u/r_1 for $y_1 = y_2 = r_1/10$.

Suppose that the beam is centered in the gap, $y_1 = y_2$; then, for small displacements, one obtains:

$$V \cong 2 \sqrt{\frac{2}{\pi}} \frac{KZPu}{r_1} e^{-2(y_1/r_1)^2} \quad (6.136)$$

The small-signal sensitivity is:

$$\alpha_{BC} \equiv \frac{1}{KZP} \left(\frac{dV}{du} \right)_{u=0} = 2 \sqrt{\frac{2}{\pi}} \frac{e^{-2(y_1/r_1)^2}}{r_1} \quad (6.137)$$

This quantity is optimized when $r_1 = 2y_1$, and the optimal sensitivity is $0.484/y_1$.

FIGURE 6.117 The normalized response $2V/KZP$ in a bicell detector as a function of u/r_1 for $y_1 = y_2 = r_1/10$.

Continuous Position Sensor

The position information in a continuous position sensor (also known as a lateral-effect photodiode) is derived from the divided path taken by photon-generated electrons to two back electrodes on the device. For a homogeneous device, the current to an electrode depends only on the distance of the centroid of the light beam from that electrode; the currents would be equal in an ideal device when the beam is located at its electrical center.

Consider the analysis of a one-dimensional continuous PSD. The current signal from each electrode is converted to a voltage signal by a transimpedance amplifier with gain, Z . Operational amplifiers are then used to provide the sum signal, $V_s = KPZA_s$, and the difference signal, $V_d = KPZA_d\alpha u$, where A_s and A_d are the sum and difference amplifier gains, respectively. The position sensor sensitivity, α , is then given by:

$$\alpha \equiv \frac{V_d A_s}{u V_s A_d} \quad (6.138)$$

which is determined by measuring V_d and V_s as a function of u .

Characterization of PSDs

The PSD characteristics presented here were measured by mounting the device to a translation stage with an optical encoder driven by a piezoelectric motor [9]; the position accuracy was $\pm 0.1 \mu\text{m}$. An appropriately attenuated He-Ne laser beam was directed at normal incidence to the PSD as it was translated past the beam. The PSD sum and difference voltages were measured with GP-IB digital voltmeters as a function of displacement; the PSD displacement and voltage measurements were computer controlled.

The operation of a knife-edge PSD can be evaluated using the signal from one side of a bicell as well as from a photodetector behind a knife edge. The transimpedance amplifier output voltage corresponding

FIGURE 6.118 Transimpedance amplifier output voltage corresponding to the current signal from one cell of a United Detector Technology (UDT) SPOT2D bicell as a function of displacement. Data are plotted as normalized cell voltage vs. u/r_1 .

to the current signal from one cell of a United Detector Technology [10] (UDT) SPOT2D bicell is shown as a function of displacement in [Figure 6.118](#). The data are plotted as normalized cell voltage as a function of u/r_1 . Since the signal from one cell of a bicell is equivalent to a knife-edge photodetector, the data can be compared with [Figure 6.115](#). The data are in reasonable agreement for $u/r_1 < 1$ and a best fit allows the inference of $r_1 = 0.4$ mm; the disagreement for $u/r_1 \geq 1$ corresponds to the laser beam partially moving off the outside edge of the cell.

The operation of a bicell PSD is evaluated by the data of [Figure 6.119](#) which shows the difference voltage as a function of displacement for the UDT SPOT2D. The deviations from the theoretical curve of [Figure 6.117](#) for $u \leq 0.4$ mm and $u \geq 1.1$ mm are due to the beam moving off the outside edges of the bicell. The linear region of the PSD is centered at the optimal quiescent point ($V_1 - V_2 = 0$); a least-squares fit of a straight line gives a slope of $A_{12} = 4.88$ mV μm^{-1} for this device. For the data of [Figures 6.118](#) and [6.119](#), $P = 0.37$ mW and $Z = 5$ k Ω ; thus, the experimental value of the responsivity is determined to be $K_{\text{exp}} = 0.65$ A W^{-1} . The nominal gap size of the SPOT2D bicell is such that $y_1 = 63.5$ μm ; thus, using this value of y_1 and $r_1 = 0.4$ mm in [Equation 6.137](#), the calculated bicell sensitivity is 3.8×10^3 m^{-1} . The experimental value of sensitivity is calculated from A_{12} , K_{exp} , P , and Z to be 4.1×10^3 m^{-1} .

Evaluation of the operation of the x -axis of a UDT SC10 two-axis continuous PSD is illustrated in [Figures 6.120 through 6.122](#). The PSD was oriented such that the y -axis was vertical; thus, ideally, V_{dy} is constant as the PSD is translated, except near the edges of the 10 mm \times 10 mm device. As shown in [Figure 6.120](#), V_{sx} is virtually constant except near the edges of the device; this means that the optical responsivity (K) does not greatly vary with the laser beam position on this detector. Variation of V_{dx} with displacement is shown in [Figure 6.121](#); this PSD has a broad linear range. The linearity of continuous PSDs can often be improved by using the ratio, $V_{\text{dx}}/V_{\text{sx}}$, as shown in [Figure 6.122](#); the sensitivity of this PSD is determined from a least-squares fit of the linear part of this characteristic to be 183 m^{-1} .

A newer class of PSDs is represented by the Sitek [11] 1L10 single-axis continuous PSD, which is typically more linear. An example of the $V_{\text{d}}/V_{\text{s}}$ versus u characteristic is shown in [Figure 6.123](#). The sensitivity is determined from a least-squares fit of the linear part of the characteristic to be 307 m^{-1} .

FIGURE 6.119 Difference voltage as a function of displacement for the United Detector Technology (UDT) SPOT2D bicell.

FIGURE 6.120 Sum voltage vs. displacement for x axis of UDT SCIO continuous PSD.

Summary

A PSD composed of a knife-edge photodetector is simple, has a sensitivity that depends only on the radius of the laser beam, and has a response time determined by the photodetector. Thus, for fast rise-time detection of small displacements, this type of PSD is to be preferred.

FIGURE 6.121 Difference voltage vs. displacement for x axis of UDT SCIO continuous PSD.

FIGURE 6.122 Ratio of difference voltage to sum voltage vs. displacement for x axis of UDT SCIO continuous PSD.

The maximal sensitivity of a bicell is about 20% greater than that of a knife-edge photodetector. It has the advantages of small size and economy. The nominal risetime of the UDT SPOT2D is of the order of 10 ns. Furthermore, two-axis detection can be readily obtained with a quadcell, with an increase in risetime due to the increased capacitance of the detector.

FIGURE 6.123 Ratio of difference voltage to sum voltage vs. displacement for Sitek 1L10 continuous PSD.

The disadvantages due to small laser beam sizes and small displacements are overcome by the continuous PSDs. Since these devices are typically much larger (available in several-inch diameters), they typically have longer risetimes than the other PSDs. However, the Sitek 1L10, with a 10 mm linear active range has a measured upper half-power frequency of 3 MHz.

In applications where the output signal from a PSD must be linearly proportional to the displacement of the beam, analog-divider operational amplifiers to obtain V_d/V_s in real time are used to extend the range of linearity of the device. Unfortunately, the frequency response of these amplifiers are often the frequency-response-limiting factors of the PSD system. In cases where high-frequency response is important, V_d alone can often be used if care is taken to operate in the linear range of the device. For large static displacements that are of the order of the size of the detector, V_d and V_s can be recorded with computer-controlled data acquisition, the calibration characteristic numerically fitted to a polynomial, and then any voltage from the detector can be related to beam position.

The noise limitations in OBD sensing are due to the laser, the nature of the reflecting surface, and the PSD. Lasers with good amplitude stability are to be preferred, but this is not an important contribution to noise when V_d/V_s is used to infer displacement. Laser beam-pointing stability, on the other hand, is important. If the reflecting surface is that of a typical solid, then negligible noise is introduced on reflection; this may not be true for a reflector such as a pellicle, where Brownian motion of the surface may be significant. The noise limitations of the PSD are the usual ones associated with the photodetector and the amplifiers.

7.2 Future Directions in Thickness Measurement

Concerning Techniques Mentioned Above • THz Technology • Nanoscale-Scanning Probe Microscopy

One can measure thickness on many scales. The galaxy is a spiral disk about 100 Em (10^{20} m) thick. The solar system is pancake-like, about 1 Tm (10^{12} m) thick. The rings of Saturn are about 10 km thick. Closer to home, Earth's atmosphere is a spherical shell about 40 km thick; the weather occurs in the troposphere, about 12 km thick. The outermost shell of the solid Earth is the crust, about 35 km thick. The ocean has a mean depth of 3.9 km. In the Antarctic, the recently discovered objects believed to be microfossils indicative of ancient Martian life are less than 100 nm thick. In terms of the man-made environment, industry must contend with thickness varying from meters, for construction projects, to millimeters on assembly lines, to micrometers and nanometers for the solid-state, optical, and coatings industries. Perhaps the most familiar way of measuring thickness is by mechanical means, such as by ruler or caliper. Other means are sometimes called for, either because both sides of an object are not accessible, the dimension is either too big or too small for calipers, the object is too fragile, too hot, or too cold for direct contact, or the object is in motion on an assembly line — it may not even be a solid. Thickness may also be a function of position, as either the object may have originally been made with nonuniform thickness, deliberately or not, or the thickness may have become nonuniform with time due either to corrosion, cracking, or some other deterioration. The thickness may also be changing with time due to deliberate growth or etching, as example for thin films. Thus it follows that, in more general terms, measuring thickness might require measuring the topography or height profile of two surfaces and taking the difference. Alternatively, the measurement technique may produce a reading directly related to the difference. [Table 7.1](#) lists some of the many techniques suited to determining thickness, together with the range of usefulness and some comments on accuracy and/or precision.

TABLE 7.1 Thickness Measuring Techniques

Technique	Range	Comments
Mechanical		
Caliper gage, micrometer	1 μm –100 mm	$\pm 3 \mu\text{m}$ accuracy
Electronic gages: LVDT	0–1 m	Precision depends on noise level
Pneumatic gaging	50 nm minimum	
Optical/focusing, shadowing, comparing		
Microscope	5 μm minimum	About 1% accuracy
Comparators/projectors	25–250 nm	
Laser caliper	100 μm –100 mm	Precision of 6 μm or better
Weighing	Range depends on area	
Capacitive gaging	From <1 μm to about 1 cm	
Inductive gaging (eddy current sensing)	0–1.5 mm	Precision of 2.5 μm
Magnetic induction	0–4 mm	10% accuracy
Hall effect gage	0–10 mm	1–3% accuracy
Far-field/time-of-flight		
Sonar/ultrasound	0.5–250 mm	25 μm accuracy
Radar	0.1 to few hundred km	
Lidar	10 m–5 km	
THz technology		
Far-field/resonance		
Resonant ultrasound		
Interferometry: spectral and spatial	1 nm–100 μm	Accuracy about $\lambda/50$
Ellipsometry	0.3 nm–10 μm	0.1 nm accuracy
Far-field/absorption, scattering, emission		
Gamma-ray backscatter	Range to 25 mm	0.5% precision
Beta-transmission	2 μm –1 mm	0.2% precision
Beta-backscatter	100 nm–50 μm	3 to 20% precision
X-ray fluorescence	0–30 μm	
Infrared absorption	Depends on material	
Scanning techniques: scanning probe microscopy		Precision better than 0.1 nm
Destructive techniques: electrolytic	15 nm–50 μm	

7.1 Descriptions of the Relatively Mature Measuring Techniques

The following descriptions will also refer to some of the relevant vendors, whose addresses are found in [Table 7.2](#). Additional vendor information, with specific price or model number identification, is found in [Table 7.3](#). The words “gage” and “gauge” are used interchangeably.

Mechanical

The fundamental tool for measuring thickness is the line-graduated instrument [1, 2]. It is the only mechanical means to make direct measurements. Graduated spacings that represent known distances are used as direct comparisons to the unknown distance. Instruments include bars, rules, and tapes generically called rulers; caliper gages, which employ a positive contact device for improved alignment of the distance boundaries; and micrometers, which typically have greater precision due to a combination of linear and circumferential scales. Caliper precision can be improved with vernier scales or linear transducers. Fixed gages are often used to measure objects on a pass/fail basis. An object of fixed geometry (length, tapered bore, thread, etc.) is compared to a test piece typically for part inspection. Variations include the master gage, an object used to represent the nominal dimension of the part; the limit gage, an object used to represent the limit condition for tolerance dimensioning; and gage blocks or Johansson blocks, an object of fixed length used as a dimensional reference standard. Dial indicators are used to sense displacement

from a reference plane and display the deviation thereof. The display can be electronically coupled for amplification and/or display purposes. The range of a measuring instrument may be extended if multiple copies of the object to be measured are available. For example, the thickness of a sheet of paper may be measured by a simple ruler if 500 sheets of paper are stacked. (Vendors: Brown & Sharpe, Starrett, Mitutoyo. Also see [3].)

Electronic Gages

A Linear Variable Differential Transformer (LVDT), utilizes multiple toroidal transformers to sense axial displacement of an iron core that is attached to a measuring contact, either directly or by another joint (such as a lever). The displacement has a direct correlation to the distance that other electronics display. Thus, the LVDT serves as a replacement for a lined ruler or micrometer, incorporating an electrical readout. (Vendors: Penny + Giles; Schaevitz; Transicoil Inc.; Trans-Tek.)

Pneumatic Gaging

Pneumatic gages have pressurized air exiting gage orifices. The air velocity differential or backpressure is a function of the separation of the gage and the part. In the direct or open jet method, the pressurized air experiences backpressure due to the impedances posed by the measured part. The typical scenario is that the gage head and the measured part have similar geometry (i.e., a cylindrical gage in a bored hole). By placing two gages on either side of a flat plate, the thickness may be inferred. In the indirect or contact method, the pressurized air pushes on a contact piece that directly contacts the part. Tolerances as small as 50 nm can be measured. (Vendors: Willrich Precision Instrument Co.; Moore Products Co.)

Optical: Focusing, Shadowing, Comparing

This includes microscopes, which can determine thickness either by comparison with a known reference, or by focusing on the front and rear surfaces of a sample, noting the difference in focus position. Comparators project onto a screen what might be noted through a microscope. Laser calipers retrieve dimensions by measuring the shadowing of a laser beam. (Vendors: NDC Systems for laser caliper; Scantron for laser profilometer.)

Weighing

Given a plate of material with known density, first measure the area with some type of calibrated video system. Then, a measurement of weight can be simply converted to an estimate of the thickness. As is common with this technique and most of the following techniques, estimating the thickness requires knowledge of some other property of the material to be measured — in this case, the density.

Capacitive Gaging

Capacitive gaging is realized by inserting a nonmetallic material into a known electric field. Knowing the gage sensor area and the material's dielectric constant, the thickness can be determined. Submicron thickness levels can be achieved. (Vendors: Ono Sokki; SolveTech.)

Inductive Gaging (Eddy Current Sensing)

The principle here is that ac currents in a coil induce eddy currents in a nearby conducting plate [4, 5]. These eddy currents can be sensed by a pickup coil, which may be the exciting coil or a second coil. The presence of the eddy currents manifests itself as a modification of the apparent inductance and/or the loss of the pickup coil. This technique is appropriate for nonferrous metals, and is especially sensitive to thickness variations due to flaws such as cracks or corrosion. There is one particular instance in which it is common to measure thickness rather than variations. That would be the thickness of a nonconducting coating on a nonferrous conducting substrate. The coating thickness creates a gap (lift-off) between the exciting coil and the eddy currents, thereby affecting the eddy current signal. The range of this technique would be about 1 mm. Fischer has an instrument designed for measuring the thickness of a newly laid road surface coating to a depth of 40 cm, by burying a conductive plate below the road. (Vendors: Fischer; deFelsko; CMI International.)

Magnetic Induction

This technique is also used to measure coating thickness, in this case a nonmagnetic coating on a ferromagnetic substrate. The nonmagnetic coating creates a gap (lift-off) between the ferromagnetic substrate and a probe. One way to measure the gap and thereby the thickness is by measuring the force required to pull away a magnetic probe. Another technique would be to magnetically couple the ferromagnetic substrate to a transformer core, with a gap between the substrate and the core. This technique would have a range of about 4 mm. CMI International has an informative brochure describing the relative merits of measuring coating thickness via eddy current, magnetic induction, beta-backscatter, microresistance, and X-ray fluorescence; the choice of technique depends, among other things, on the material to be tested. (Vendors: Fischer; CMI International; Electromatic; deFelsko.)

Hall Effect Gage

This sensor measures the thickness of nonferrous materials with 1% accuracy by sandwiching the material being measured between a magnetic probe on one side and a small target steel ball on the other side [6].

It measures up to 10 mm. The Hall effect sensor is used to measure the magnetic field, as a dc measurement; ac Hall effect measurements can be made more precisely because they eliminate bias and are done with less noise. (Vendor: Panametrics.)

Far-Field/Time-of-Flight: Ultrasound, Radar, Lidar

Using 1940s sonar principles and today's microprocessor technology, high-frequency (1–20 MHz) ultrasound waves can be used to measure thickness by sending pulsed sound waves through a material and measuring the transit time of the reflected signal [5, 7]. Knowing the sound velocity of the material, materials from 0.5 mm to 250 mm can be measured, often as fine as 25 μm . Media include metal, glass, ceramic, liquid, rubber, fiberglass, plastic, and concrete. Ultrasound can also be used to measure living tissues, as is often done in the agricultural and medical fields. Fat layers of cattle and pigs can influence marketability. Skin burn depths can direct treatment procedures. The depth of foreign objects in the body is useful for microsurgery. Ultrasonic thickness determination has expanded to include multidimensional echolocation applications, such as imagery and acoustic microscopes that can resolve in the submicron level. The principles behind ultrasound also apply to electromagnetic waves. In the gigahertz range, this is called radar. Radar can be used to estimate the thickness of atmospheric layers such as cloud layers. The light-wave version of radar, called lidar, can be used to measure the thickness of water vapor layers in the lower atmosphere. (Ultrasonic vendors: KTa-Tator; deFelsko; Stresstel; Magnetic Analysis Corp.; Panametrics; Electromatic.)

Far-Field/Resonance: Ultrasound, Interferometry, Ellipsometry

The idea here is that when waves such as ultrasound impinge on a plane-parallel slab of material, there will be reflected power from both the front and rear surfaces; depending on whether the slab thickness is an odd or even number of quarter-wavelengths, the reflected beams will be in constructive or destructive interference. If the frequency is swept, the distance in frequency between successive maxima and minima may be related to the slab thickness, if the index of refraction is known. Since the natural, or resonant, modes of an object depend on the properties and dimensions of an object, knowledge of the properties enables estimation of dimensions from the resonant frequencies. Compared with time-of-flight ultrasound, resonant ultrasound is much less common. It has been used to characterize concrete, and is quite sensitive to flaws, as anyone who has heard a cracked bell would know. Resonant techniques are much more common with visible [8], infrared, or microwave [4] radiation. Spectral interferometry would be appropriate to characterize the thickness of transparent substrates with reasonably flat surfaces, sufficiently parallel to one another. A common way to do this would be to measure a transmission spectrum with a spectrometer such as a Fourier transform spectrometer (FTS). The successive maxima and minima are here called the Fabry–Perot effect, and their appearance in a spectrum is called channeling. Thickness can also be measured with spatial interferometry, which is essentially a way of measuring surface topography. An example would be the phenomenon of Newton's rings, which occur when the surface to be tested is in contact with an optical flat. Using a transparent optical flat, transmit monochromatic light such as a mercury lamp through the flat and onto the interface between the flat and the test surface. If there are variations in the height of the test surface, then the two return beams from the optical flat and the test surface will alternate between constructive and destructive interference, producing fringes or rings. The sensitivity is not limited to the scale of the wavelength λ : with sufficient stability and signal-to-noise, dimensions down to 1/1000 of a fringe can be measured. With sources of longer coherence length, such as lasers, the test surface and the optical flat need not be in direct contact.

Another optical way to measure thickness is with ellipsometry [9], typically used to measure properties of thin, transparent films from a few tenths of nanometers to several hundreds of nanometers thick. This includes metals, as long as the metal is sufficiently thin to be partially transparent. By measuring the change in polarization state for nonnormal incidence light, both the thickness and refractive index of a thin layer may be inferred. Additional information (e.g., the properties of multiple layers) can be obtained

by varying the angle of incidence and by observing at multiple wavelengths. The ability to estimate both thickness and refractive index is an important advantage of this technique, as often the refractive index of a material in thin film form is not the same as the bulk value, and indeed may be a property of the deposition conditions. (FTS vendors: Bomem; Digilab; Mattson; Midac; Nicolet; Perkin-Elmer. FTS system pricing may range from about \$15,000 to over \$100,000, depending on the application. Spatial interferometer vendors: Zygo; Wyko, Phase-Shift Technology. Ellipsometer vendors: J.A. Woollam Co., Inc.; Rudolf Instruments; Sentech. The cost of an ellipsometer may range from \$10,000 for a manual, single-wavelength system to \$200,000 for an automatic, multiwavelength system. Microwave resonance vendor: Hewlett-Packard.)

Far-Field/Absorption, Scattering, Emission: Beta, Gamma, X-Ray, Infrared

These techniques depend on the extinction (scattering or absorption) or emission of photons or massive particles (electrons, protons, neutrons) when transiting the material to be measured. Typically, the extinction or emission shows an exponential dependence on thickness; the dependence becomes linear if the absorption is sufficiently low. These techniques, in particular gamma-ray backscatter and beta-ray transmission, are used to measure continuously moving web materials (paper, metals, fabrics) on assembly lines. Infrared absorption is also suitable if the moisture content is controlled. Beta-backscatter and X-ray fluorescence [10] are used for measuring coatings. In X-ray fluorescence, upon exposure to X-rays, certain elements fluoresce (emit) X-rays at characteristic wavelengths. The strength of this emission is related to thickness. These absorption/emission techniques may sometimes be better suited than time-of-flight ultrasound to the dimensional measurement of objects with complex shapes. (Gamma gage vendor; NDC Systems. X-ray absorption vendor: Measurex. X-ray fluorescence vendors: Fischer; NDC Systems; CMI International. Beta-backscatter vendor: Fischer; Electromatic; CMI International; Measurex. Infrared absorption vendor: NDC Systems. The prices for these systems will depend on the application; a typical system could cost \$500,000.)

Destructive Techniques

Fischer markets a system that removes a coating into an electrolyte and then electrolytically deposits the removed coating. The electrical charge required for deposition is related to the coating thickness.

7.2 Future Directions in Thickness Measurement

Concerning Techniques Mentioned Above

Concerning capacitive sensors, the NASA Langley Research Center is developing sensors based on patterns of conductors sandwiched between insulating layers. The presence of ice over the conductors changes the capacitance, providing a way of sensing ice build-up on aircraft wings. With respect to eddy current sensing, one limitation is that a nonsuperconducting sense coil responds best to high-frequency excitations, and not at all to dc magnetic fields. This limits the technique to fairly high frequencies and thus low penetration depths, since the skin depth becomes shallower with increasing frequency. One possibility is to use a SQUID (superconducting quantum interference detector) as the sensor, since the SQUID is probably the most sensitive sensor of dc and low-frequency magnetic fields. One disadvantage of the SQUID has been the need for liquid helium for cooling for low-temperature superconductors; with the recent availability of high-temperature superconductors (HTS, above 90 K) and now HTS SQUIDS, cooling can be done with liquid nitrogen or single-stage mechanical coolers. In the area of spatial interferometry, work at Lawrence Livermore National Laboratory replaces the reference surface with a single-mode fiber in a process called phase-shifting diffraction interferometry. A measurement accuracy of 1.44 nm rms is quoted, with a goal of 0.1 nm rms. (HTS SQUID vendor: Conductus.)

THz Technology

With the availability of femtosecond pulsed lasers, Bell Labs has been investigating a technique using 100 fs pulses to pulse an antenna in the range of 0.1 THz to 3.0 THz. The terahertz pulses are sent through the material to be tested, detected, and the received pulse shape is analyzed to extract constituent information. This technique may also provide information on thickness.

Nanoscale-Scanning Probe Microscopy

Scanning probe microscopes (SPMs) are used in a wide variety of disciplines, including fundamental surface science, routine surface roughness analysis, and spectacular three-dimensional imaging — from atoms of silicon to micron-sized protrusions on the surface of a living cell [11]. The scanning probe microscope is an imaging tool with a vast dynamic range, spanning the realms of optical and electron microscopes. It is also a profiler with unprecedented 3-D resolution. In some cases, scanning probe microscopes can measure physical properties such as surface conductivity, static charge distribution, localized friction, magnetic fields, and elastic moduli. As a result, applications of SPMs are very diverse. The scanning tunneling microscope (STM), the progenitor of SPMs, utilizes a sharp conductive tip with a bias voltage applied between the tip and the sample. When the tip is within 1 nm of the sample, electrons from the sample begin to tunnel through the 1 nm gap into the tip. If the bias voltage is reversed, the tunneling occurs into the sample. The tunneling current is a function of the separation. Both the tip and the sample must be conductors or semiconductors.

The atomic force microscope (AFM) utilizes a small tip at the end of a cantilever. Forces between the tip and sample cause a deflection in the cantilever, which is translated into a signal. The tip or sample can be scanned covering a large area, producing a topographical map. AFMs can be used on insulators or conductors. AFMs are used in two modes: contact and noncontact. In contact mode, the tip is brought within about 200 pm — about the length of a chemical bond. The electron clouds of the tip and sample atoms interact, netting a repulsive force. For this reason, the contact mode is also called repulsive. Vertical resolution of about 50 pm can be achieved. In noncontact mode, a vibrating cantilever is used in the attractive regime of the van der Waals interactions. The cantilever is typically 2 nm to 20 nm away from the sample surface and has low total force. Noncontact AFM is subsequently less sensitive; thus, sensitive ac detection systems must be employed. The low force does have the advantage of not contaminating the sample surface and is preferred for applications involving silicon wafers and soft or elastic tissues. In noncontact mode, the cantilever is resonated with a small amplitude. As the tip comes near the sample surface, the resultant force changes the spring constant, translating into a deviation of the resonance frequency. This change in resonance (or vibrational amplitude) reflects changes in the sample topology.

Intermittent-contact mode is a combination of noncontact and contact modes and best suited for soft, adhesive, or fragile samples. Contact mode can damage the tip and the sample due to frictional or shear forces and/or create data artifacts from tip/surface adhesion. Noncontact mode produces lower amplitudes and hence lower resolution. Furthermore, surface monolayers of adsorbed gases such as water vapor can produce erroneous results. Intermittent-contact mode avoids these pitfalls by placing the tip in contact with the surface, providing high resolution and then removing the tip to prevent dragging and/or lateral forces. The cantilever is resonated via a piezoelectric crystal (50 kHz to 500 kHz in ambient, 5 kHz to 40 kHz in fluids) overcoming the tip/sample adhesion forces.

In magnetic force microscopy (MFM), the noncontact mode is employed using a tip coated with a ferromagnetic film. Both magnetic and van der Waals interactions are present, but at larger tip/sample separations, the magnetic forces dominate. Multiple scans as a function of tip/sample distance allow differentiation of magnetic forces and topographic information. Magnetic domain structures are resolved to 50 nm via this technique. Current applications of MFM include data storage devices, imaging of micromagnetic structures, IC analysis, imaging of magnetotactic bacteria, and magnetic geophysics. Lateral force microscopy (LFM) is used to generate profiles of changes in surface friction and/or height variations. The probe tip is deflected laterally, indicating some sort of twist. Electronics measure the cantilever deflection. To differentiate between the two effects, LFM and AFM images should be obtained

simultaneously. Phase detection microscopy or phase imaging is an extension of intermittent-contact AFM. It utilizes the phase lag between the driving frequency (cantilever) and the output signal frequency, generating a map of specific mechanical properties such as adhesion, elasticity, and friction. Identification of contaminants, composite materials, and regions of hardness and low surface adhesion can be obtained at the nanometer scale. Additional techniques include force modulation microscopy, where a periodic signal is applied to the cantilever, generating a map of the sample's elastic modulus and/or contaminants; electrostatic force microscopy, where a charged tip is scanned over the sample, revealing the locally charged domains generating a map of the charge carrier density; scanning capacitance microscopy, where a charged tip, kept at a constant tip/sample distance, generates a map of capacitance correlated information such as dielectric material thickness and subsurface charge carrier distributions (i.e., dopant profiles of ion implanted semiconductors); thermal scanning microscopy, where the tip in noncontact mode and a bimetal cantilever are used to map the thermal conductivity of the sample. (Vendors: Park Scientific Instruments; Digital Instruments; Oxford Instruments.)

- 8.1 Proximity Definition
- 8.2 Typical Sensor Characteristics
- 8.3 Technologies for Proximity Sensing
Electro-Optical Sensors • Capacitive Sensors • Ultrasonic
Sensors • Magnetic Sensors

The objective of this chapter is to review the state-of-the-art in proximity-sensing technologies for robotics. Special attention is paid to the sensing needs of robotic manipulators for grasping applications, in contrast to the needs of mobile robots for navigation purposes. For a review of the application of proximity sensing to mobile robots, the reader is referred to [1].

Robotic sensors can be categorized into three groups: medium-range (object recognition and gross position/orientation estimation) sensors, short-range (proximity) sensors, and contact sensors. Recent literature [2–6] suggests that robotic end effectors should be equipped with both short-range proximity and contact sensors.

Proximity sensors should be able to measure the position and orientation (pose) of an object's surface. The range must be sufficiently large to compensate for uncertainties in the medium-range pose-estimation process, while maintaining sufficient accuracy to permit effective grasping of the object.

Transducers used by current proximity sensors vary in sophistication. Despite their great variety, however, these transducers and their accompanying electronic interface circuits (together comprising the proximity sensor) cannot presently meet the stringent robustness requirements of most industrial robotic applications. Novel sensing algorithms and techniques still must be developed in order to improve on their current characteristics, and, furthermore, to control both the sensing and grasping processes.

8.1 Proximity Definition

The term “proximity,” quantified by “pose” in this chapter, refers to three geometrical parameters x , u , and v as shown in [Figure 8.1](#), where:

x = the translation from the origin of the sensor's reference coordinate frame, F_p , to a target point on the surface of the object measured along X_p . This target point defines the origin of the surface-frame, F_r .

u = the *vertical* orientation of the object's surface, defined as a rotation around Y_p (of the translated frame), thereby specifying the new Z_r .

v = the *horizontal* orientation of the object's surface, defined as a rotation around Z_r , thereby specifying Y_r .

FIGURE 8.1 Proximity parameters.

8.2 Typical Sensor Characteristics

Conventionally, proximity sensors should be capable of measuring distances of up to 50 mm, and two degree-of-freedom orientations equivalent to an overall inclination of up to $\pm 30^\circ$. The intended principal application of the sensor is to act as a guide for the robot. Thus, it would be desirable to have higher sensitivity and accuracy as the gripper approaches the object, namely when both the relative orientation and the distance approach near-zero values.

The signals received by the electronic interface circuit should be processed without limiting the required operating range of the sensor. The interface circuit should also minimize the effect of interference from the surroundings. It should therefore employ solutions to reduce background-noise interference and dynamic-range limitations.

The operation of the robot should not be slowed down by the sensor. Namely, a pose of the object should normally be estimated in 1 ms to 10 ms.

8.3 Technologies for Proximity Sensing

Proximity sensors have employed various transduction media, including sound waves, magnetic fields, electric fields, and light. Presently, electro-optical techniques seem to be the most appropriate for robotic-grasping applications. Such sensors are relatively small in size, have a large range of operation, and impose almost no restrictions on the object's material. However, recently, some new ultrasonic and capacitive proximity sensors have been fabricated directly as ICs, also showing the possibility of very-small-size proximity sensors based on these technologies [7, 8].

Brief descriptions of the principles of the primary technologies used by proximity sensors are given below, with the main emphasis being on optical transducers. A survey of commercial proximity sensors capable of measuring distances can be found in [6].

FIGURE 8.2 The basic phase-modulated proximity-sensor configuration.

Electro-Optical Sensors

Many proximity sensors use light, directly scattered from a target surface, to determine the distance and orientation of the target object from the gripper. The mechanism by which light is reflected can be explained by a model that specifies four different reflection phenomena. According to this model, light reflects from the surface primarily as a result of one or more of the following interactions:

1. *Single surface reflection*: Light waves that reflect specularly a single time off a planar microfacet, whose dimensions are significantly larger than the wavelength.
2. *Multiple surface reflection*: Light waves that reflect specularly at least twice between multiple microfacets.
3. *Reflection after penetration*: Light waves that penetrate into the material, refract, and then reflect back out as diffused light.
4. *Corner reflection*: Light waves that diffract from interfaces with surface details about the same size or smaller than the wavelength (such as from corners of microfacets).

The primary phenomenon (1) usually exists in both dielectrics and metal. However, due to the high conductivity of metal surfaces, most of the light reflects specularly off the interface between the metal and the air, while the portion that penetrates into the metal surface is absorbed. Accordingly, the reflection intensity originating from internal refraction in metals is practically zero. In dielectrics, however, a large portion of the light penetrates into the surface, and then reflects back out as diffused light (3). The secondary phenomena (2) and (4) exist both in metals and dielectrics and add to the diffused reflectance.

Common measurement techniques used in optical proximity sensing utilize one or more of the reflected components to determine the pose of the object in relation to the transducer.

Phase Modulation

A phase-modulated (PM) proximity sensor usually consists of two light sources and one or more photodetectors. The light sources are driven by modulated sinusoidal signals having a 90° phase relationship (Figure 8.2).

The emitter control voltages of the emitters, V_{em1} and V_{em2} , have amplitudes of a and b , respectively:

$$V_{em1}(t) = a \cdot \cos \omega t \quad (8.1)$$

$$V_{em2}(t) = b \cdot \sin \omega t \quad (8.2)$$

FIGURE 8.3 Sensor head reported in [9].

The signal detected by the receiver is a superposition of the two reflected signals, having corresponding attenuations of A and B .

$$V_{\text{rec}}(t) = A \cdot V_{\text{em1}} + B \cdot V_{\text{em2}} \quad (8.3)$$

The signal attenuation is a function of the geometrical and electrical parameters of the sensor, the reflectivity characteristics of the object's surface, and the surface's distance and orientation with respect to the sensor. The combined signal at the receiver is therefore:

$$V_{\text{rec}}(t) = M \cdot \sin(\omega t + \phi) \quad (8.4)$$

where M = the combined attenuation-function, and
 ϕ = the combined phase-shift.

Usually, only the phase information ϕ is used, and the amplitude is completely neglected or used only for verifying the likelihood of error and its potential magnitude.

A proximity sensor that uses this technique has been reported in [9]. Figure 8.3 shows a *sensor head*; it comprises six light sources (LEDs) and a photodetector (a phototransistor). This sensor can measure the distance from the sensor's coordinate frame to the target point on the surface of the object (x), as well as the horizontal and vertical orientation of the object surface (u , v).

A simple model for the sensor was developed assuming that the light sources (LEDs) have low directivity, the photodetector (phototransistor) has high directivity, and the surface has diffused reflectivity. Figure 8.4 shows the basic configuration for the measurement of distance (x) and orientation (u and v). Table 8.1 shows the combinations of the driving signals in each LED needed for the measurement of distance and orientation.

For the measurement of the distance x , LED1 and LED3 are modulated by $K_1 \sin \omega t$, and LED2 and LED4 by $K_2 \cos \omega t$, respectively. The brightness detected by the photodetector can be calculated (using Lambert's law) to be:

$$L_p = C \left(G_1 \frac{\cos(\alpha - \nu)}{a^2 + x^2} + G_2 \frac{\cos(\beta - \nu)}{b^2 + x^2} + G_3 \frac{\cos(\alpha + \nu)}{a^2 + x^2} + G_4 \frac{\cos(\beta + \nu)}{b^2 + x^2} \right) \quad (8.5)$$

where G_i ($i = 1, 2, 3, 4$) are the intensities of the light sources, and C is the reflection factor of the surface at point P . Considering that for this case: $G_1 = G_3 = K_1 \sin \omega t$, $G_2 = G_4 = K_2 \cos \omega t$, $\cos \alpha = x / \sqrt{a^2 + x^2}$ and $\cos \beta = x / \sqrt{b^2 + x^2}$, Equation 8.5 can be rewritten as:

FIGURE 8.4 Measurement parameters for the sensor reported in [9].

TABLE 8.1 Combinations of the LED Driving Signals

Mode	LED1	LED2	LED3	LED4	LED5	LED6
Distance (x)	$\sin \omega t$	$\cos \omega t$	$\sin \omega t$	$\cos \omega t$	—	—
Orientation (u)	—	$\cos \omega t$	—	$\sin \omega t$	—	—
Orientation (v)	—	—	—	—	$\cos \omega t$	$\sin \omega t$

$$L_p = 2Cx \left\{ \frac{K_1}{(a^2 + x^2)^{3/2}} \sin \omega t + \frac{K_2}{(b^2 + x^2)^{3/2}} \cos \omega t \right\} \cos v = M \sin(\omega t + \phi_x) \quad (8.6)$$

The amplitude M and the phase shift ϕ_x are given by:

$$M = 2Cx \left\{ \frac{K_1^2}{(a^2 + x^2)^3} + \frac{K_2^2}{(b^2 + x^2)^3} \right\}^{1/2} \cos v \quad (8.7)$$

and

$$\phi_x = \tan^{-1} \left[\frac{K_2 (a^2 + x^2)^{3/2}}{K_1 (b^2 + x^2)^{3/2}} \right] \quad (8.8)$$

From Equation 8.8, it can be observed that the distance (x) can be obtained from ϕ_x . It is important to note that, in theory, the calculation is not affected by the reflection factor (C) of the surface.

FIGURE 8.5 The basic amplitude-modulated proximity sensor configuration.

Similarly, the orientation angles u and v can be obtained by driving the LEDs as indicated in Table 8.1. For example, v can be determined by modulating LED4 and LED2 by the signals $K_1 \sin \omega t$ and $K_2 \cos \omega t$, respectively. For this case, the phase shift associated with the brightness of the object at point P is given by:

$$\phi_v = \tan^{-1} \left[\frac{K_2 (x - b \tan v)}{K_1 (x + b \tan v)} \right] \quad (8.9)$$

Note that, in order to recover v from Equation 8.9, x must be known. Accordingly, the distance x must be determined first. Correspondingly, the orientation angle (v) can be calculated from the new phase shift ϕ_v . The angle u can be calculated by modulating LED6 and LED5 with $K_1 \sin \omega t$ and $K_2 \cos \omega t$, respectively, and then determining the corresponding phase shift of the associate brightness at point P .

The pose-estimation results using this sensor were quite satisfactory and showed a good agreement between the theory and experiment.

In [10], an experimental setup of a PM distance sensor, similar to the one in [9], was reported for investigating the effect of the geometric and electronic parameters on the performance of the sensor. Optimal parameters were obtained for some targeted sensor-operation characteristics.

Amplitude Modulation

In amplitude-modulated (AM) sensors, the magnitude of the light reflected from a surface is utilized to determine the pose of the object.

AM transducers usually consist of one light source and several photodetectors (Figure 8.5). They were redesigned and optimized several times over the past decade to yield better measurement accuracy [11–14].

Many AM proximity sensors utilize optical fibers to illuminate and collect light from the surfaces of objects. The use of optical fibers, in a Y-guide configuration (Figure 8.6), facilitates the operation of sensitive low-noise circuitry in a shielded environment appropriately remote from the robot's electromagnetic interference sources.

AM transducers primarily use variations of the basic Y-guide transducer. Two important parameters can be varied in the design of Y-guides: the distance, d , between the emitting and receiving fibers (referred to hereafter as the emitter and the receiver, respectively), and the inclination angle, ϑ , of the receiver fiber with respect to the transducer's surface. The emitter is usually placed perpendicular to the transducer's surface, due to symmetry requirements, as will be explained later in this section.

The collection of a sufficient amount of reflected light requires the use of relatively wide-diameter fibers, typically having a 0.3 mm to 2 mm core size. This requirement demands the use of relatively low-grade plastic fibers. Although attenuations of up to 1 dB m^{-1} are common in such plastic fibers, this loss rate is relatively insignificant for Y-guide applications because of the short length of the cables normally used. The numerical aperture (NA) of the plastic fibers, on the other hand, is an important parameter

FIGURE 8.6 Y-guide transducer.

FIGURE 8.7 Y-guide response for distance measurement.

FIGURE 8.8 Typical receiver-pair constellation for orientation measurements.

in the transducer design, since lenses are rarely used in conjunction with AM-type transducers. In particular, the acceptance angle of the fiber is fixed and given by $\alpha = 2\sin^{-1} \text{NA}$.

For a Y-guide, the intensity of the light reflected from the surface is not a monotonic function of the distance. Thus, the minimum operating distance of the transducer (x_{min}) is usually limited to a value that will guarantee a monotonic response (Figure 8.7).

For the measurement of surface orientation, a symmetrical three-fiber constellation (Figure 8.8) can be used. In this Y-guide configuration, the emitter is at the center and the two receivers are positioned symmetrically on either side [12]. The light intensities detected by the receivers, for the transducer shown in Figure 8.8, are illustrated in Figure 8.9 as a function of the surface orientation.

In the usual operating range of an AM transducer, the intensity of the light at the receiver is inversely related to the distance squared. As a result, it is conceptually possible to configure a transducer such that

FIGURE 8.9 The light intensity detected by each receiver as a function of the surface orientation (u).

FIGURE 8.10 An asymmetrical receiver-pair constellation for distance measurements.

its sensitivity and accuracy will increase as the gripper nears the contact point, at which both the distance and the orientation of the object's surface are zero [10, 12]. However, in practice, because of the limited dynamic range of the electronic transducer interface, a trade-off exists between the desired maximum accuracy near contact, and the maximum range of operation. These and other considerations must be taken into account when establishing the geometric features of the transducer.

Another important factor to take into account in the design of an AM sensor is the need to reduce, as much as possible, the effect of the variation in the emitting power of the light source, P_o , on the transducer's measurements. This normally leads to the employment of a pair of receivers. A normalized differential voltage (DV) estimation scheme, such as the following, is then applied to the pair of measurements:

$$DV = \frac{V_{rec_1} - V_{rec_2}}{V_{rec_1} + V_{rec_2}} \quad (8.10)$$

where V_{rec_1} , V_{rec_2} are the voltages measured by receivers 1 and 2. However, in order to eliminate the effect of P_o on DV, each receiver must linearly convert the light intensity to a corresponding voltage measurement.

In order to use a DV scheme for the measurement of distance, an asymmetrical transducer configuration can be used (Figure 8.10). However, one must note that, although orientation measurements are not affected by variations in distance, distance measurements are significantly affected by the orientation of the surface, e.g., [15].

Accordingly, in using an AM proximity sensor with a DV scheme, the orientation is first approximated, and subsequently the distance is determined. The accuracies of the measured distance and orientation angle can be further improved by an iterative process.

FIGURE 8.11 AM transducer design for the sensor reported in [14]: (a) top view; (b) front view.

Based on the above issues and observations, the outputs of the three receivers of the basic AM proximity sensor (Figure 8.5) can be paired for measuring both distance and orientation: the pair rec_1-rec_2 can be used for orientation measurement, while the pair rec_1-rec_3 can be used for distance measurement.

An experimental AM proximity sensor, capable of estimating the pose of an object with high accuracy, was reported in [14, 16, 17]. The transducer consists of one emitter, placed perpendicularly to the sensor head, and eight inclined receiver elements (Figure 8.11). The receivers of this transducer were paired for the specific measurements of distance, as well as of the vertical or horizontal orientation. However, the pose of the surface was determined with higher accuracy by using a polynomial fit technique (as opposed to the DV scheme described above), that provided relationships between the individual estimated parameters (x , u , and v) and all eight signals received.

The sensor presented in [14], and shown in Figure 8.11, operates in the range of 0 mm to 50 mm and $\pm 20^\circ$. It can achieve an accuracy of $6.25 \mu\text{m}$ in distance and an accuracy of 0.02° in angular measurements in the near-contact region (0 mm to 6 mm range), using a general calibration-per-group strategy for different material groupings. This implies that the measured object's material belongs to a calibration group, which includes similar object surface characteristics; for example, machined metals. Better accuracies can be achieved using a calibration-per-surface strategy.

A similar configuration to the one shown in Figure 8.11 was reported earlier in [18] for the measurement of distances, where the orientations of each receiver pair relative to the emitter ϑ_1 and ϑ_3 were set at 10° . However, in this case, the apertures of the emitter and receiver were severely restricted by a collimating graded index (GRIN) lens. The emitter diameter was larger than that of the receivers in order to transmit more light. The measurements of the transducer were then processed in two phases: (1) the DVs of all the receiver pairs were processed independently to provide four distance estimations; and, (2) the four distance estimations were then averaged to provide a more accurate estimate, eliminating adverse effects due to variations in surface orientation.

FIGURE 8.12 Basic principle of a proximity sensor for measuring distance based on triangulation.

Geometrical Techniques

Proximity sensors based on geometrical techniques determine the pose of the object by examining the geometrical attributes of the reflected and incident light beams. Two of these techniques, one based on triangulation and the other based on the Gaussian lens law, are presented here.

Figure 8.12 shows the basic configuration of a proximity transducer for measuring distance (x) based on the triangulation technique [19, 20]. The sensor head consists of a laser light source and a linear array of photodetectors (R_i , with $i = 1, 2, \dots, n$). A narrow light beam illuminates point P , and the receivers detect the reflected light from the illuminated point through a transmitting slit. The geometry of the ray trajectory provides the basic information for the estimation of the distance (x). While the light source illuminates the surface of the object, the photodetector array is scanned to detect the light path used for making the output signal maximum. The light path obtained by this scanning is called the effective light path [19]. This light path is the one indicated in Figure 8.12. The distance (x) can be determined by accurately detecting the position (y_i) and precisely measuring the dimensions (h) and (y_o),

$$\frac{x}{x+h} = \frac{y_o}{y_i} \quad (8.11)$$

or

$$x = \frac{y_o h}{y_i - y_o} \quad (8.12)$$

In [26], it is claimed that such a sensor has the following properties: (1) the influence of irregularities, reflectivity, and orientation of the object is negligible; (2) the distance measurement is not affected by illumination from the environment and luminance of the object (their influence is eliminated by comparison of two sensor signals obtained in successive on-and-off states of the light source); and (3) the sensor head is sufficiently small to be used in a robot hand.

An experimental proximity sensor configuration, based on triangulation and capable of measuring both distance and orientation, is shown in Figure 8.13 [21]. The sensor uses six infrared LEDs as light sources, an objective lens, and an area-array detector chip for detecting spot positions. The directions of

FIGURE 8.13 Multilight source proximity sensor reported in [21].

the beams are aligned to form a fixed cone of light. This sensor is of a type called scanning-emitter since each LED is sequentially pulsed to perform the measurements. As each LED is sequentially pulsed, the sensor IC detects the position of the spot projected by the reflected light beam from the object's surface. Knowledge of the spot's position, together with the camera's optics and the trajectory of each light beam, can be used to perform a triangulation to determine the three-dimensional coordinates of each light spot on the target surface. A set of six 3-D points are obtained for the six LEDs. Then, by fitting a plane to those points, the distance and orientation of the object's surface are approximated.

Another scanning-emitter-type proximity sensor was reported in [22]. In this case, a mechanical scanning system was utilized. One notes that inherent problems with sensors that use mechanical scanning devices include lower reliability and increased overall size.

Some recently reported triangulation sensors are sufficiently small in size to be mounted on a gripper [5]. However, they are still susceptible to errors due to distortion and separation of the light beam's reflection caused by surface irregularity, and can also have blind spots as a result of discontinuities associated with the shape of the sensed object.

Another group of geometrical electro-optical proximity sensors are those based on the Gaussian lens law [23, 24]. The basic configuration of such a transducer is shown in Figure 8.14. A light beam, collinear to the optical axis, forms a spot on the target's surface. The light scattered from the spot is collected by the lens. In Figure 8.14, PN represents the limiting ray that can be collected by the lens. The target distance (x) can be calculated in terms of the focal length of the lens (f) and the image position (w). Applying the Gaussian lens law, the distance x can be calculated as:

$$x = \frac{fw}{w - f} \quad (8.13)$$

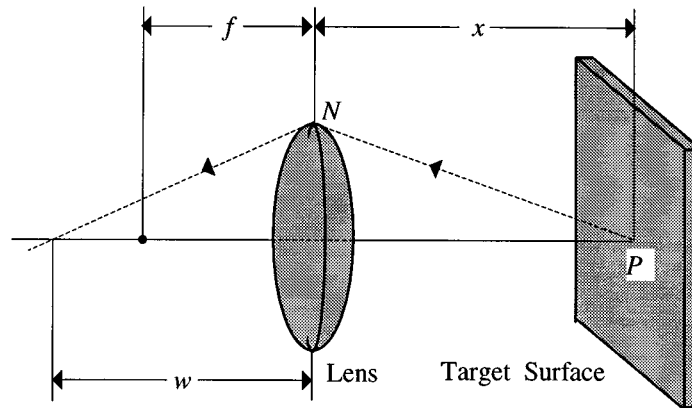

FIGURE 8.14 The principle of proximity sensing based on the Gaussian lens law reported in [7].

FIGURE 8.15 Configuration of HexEye (top view).

A proximity sensor (the HexEye) based on this lens principle is shown in Figure 8.15 [23, 24]. The sensor consists of seven identical “sensing units” arranged in a hexagonal pattern. Each sensing unit in turn comprises four main parts: an objective lens, a conical mirror, six linear receiver arrays, and a laser diode light source.

The light beam generated by a light source forms a spot on the target surface, and the light flux scattered from the spot is collected by the objective lens and projected onto the receiver arrays in each sensing unit. The target distance is determined by the position, size, and shape of an image formed on individual receiver arrays of the unit.

The sensor operates in two modes, either distance or orientation. In the distance measurement mode, the seven light sources are activated one at a time to generate a light spot on the target surface, while all the sensing units receive the light flux scattered from the same light spot. The active unit determines the distance using the principle of the Gaussian lens law, while the nonactive units determine the distance based on triangulation. For the orientation measurement mode, the seven sensing units are grouped into orientation measurement units (OMUs). Each OMU comprises three neighboring sensing units around the center, resulting in a total of six possible OMUs. The local orientation of the surface is estimated by integrating the six orientation measurements.

The mapping between the light distribution on the arrays of light detectors and the target distance is obtained through calibration. Using the light distribution (instead of light intensity as in the case of AM sensors), it is intended that the mapping be independent of surface properties such as color, material, diffusion, and reflectance factors. However, it has been shown that the mapping may be corrupted by “noise” from several sources, including reflection patterns and ambient light.

FIGURE 8.16 Capacitive proximity sensor based on the principle of parallel plates, (a) structure and (b) sensor response.

Using the Gaussian lens law has the following advantages over the triangulation principle: (1) the light source can be located at the center of the objective lens, allowing not only the sensor to be compact, but also the amount of light flux input to the lens to be maximized, and (2) the sensitivity can be optimized for a certain range of measurement distance by controlling f .

Time-of-Flight

Time-of-flight-measuring electro-optical sensors are radar-type systems. However, unlike regular radar, which transmit a pulse of radio-frequency energy, these sensors normally use a modulated light beam. The distance to the target is extracted from the measured phase shift of the reflected light. Two problems associated with such sensors are: difficulty in measuring short distances (which requires a very high modulation frequency), and the need for a mechanical scanning/switching system to get additional information (such as orientation) [5, 25].

Photothermal Effect

The photothermal effect transducer uses a strong light beam directed toward the object's surface. The distance to the object is extracted from measurements of the thermal wave generated by the light absorbed by the object. The detection scheme and signal processing are similar to those used in an AM sensor. Since the shape of the thermal wave generated at the surface is surface-texture independent, the photothermal sensor does not suffer from the surface robustness problem associated with AM sensors. However, the photothermal sensor is rather slow, and limited to highly absorbing surfaces [26].

Capacitive Sensors

Capacitive sensors generate and measure changes in an electric field caused by either a dielectric or conducting object in their proximity.

There are basically two types of capacitive proximity sensor. One type uses the principle of a parallel plate capacitor, the other uses the principle of fringing capacitances [8, 27, 28]. For the parallel plate type proximity sensor, the transducer forms one plate and the object measured forms the other plate. The structure of a parallel plate type proximity sensor and its typical response are shown in [Figure 8.16](#) [8].

The parallel plate type proximity sensor is widely applied in industry. However, this type of a sensor has three major limitations: (1) the object being measured must be conductive; (2) the inverse gap-capacitance relationship is highly nonlinear and (3) the sensitivity drops significantly in the case of large gaps.

The second type of capacitive proximity sensor uses the principle of fringing capacitance [8]. The sensor has two "live" electrodes and the object being measured does not need to be part of the sensor system. The target object could be either conductive or nonconductive. However, the measurement of distances is affected by the type of object material. Therefore, separate calibrations must be carried out for different materials.

FIGURE 8.17 (a) Configuration of the ultrasonic sensor and (b) surface inclination versus δ .

In [30], an innovative capacitive microsensor was presented. Using micromachining technology, the electrode thickness can be significantly reduced and the fringing effect increased when compared with other capacitive sensors. Consequently, this sensor yields a better sensitivity. An array of such transducers can be implemented to measure the distance and orientation of an object.

Proximity capacitive sensors have the following general advantages: (1) low energy consumption and (2) simple structure. The major disadvantages, however, are that they are influenced by external signals and a calibration-per-surface technique must be carried out, since their operation directly depends on the object's material.

Ultrasonic Sensors

The basic principle underlying ultrasonic ranging sensors is the measurement of the time required for a sound wave to travel from the emitter to the object's surface and return to the detector. By using several such emitters and detectors, one can obtain information about the distance and orientation of the surface.

In [19], a novel method is proposed to measure the orientation angles of an object's surface using the phase differences of reflected echoes. Figure 8.17(a) shows the configuration of a planar sensor head with n receivers, which are equally spaced and located on a circle of radius R around the transmitter T. A linear relationship exists between the difference in lengths, δ , of two reflecting paths for an adjacent pair of receivers and the object inclinations.

In Figure 8.17 (b), the relationship between the inclination of the target surface and δ is shown. It can be observed that the measuring range of the sensor can be enlarged with an increase in the number of receivers. In [29], it is also shown that the measuring range can be enlarged by reducing R . However, it was noted that measurements carried out with a small sensor are potentially less accurate.

Experimental results using a transducer with six ($R = 30$ mm) and eight ($R = 20$ mm) receivers were reported in [29]. With the six-receiver transducer, the measuring range of the orientation angles was $\pm 15^\circ$; while for the eight-receiver transducer, the maximum measuring range was $\pm 30^\circ$. With the six-receiver transducer, the orientation angle could be determined with an accuracy of 0.5° , in the measuring range of $\pm 15^\circ$, and 0.2° when the range was restricted to $\pm 5^\circ$.

One of the major disadvantages of ultrasonic proximity sensors is that they are relatively large in size. However, implementing these sensors using micromachining could solve this problem. In [7], the generation and detection of ultrasound, for proximity sensing, was investigated using micromachined resonant membrane structures.

Magnetic Sensors

A magnetic-type sensor creates an alternating magnetic field, whose variation provides information about the object's position.

The simplest magnetic sensors are reed microswitches or Hall effect switches. However, the most commonly used sensors in robotics are based on the electromagnetic inductive principle, emphasizing

eddy current generation. The basic principle consists of creating a magnetic field using appropriate coils around a core with high permeability and an oscillator with a frequency excitation high enough to minimize the penetration of the field inside a conductive material. The main problems with magnetic sensors are their high size/range ratio and difficulty in providing reliable distance measurements in varying magnetic environments.

The tools and techniques of distance measurement are possibly one of humankind's longest-running inventive pursuits. The scale shown in [Figure 9.1](#) illustrates the enormous range of distances that science and engineering have an interest in measuring [1]. This chapter concerns itself with methods to measure a relatively small segment of this range — from centimeters to kilometers. Even within this limited segment, it would hardly be possible to list, much less describe, all of the distance measurement approaches that have been devised. Nevertheless, the small sampling of technologies that are covered here should be of help to a broad range of readers.

Distance measurement, at its most basic, is concerned with determining the length of a unidimensional line joining two points in three-dimensional space. Oftentimes, a collection of distance measurements is called for, so that the shape, the orientation, or the changes in position of an object can be resolved. Therefore, one must consider not only the measurement of distances, but also their spatial and temporal distributions. The terminology “ranging” will be used in reference to systems that perform single sensor-to-target measurements, “range-imaging” for systems that collect a dense map or grid of spatially distributed range measurements, and “position tracking” for systems that record the time history of distance measurement to one or several targets.

9.1 Basic Distinctions Between Range Measurement Techniques

Range measurement devices may be classified according to some basic distinctions. Generalizations can be made based on these broad classes, thereby facilitating the process of comparison and selection. The following subsections identify the fundamental bases for classification.

FIGURE 9.1 From the interatomic to the intergalactic, the range of measurable distances spans at least 30 orders of magnitude. The box outline indicates the relatively small segment that concerns this chapter.

Contact or Noncontact

A common approach to measuring the distance to a point on an object is through a calibrated mechanical device that simultaneously connects the selected point to a reference position. Any tape measure, feeler gage, or dial gage may be considered an example of a simple contacting measurement device. Mechanical/electronic devices are available that allow a user to “digitize” discrete point positions on a three-dimensional surface. A gimbaled probe on the end of an *X-Y-Z* positioner or articulated arm is used to touch a specific point, and sensory information of the linear positions or joint articulations provide an accurate position estimate. Mechanical, contact-based methods are widely used in industry and can be extremely accurate. Some coordinate measuring machines (CMMs), for example, can achieve $1\ \mu\text{m}$ repeatability.

The chief disadvantage of mechanical approaches is that they are usually restricted to distances and work volumes up to a few meters at maximum. This is due to fundamental scaling laws for mechanical structures. As the requirement to span larger distances increases, the mass and mechanical tolerancing requirements on the machine make designs impractical. Also, mechanical approaches are too slow to make multiple measurements in rapid succession, as is typically required in range imaging or position tracking, when the measurement involves large sets of spatially or temporally distributed data.

Noncontact techniques for performing ranging, range imaging, and position tracking are many and varied. Besl [2] reviews and compares several of these. In the centimeters to meters range, most do not approach the accuracy of CMMs; but at larger scales and for large quantities of data, they become a practical necessity. The rest of this chapter will review noncontact approaches only.

Active or Passive

Noncontact distance measurement may be divided into *active* or *passive* techniques. Active techniques involve some form of controlled energy (field or wave) linking a known reference location to the unknown target location. The source of energy is typically associated with the reference location, but in some cases the target, or both target and reference, may be active. Passive techniques rely on an externally occurring source of energy (e.g., sunlight or target/background temperature contrast) to make the target detectable.

An active approach can often simplify the distance measurement problem because it allows a greater degree of control over the many factors that can influence a measurement. For example, the choice of the form of energy and the power level of the active source can minimize the effect of uncontrolled variables like ambient illumination, weather, and atmospheric conditions. Furthermore, an active approach provides an opportunity to selectively localize the measurement spatially and temporally, eliminating possible ambiguity about which target point was measured at a given time. In contrast, passive

systems (e.g., stereo ranging) sometimes suffer from the so-called “correspondence problem,” which is concerned with how to determine whether a given target point, detected from two or more viewpoints, or over two or more instants, is in fact the same physical point.

A common use of active approaches is to make range measurements “through” materials that are mechanically or optically impenetrable. Examples include medical imaging, where various forms of directed energy (ultrasound, X-rays) are used to build surface or volumetric maps of organs and bones; sonar, which penetrates water better than light does; and ground-penetrating radar, which can detect objects and their depth beneath ground surface.

Passive approaches, while not offering the same range of control and flexibility of active approaches, offer certain advantages. First, because they emit no energy, their existence cannot be detected by another remote detection system. This feature is very important in military applications. Second, passive systems can often collect multiple point range measurements more quickly because they are not limited by the rate at which they can direct an energy source toward a target point, as is the case with most active systems. For example, a stereo ranging system effectively collects all resolvable target points in its field of view simultaneously, while a scanning laser, radar, or sonar ranging system collects each measured point sequentially. Finally, the absence of a directed energy source is a simplification that can significantly reduce the size, cost, and hardware complexity of a device (although at the expense of increased signal processing complexity).

Time-of-Flight, Triangulation, or Field Based

There are many different classes and instances of noncontact ranging devices, but with very few exceptions they are based on one of the following three basic principles:

1. Energy propagates at a known, finite, speed (e.g., the speed of light, the speed of sound in air)
2. Energy propagates in straight lines through a homogeneous medium
3. Energy fields change in a continuous, monotonically decreasing, and predictable manner with distance from their source

The techniques associated with these basic phenomena are referred to as time-of-flight, triangulation, and field based, respectively.

Time-of-Flight

Time-of-flight (TOF) systems may be of the “round-trip” (i.e., echo, reflection) type or the “one-way” (i.e., cooperative target, active target) type. Round-trip systems effectively measure the time taken for an emitted energy pattern to travel from a reference source to a partially reflective target and back again. Depending on whether radio frequencies, light frequencies, or sound energy is used, these devices go by names such as radar, lidar, and sonar. One-way systems transmit a signal at the reference end and receive it at the target end or vice versa. Some form of synchronizing reference must be available to both ends in order to establish the time of flight.

A characteristic of many TOF systems is that their range resolution capability is based solely on the shortest time interval they can resolve, and not the absolute range being measured. That is, whether an object is near or far, the error on the measurement is basically constant.

Triangulation

Triangulation techniques were known and practiced by the Ancients. Triangulation is based on the idea that if one knows the length of one side of a triangle and two of its angles, the length of the other sides can be calculated. The known side is the “baseline.” Lines of detection extend from either end of the baseline to the target point as shown in [Figure 9.2](#). If the angles formed between these lines and the baseline can be determined, the distance is calculated as:

$$R = b \sin \alpha_{\text{left}} \sin \alpha_{\text{right}} / \sin(\alpha_{\text{right}} - \alpha_{\text{left}}) \quad (9.1)$$

FIGURE 9.2 The basic triangulation geometry as used in classical surveying determines the distance to a remote point by sighting it from two locations separated by a known baseline. The pointing angles α_{left} and α_{right} are measured locally.

Classical surveying is a passive range-finding technique based on the above formula. A surveyor uses a precision pointing instrument to sight a target from two positions separated by a known baseline. Reference [3] notes that the distance to a nearby star may be calculated by observing it through a pointing instrument at 6-month intervals and using the diameter of Earth’s solar orbit as the baseline. Stereo ranging, which compares the disparity (parallax) between common features within images from two cameras, is another form of passive triangulation. It is of interest to note that human vision estimates distance using a variety of cues, but two of the most important — stereopsis and motion parallax — are fundamentally triangulation based [4].

Active triangulation techniques use a projected light source, often laser, to create one side of the triangle, and the viewing axis of an optical detection means to create the second side. The separation between the projector and detector is the baseline.

A fundamental issue for all triangulation-based approaches is that their ability to estimate range diminishes with the square of the range being measured. This may be contrasted with TOF approaches, which have essentially constant error over their operating range. Figure 9.3 illustrates how, conceptually, there is a “crossover” distance where TOF techniques become preferable to triangulation techniques.

Field-Based Approaches

Whereas TOF and active triangulation techniques employ the wave propagation phenomena of a particular energy form, *field-based* approaches make use of the spatially distributed nature of an energy form. The intensity of any energy field changes as a function of distance from its source. Moreover, fields often exhibit vector characteristics (i.e., directionality). Therefore, if the location of a field generator is known and the spatial characteristics of the field that it produces are predictable, remote field measurements contain information that may be used to infer distance from the source.

FIGURE 9.3 Time-of-flight (TOF) and active triangulation techniques tend to exhibit error characteristics related to their fundamental principles of operation. The dominant error source in TOF systems is usually the shortest measurable time interval, but this is a detection issue and is essentially independent of distance. Active triangulation systems are typically more accurate at close distances, but geometry considerations dictate that the effects of their error sources will increase with the square of distance.

An interesting distinction between field-based approaches and wave-based approaches is that the former, although they employ energy fields, do not rely on the propagation and conversion (and concomitant losses) of energy. That is, they may employ stationary fields, like those generated by a magnet or static charge. Such fields encode position information by their very shape. Sound and light, although having a wave nature, can be exploited in the same manner as stationary fields because of their distance-dependent intensity.

Field-based techniques must confront some basic issues that limit their range of application. First, the characteristics of most practically exploitable fields are typically influenced by objects or materials in the vicinity, and it is not always possible to ensure that these influences will remain constant. Second, the variation of fields through space is highly nonlinear (typically inverse square or inverse cube), implying that the sensitivity of a measurement is strongly affected by proximity to the source. Notwithstanding these concerns, devices have been developed and are available that perform very well in the situations for which they are intended [7].

Form of Energy

As discussed above, all noncontact, active ranging devices employ some form of energy. This is true whether time-of-flight, triangulation, or field-based principles apply. The following subsections describe the various forms of energy employed and some generalizations about the effectiveness of each in various situations.

Sound

Ranging systems based on sound energy are usually of the pulsed-echo TOF type and employ carrier frequencies in the so-called “ultrasonic” (beyond audible) range of frequencies. Besides being inaudible

(an obvious benefit), ultrasonic frequencies are more readily focused into directed beams and are practical to generate and detect using piezoelectric transducers. Ultrasonic signals propagate through air, but long-distance transmission is much more effective in liquids, like water, where higher density-to-viscosity ratios result in higher wave velocity and lower attenuation per unit distance. Ultrasonic ranging techniques (or SONAR, for SOund NAVigation and Ranging) were first developed for subsea applications, where sound is vastly superior to electromagnetic energy (including light) in terms of achievable underwater transmission distances [5]. Low-cost, portable sonar systems are widely used by sport fisherman as “fish finders” [6].

The frequencies typically used in sonic ranging applications are at a few tens of kilohertz to a few hundred kilohertz. A basic trade-off in the choice of ultrasonic frequency is that while high frequencies can be shaped into narrower beams, and therefore achieve higher lateral resolution, they tend to fade more quickly with distance. It may be noted that beam widths narrow enough for range imaging applications (less than 10°) are effective in a fluid medium, but attenuate too quickly to be practical in air. Interestingly, although sound energy attenuates more rapidly in air than in water, useful short-range signals can be generated in air with relatively low power levels because the much lower density of air requires smaller dynamic forces in the transducer for a given wave amplitude.

When comparing sound energy to electromagnetic energy for TOF-based techniques, one needs to remember that sound, unlike light, propagates at not only much lower speeds, but with considerably more speed variation, depending on the type and state of the carrying media. Therefore, factors like air humidity and pressure will affect the accuracy of a TOF ranging device. For underwater applications, salinity and depth influence the measurement. The lower speed of sound has a detrimental impact on the rate at which range samples can be collected. For example, a target 10 m away takes at least 60 ms to measure through an air medium. This may not seem like a long time to wait for a single sample, but it becomes an issue if the application involves multiple sampling, as in motion tracking or collision avoidance sensing.

Stationary Magnetic Fields

Stationary or pseudostationary (i.e., low frequency) magnetic fields are only used in field-based approaches. An advantage of such fields is that they are easily and cheaply produced by either a permanent magnet or electrical coil. Since stationary fields do not transmit energy, the targets cannot be passive — they must actively sense the properties of the field at their particular location. A variety of sensing technologies may be used to make measurements of the direction and intensity of a magnetic field, including flux gate, Hall effect, and magnetostrictive type magnetometers. A comprehensive list of such technologies is given in [7].

Radio Frequencies

Echo-type TOF ranging systems based on the band of the electromagnetic spectrum between approximately 1 m and 1 mm wavelength are known as RADAR (RADio Detection And Ranging). Radio waves can be used for long-distance detection in a variety of atmospheric conditions. As in the case of sound waves, there are trade-offs to be addressed in the choice of frequency. Long waves tend to propagate better over long distances, but short waves can be focused into narrow beams capable of better lateral discrimination. An interesting application of short-range radar is ground-penetrating radar, which can be used to locate and image subsurface objects [8]. Here, the frequency vs. range trade-off is particularly acute because of the need to balance reasonable imaging capability (narrow beam) with good depth penetration (long wave).

An example of a TOF one-way (active receiver) system that uses radio frequencies is the global positioning system (GPS). The distance between a receiver on land is determined by each of several orbiting satellites equipped with a transmitter and a very precise Cesium clock for synchronization. A good description of GPS and its use in vehicle navigation is available in [9].

Light Frequencies

Beyond the radio portion of the electromagnetic spectrum are the infrared, visible, and ultraviolet frequencies. These frequencies can be produced by lasers and detected by solid-state photosensitive devices and are useful for both TOF and active triangulation ranging. Echo-type TOF techniques are known as LIDAR (Light Detection And Ranging), in keeping with the terminology introduced earlier.

While light frequencies attenuate more than radio frequencies through cloud and fog, they can have very narrow beam widths, allowing superior lateral resolution and target selectivity.

Coherent or Noncoherent Detection

Echo-type TOF devices, whether sonar, radar, or lidar, can be further classified according to whether the detection approach measures time-of-flight directly (noncoherent) or exploits an inherent periodicity in the emitted energy to ascertain the flight distance (coherent).

Noncoherent techniques face the problem of timing short intervals. This is not a serious challenge in the case of sound waves, where a meter round trip corresponds to 6 ms, but is somewhat more problematic for light and radio waves, where that distance equates to only 6 ns. Accuracy of noncoherent detection typically relies on the averaging of repeated measurements.

Coherent detection is achieved by combining a portion of the emitted signal with the reflected signal to produce a third signal indicating the amount of phase delay. The signals are continuous wave (CW) as opposed to pulsed. Coherent detection techniques are classified as amplitude modulated (AMCW) or frequency modulated (FMCW).

A basic issue with coherent detection techniques is the inability to distinguish between integral multiples of the basic modulation wavelength. Any coherent detection system must employ techniques to resolve the so-called “ambiguity interval.” Noncoherent techniques do not face this problem.

Ranging, Range Imaging, or Position Tracking

Ranging devices are typically pointed toward a target to produce a single range reading. A common example of simple ranging is the feedback sensor used in auto-focus cameras. There are many active ranging devices currently available based on TOF (i.e., radar, sonar, lidar) and active triangulation principles.

Range imaging devices use the same principles as ranging devices, except that they include some form of scanning that is employed to generate an array of spatially distributed range samples. Sometimes, the scanning action is accomplished by means intrinsic to the sensor (e.g., spinning and nodding mirrors, or phased-array antenna) so that the reference location remains fixed. In this case, the data are recorded in the polar form (range, elevation, azimuth) as shown in [Figure 9.4](#). In other cases, the sensor might scan on only one axis internally while the second scan dimension is realized by moving the sensor location through some set pattern. It is not uncommon to record the “intensity” or return energy associated with a range sample as well. The intensity map may be presented as a “gray scale” image and, like a black and white photograph, often contains additional information useful in interpreting a scene. Range images can be used to produce three-dimensional graphic representations of scenes and objects. A common use of range imaging is aerial terrain mapping.

Position tracking devices are used to measure the change in an object’s position and orientation over time. Basic issues in position tracking are the acquiring of, and locking on to, specific target points. These issues can be avoided by employing active targets, and most systems available today are of this type.

9.2 Performance Limits of Ranging Systems

The performance characteristics of available ranging systems vary widely, as do the requirements of the applications for which they are designed. The following subsections review the most basic performance categories and the technical issues of performance limits.

FIGURE 9.4 Range images are typically an array of individual range values sampled while changing the pointing direction (e.g., azimuth and elevation angles) of a ranging device. A digital range image of the polar form shown can be readily transformed into rectangular coordinates if required.

Range Accuracy

As illustrated in Figure 9.3, TOF and active triangulation techniques differ fundamentally in their error vs. distance characteristics. Currently available systems based on active triangulation achieve better repeatability and accuracy in the less than 1 m range than do TOF systems, but are seldom used at distances of several meters. Hymarc Ltd. and Perceptron Inc. each offer laser triangulation systems with 3σ accuracy of 25 mm and 50 mm, respectively [10, 11].

In principle, TOF systems could achieve accuracy rivaling active triangulation, but the most promising detection technique — a variation of laser interferometry, which solves the ambiguity interval problem [12] — has yet to make its commercial debut.

Depth of Field

Depth of field refers to the interval of distance through which a stationary reference ranging system can measure without resorting to a change in configuration. Large depth of field is often an important characteristic in practical applications. For example, if the distance to the target is poorly known a priori, then a large depth of field is desirable.

Passive optical triangulation approaches like stereography and photogrammetry tend to have restricted depth of field because they rely on camera-type imaging, which is inherently limited by depth of focus. Timed-interval TOF systems have excellent depth of field because they do not rely strongly on optical imaging except to concentrate the collected return energy on the detector. Some active triangulation systems do rely on optical imaging of the projected laser spot, but the design employed by Hymarc Ltd. regains a large depth of field by tilting the detector array with respect to the lens plane [13].

Maximum Range

Any active ranging, range imaging, or position tracking system has a practical maximum distance that it can measure. This is because the controlled energy, whether propagated as a wave or established as a field, must spread before reaching the detector. The spreading inevitably increases with distance and all detectors, no matter what form of energy they measure, require a certain minimum amount to exceed their inherent “noise floor.”

The “classical radar range equation” is introduced in many texts on radar (e.g., [14]). Jelalian [15] points out that the equation is equally applicable to lidar, which, after all, just employs a higher frequency version of electromagnetic wave. In fact, the same idea applies to sonar and to active triangulation systems as well. The equation computes the power of the received signal as:

$$P_R = P_T G_T / 4\pi R^2 \times \rho A / 4\pi R^2 \times \pi D^2 / 4 \times \eta_{\text{atm}} \eta_{\text{sys}} \quad (9.2)$$

where P_R = power at the receiver
 P_T = power transmitted
 G_T = transmitter gain
 R = range to target
 ρ = reflectivity of target
 A = effective area of target
 D = diameter of collecting aperture
 η_{atm} = atmospheric transmission coefficient
 η_{sys} = system transmission coefficient

Equation 9.2 applies when the target area is smaller than the footprint of the incident beam, which is often the case for radar and sonar ranging. However, in the case of laser-based systems, the relatively narrow beam usually means that the laser spot is small compared to the target. For a transmitted beam that spreads with a solid angle θ_T , the illuminated patch area is:

$$\sigma_{\text{spot}} = \pi R^2 \theta_T^2 \quad (9.3)$$

The definition of transmitter gain is based on the notion of the solid angle beam width as compared to an omnidirectional transmitter

$$G_T = 4\pi / \theta_T^2 \quad (9.4)$$

One can substitute for Equation 9.4 for G_T and Equation 9.3 for the variable s in Equation 9.2 to produce the range equation for a small spot size.

$$P_R = P_T / R^2 \times \rho / 4 \times \pi D^2 / 4 \times \eta_{\text{atm}} \eta_{\text{sys}} \quad (9.5)$$

The importance of this equation is primarily in the $1/R^2$ dependence. Any ranging system that works by bouncing energy off a diffuse reflective target encounters severe signal attenuation with increasing distance. Given a detector with a fixed noise floor, the only ways to improve maximum range are to increase the transmitted power or the collecting area. In practice, there are design constraints that limit both of these measures. For example, laser power must sometimes be limited for eye-safety considerations, and increased collecting area can imply a proportional increase in sensor packaging volume.

Lateral Resolution

In range imaging applications, it is generally desirable to use the narrowest possible beam width to provide good lateral discrimination of target surface features. Lasers, because of their short wavelength, can be optically collimated to produce much narrower beam widths than are possible with radio sources. However, even lasers cannot produce arbitrarily narrow beams. The interested reader is referred to [13] for a discussion of Gaussian beam propagation and optimal focusing. There are basically two ways to project laser light. The beam can be “focused down” to produce the smallest possible spot at a particular point inside the measurement range, in which case the beam will diverge as the distance from that point increases; or the beam can be focused at infinity or some very distant point so as to minimize the divergence through the entire measurement range. The former approach provides higher lateral resolution at the focus distance, but by implication restricts the practical depth of field. The latter compromises spot size for increased depth of field.

Rate of Acquisition

The rate at which a ranging sensor can acquire range samples is important when the target object is changing shape or position, or when the required sample density of a range image is very high. There are several potential factors that can limit sample acquisition rate: the amount of time required by the detector to integrate the weak return signal to a sufficient level (integration time); the time constant of any filtering or averaging that must be performed to realize an acceptably “clean” signal (smoothing time); the rate at which samples can be transferred through the signal processing stages (transfer time); and the velocity limits of mechanical scanning apparatus (scanning bandwidth). Acquisition rates vary widely: from tens of hertz for acoustic ranging devices to tens of kilohertz for some laser-based systems. It is worth noting that, in general, there is a trade-off between rate of acquisition, accuracy, and maximum range. Some systems permit control over basic parameters so that this trade-off may be optimized for a particular application. The reader should be aware that data sheets may not be clear as to whether stated performance figures for these three specifications are valid in combination.

9.3 Selected Examples of Ranging, Range Imaging, and Motion Tracking Systems

The following sections review selected examples of some specific ranging, range imaging, and position tracking sensor systems. The list is by no means exhaustive, but offers a reasonable sampling of available technologies.

Laser-Based Active Triangulation Ranging and Range Imaging Sensors

Active Triangulation Basics

Figure 9.5 illustrates the basic active triangulation geometry. In this so-called “pinhole camera” model, practical aspects like lenses for projection and detection and mirrors for scanning are eliminated for clarity. It can be shown by means of similar triangles that the range is inversely proportional to the deflection of the imaged spot.

$$R = bf/u \tag{9.6}$$

where R = distance to object

b = baseline distance

f = lens to detector distance

u = detected spot position in the image plane

FIGURE 9.5 A simple pinhole camera model illustrates the basic active triangulation principle. As the distance R to the target surface changes, the spot position u on the detector changes, maintaining similarity between the large triangle outside the camera and the small triangle inside. There is an inverse relationship between R and u .

The sensitivity of the range measurement, or the incremental change in u with R , is

$$\left| \frac{du}{dR} \right| = bf / R^2 \quad (9.7)$$

The significance of Equation 9.7 is that range estimating performance is expected to fall as distance increases. Improvements in accuracy are realized by increasing the baseline or the lens to detector distance (i.e., the focal length).

Synchronized Scanning Principle

Lateral scanning of an active triangulation ranging sensor is accomplished by an elegant and effective technique developed at Canada's National Research Council and now marketed by Hymarc Ltd. under the name "HYSCAN" [10]. A two-sided oscillating mirror simultaneously steers the outgoing beam on one face and directs the collected light to the spot-imaging optics on the opposite face. By synchronously scanning both the beam and the axis of the detection system, rather than the beam only, as conventionally practiced, significant performance improvements are made. Figure 9.6 is a schematic illustration of the approach. Note also that the detector plane is tilted with respect to the lens plane. This feature increases the depth of focus so that the ranging performance is maximized over the measuring volume. The Hyscan sensor produces a single-axis sweep, or so-called "line scan." Full-dimension range images are acquired by translating the sensor over a target surface with a controlled motion pattern.

Light Plane Principle

Perceptron Inc. offers a similar line-scan system under the name "TriCam" [11]. In this case, the laser is not swept. Instead, the beam is transformed to a focused plane by means of cylindrical lenses. A two-dimensional detector is used to generate range profiles through the analysis of a deformation of the laser line as the sensor is translated over the object surface.

FIGURE 9.6 The Hymarc laser triangulation line scanner uses the synchronized scanning principle. Both sides of an oscillating mirror are used to sweep both the projected beam and the axis of detection over the target. The detector array is tilted to the lens plane to maximize the depth of focus.

Laser-Based Lidar Range Imaging Sensors

AM Lidar (Phase-Based Detection)

Perceptron Inc. also offers a scanning lidar under the name “LASAR” that can produce high-resolution range images through a large measurement volume. The device uses a near-infrared laser that is projected through a collimating telescope to form a spot on the first surface encountered. The spot is swept over

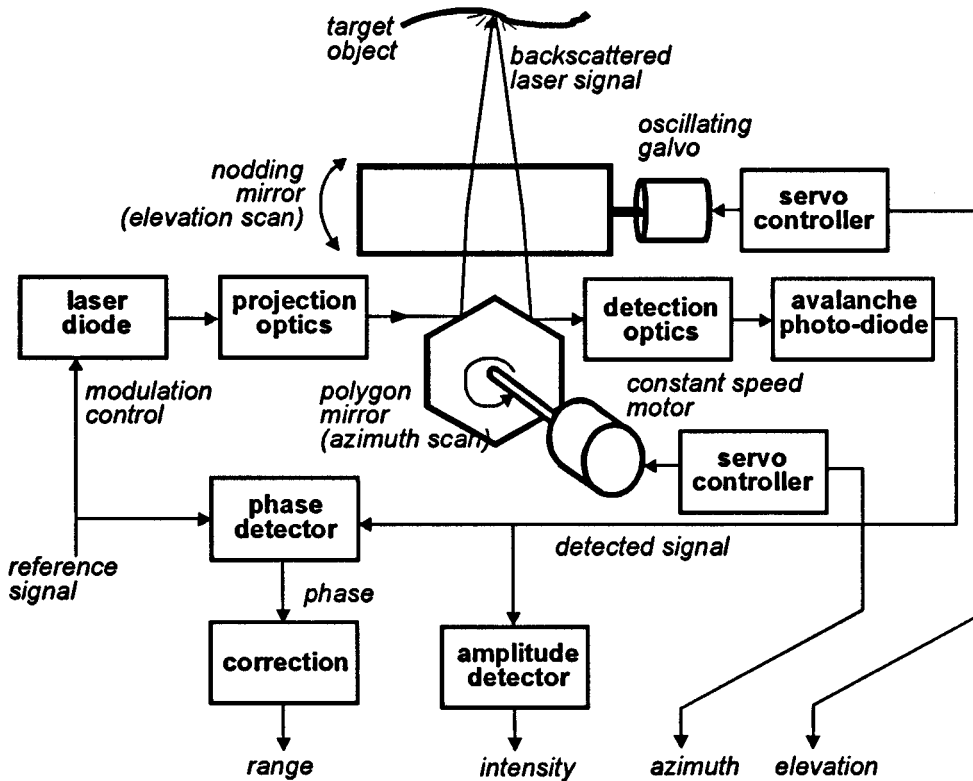

FIGURE 9.7 The Perceptron AM Lidar system described in U.S. patent 5,006,721 uses a rotating polygon mirror for synchronized scanning. A “nodding mirror” is also added to sweep at a slower rate in the orthogonal direction, producing a raster scan pattern. Range measurement is determined by comparing the phase of the outgoing and returning AM laser signal.

a programmable field of view in a raster pattern by means of a spinning polygon mirror and an oscillating “nodding mirror.” Some of the backscattered light is collected and directed by means of an adjacent facet of the polygon mirror. The projected laser light is amplitude modulated at a reference frequency by controlling the power to the laser diode source. The return signal, although orders of magnitude weaker than the outgoing signal, is phase-compared to determine the range for a particular azimuth and elevation. The intensity of the return energy is also recorded. The Perceptron sales literature claims a maximum measurement volume of $60^\circ \times 72^\circ \times 40$ m, a range image grid resolution of 1024×2048 pixels and a maximum acquisition rate of 360,000 pixels/s. A schematic diagram of the LASAR™ system is shown in Figure 9.7. Details of the Perceptron technical approach may be found in [16].

Resonating Lidar (Frequency-Based Detection)

Acuity Research Inc. has developed a laser-based TOF ranging sensor based on a simple but effective idea. The detector controls the laser output such that the absence of a signal drives the laser on and the presence of a signal turns it off. The finite transit time of the light bounce turns this arrangement into a two-state resonator, with the period being proportional to the target distance. Rather than measuring the period, which is extremely short and difficult to time, the frequency is measured using conventional counting techniques for as many cycles as necessary to yield the required accuracy. The AccuRange 4000, as it is named, is also available in a 360° line-scanning arrangement suitable for robotic vehicle navigation applications [17]. Details of the technical approach may be found in [18].

Position Tracking with Active Targets

Active target approaches are not convenient in some applications, but they are an excellent way to track the changing positions of several target points simultaneously. Active targets are a way of getting around the “correspondence problem” mentioned earlier. The two systems introduced here are interesting to compare. One employs light energy and triangulation; the other uses a magnetic field-based approach. They are both used for real-time tracking and recording of human kinetics, robotics, and other moving objects.

Active Target Triangulation

The “OPTOTRAK” system offered by Northern Digital Ltd. [19] uses infrared light emitting diodes (LEDs) as targets. The LEDs are multiplexed so that only one at a time can be seen by the camera system, avoiding the correspondence problem. The unique form of stereo ranging is based on three line detectors with lenses that transform the point source LED illumination into a focused line. The simplified triangulating geometry is shown in Figure 9.8. It may be shown from this geometry that the target position (x_p, y_p, z_p) can be determined from the detector outputs u_{left} , u_{right} , and v as follows:

$$x_p = b(u_{\text{right}} + u_{\text{left}}) / 2(u_{\text{right}} - u_{\text{left}}) \quad (9.8)$$

$$y_p = bv / (u_{\text{right}} - u_{\text{left}}) \quad (9.9)$$

$$z_p = fb / (u_{\text{right}} - u_{\text{left}}) \quad (9.10)$$

where f and b are the lens-to-detector distance and the baseline separation respectively. In practice, the image space to object space mapping is much more complicated than Equations 9.8 to 9.10, and involves a camera model with more than 60 parameters that are determined through a calibration process.

OPTOTRACK offers high sampling rate, large measurement volume, and high accuracy compared to many other position tracking systems.

Magnetic Position Tracking

A position/orientation tracking sensor based on a three-axis magnetic dipole transmitter and a three-axis magnetic loop detector has been developed by Polhemus Inc. [20]. The transmitted fields are alternating current for ease of detection (i.e., transformer coupled) and time-multiplexed so that the field due to each axis can be distinguished from the others. Distance between transmitter and detector is determined by exploiting the $1/R^3$ relationship between field strength and distance from the source. Orientation of the detector is determined by exploiting the directionality of magnetic fields and the direction sensitivity of loop detectors.

An issue with respect to the use of ac fields is the distortions in field shape that occur if metal objects are present, and the consequent effect on sensor accuracy. These distortions result from eddy currents in the conducting metal. Ascension Technology Corp. has developed a variation on the Polhemus sensor based on dc magnetic fields. The switching transient due to time-multiplexing does produce an eddy current effect, but it is allowed to die out before measurement is made. Details of the dc technique are available in [21].

An important difference between optical and magnetic tracking technologies is that the former require an unbroken line of sight to the targets while the latter do not. This gives magnetic trackers an advantage in some applications. On the other hand, the $1/R^3$ field distribution characteristic of magnetic tracking

FIGURE 9.8 The OPTOTRAK position tracking system employs a novel arrangement of cylindrical optics and one-dimensional detectors to triangulate the 3-D position of an infrared LED target. Up to 255 individual multiplexed targets can be tracked by the system.

implies an extreme sensitivity loss with distance, whereas optical triangulation has a more benign $1/R$ characteristic. This, to some extent, explains why the volume of measurement and accuracy of optical triangulation systems is generally much better than for magnetic systems.

9.4 A Sampling of Commercial Ranging, Range Imaging, and Motion Tracking Products

Table 9.1 contains information collected from vendor literature. Be advised when comparing specifications that test conditions, standards, and interpretations can vary significantly. The specifications, therefore, should serve only as a rough guide.

TABLE 9.1 Ranging, Range Imaging, and Position Tracking Products and Vendors

Class	Trade Name	Principle	Features	Contact
Ranging (contact)	MicroScribe-3DX	Instrumented arm	50 in. spherical work volume, 0.3 mm accuracy	Immersion Corp. (408) 467-1900, info@immerse.com
Ranging (noncontact)	LASERVISION	TOF, laser	50 m range, 4.9 mm accuracy @ 15 m, integrated electronic level	ZIRCON Corp., (408) 866-8600
Range-Imaging (line scan)	HYSCAN	Active triangulation laser	40 mm depth of field, 70 mm swath, 0.025 mm accuracy, 10,000 points/s	Hymarc Ltd., (613) 727-1584, info@hymarc.com
Range-Imaging (line scan)	TriCam	Active triangulation laser	120 mm depth of field, 60 mm swath, 0.05 mm accuracy	Perceptron Inc., (810) 478-7710, inquiry@perceptron.com
Range-Imaging (line scan)	ALTM 1020	TOF laser time-interval	330-1000 m range, 15 cm accuracy, 20° swath	Optech Inc., (416) 661-5904
Range-Imaging (area scan)	Rangecam 7000	Laser or strobe triangulation	uses standard CCD camera and light plane projector	Range Vision Inc. (604) 473-9411
Range-Imaging (area scan)	LASAR	TOF, AM Lidar	2–40 m range, 60 × 70° max field of view, 360,000 samples/s	Perceptron Inc., (810) 478-7710
Position Tracking	OPTOTRAK	Active target triangulation	up to 255 targets, submillimeter accuracy, 5000 3 DoF samples/s	Northern Digital Inc., (519) 884-5142
Position Tracking	Flock of Birds	Magnetic field based	up to 30 position/orientation targets, approx. 10 mm accuracy, 144 6-DoF samples/s	Ascension Technology Corp. (802) 860-6440

10.1 Altitude Measurement

Dimitris E. Manolakis

Accurate monitoring of aircraft cruising height is required in order to reduce vertical separation to a minimum standard. Interest here focuses on the measurement of the distance between aircraft level and the sea surface level. This distance can be estimated onboard via barometric altimeters or it can be measured — either onboard or in ground stations — via electronic radio wave systems. The indication of the first equipment is referred to as pressure altitude, or simply altitude, whereas that of the second category is referred to as geometric height or simply height.

The altitude information at air traffic control (ATC) centers is based on pressure altitude measurement that the aircraft transponder system sends after it receives an appropriate interrogation — known as mode C interrogation — transmitted by a secondary surveillance radar. Actually, the altitude information is an atmospheric pressure measurement transformed to altitude indication through a formula expressing the pressure/altitude relationship. When a flight level is cleared for an aircraft, it actually means that the pilot must keep flying on an isobaric surface. However, the altimetry system may present systematic errors (biases) that are different for each airplane, and that significantly affect safety. Thus, the altimetry

system performance as well as the aircraft height keeping performance must be monitored by an independent radar or satellite system.

Radar or satellite systems determine the position of an object through algorithms that are fed with range, or range difference, or range sum, or range and bearing measurements, and they estimate the object position vector employing appropriate techniques such as triangulation or trilateration. The primary radar measurements are contaminated by two kinds of errors: random and systematic errors. The effect of random errors can be reduced by the use of appropriate noise rejection filters, such as a Kalman filter. The second kind of error is usually removed by calibrating the instrument if this is possible; otherwise, suitable algorithms must be invented to anticipate it.

The estimation may be derived in ground stations or onboard the aircraft according to where the data acquisition and processing is performed. In the latter case, the vertical position estimation has to be downlinked to the appropriate ATC center. Also, the estimation may be performed off-line or on-line. Ground-based methods or systems are the Navigation Accuracy Measurement System (NAMS), the height estimation method with a single air traffic control radar, the method with one Secondary Surveillance Radar (SSR) and one omnidirectional radar, the Dual synchronized Autonomous Height Monitoring System (DAMS) and methods that use multiple SSRs and estimate the height by quadrilateration, or by the use of pseudorange measurements, or by the use of range difference measurements. On-board height measurement methods derive their estimates by trilateration using the Distance Measuring Equipment (DME) or the Global Positioning System (GPS) signals.

Ground-Based Height Estimation

The radars used to derive the original measurements are either primary or secondary surveillance radars. A primary radar sends a signal and scans for the arrival of its reflection. The range to the object reflecting the signal is derived from the time elapsed between transmission and reception. With secondary radar, the radar sends an interrogation to aircraft — to all aircraft or to a selected one — and the appropriate aircraft sends a reply via its transponder. The range to the aircraft is computed from the time elapsed between the signal transmission and the signal arrival, taking into account the nominal delay time of the transponder. Most of the methods estimating the aircraft height make use of the SSR equipment because it is cost effective, the transponder reply signal is stronger than that reflected to a primary radar, and the system can operate more reliably in dense traffic areas.

Any systematic errors in the primary radar and in the ground equipment of the SSR can be corrected by calibration. However, the problem encountered with SSR is that it involves the transponder delay time in the range measurement process. Thus, any systematic error in the transponder delay time causes range bias errors that are different for each aircraft and thus suitable methods must be used to anticipate for it in the subsequent measurement data processing.

Navigation Accuracy Measurement System

Nagaoka has proposed an off-line height estimation system [1–3]. It is composed of a primary marine radar located under an airplane and measures range R and depression angle β . Figure 10.1 shows the geometry of the system. The antenna rotates about a vertical axis and scans the area above it with rate equal to 1 rotation per 3 s. The principle exploited to derive the height estimate is that the range varies as the aircraft passes through the data acquisition area. The rate of change of range is mainly a function of the flight height z and secondarily of depression angle. It is easily derived from Figure 10.1, that the relation between the above quantities and the position x along the x axis at time t is:

$$R(t) = \sqrt{x^2(t) + R'(t)^2} = \sqrt{x^2(t) + \frac{z^2}{\cos^2 \beta(t)}} \quad (10.1)$$

Let x_0 denote the position of the aircraft at time t_0 . Assuming the aircraft flies in straight and level flight, this means that the velocity V_x , the depression angle, and the height h remain constant during the data

FIGURE 10.1 Geometry of the Navigation Accuracy Measurement System (NAMS). $BA = x$, $CB = y$, $OC = z$, $R' = z/\cos(\beta)$.

collection period. The above quantities and the range measurement at time t_i are related through Equation 10.2.

$$R_i = \sqrt{\left[x_0 + V_x (t_i - t_0) \right]^2 + \frac{z^2}{\cos^2 \beta}} = f(t_i, \beta, \mathbf{q}) = f_i(\mathbf{q}) \quad (10.2)$$

where \mathbf{q} is the unknown quantities vector, $\mathbf{q} = [x_0, V_x, z]^T$.

Measurements of R_i and β are collected at times t_0, t_1, \dots, t_n , and their set is briefly expressed as a vector function of the unknown quantities with the following matrix equation:

$$\mathbf{R} = \mathbf{f}(\mathbf{q}) \quad (10.3)$$

where

$$\mathbf{R} = \begin{bmatrix} R_0 \\ R_1 \\ \cdot \\ R_n \end{bmatrix} \quad \mathbf{f} = \begin{bmatrix} f_0 \\ f_1 \\ \cdot \\ f_n \end{bmatrix}$$

Equation 10.3 is nonlinear. Thus, a nonlinear least square method, such as the Gauss-Newton iterative method, must be used to estimate the unknown vector. Let $\hat{\mathbf{q}}_k$ be the estimate at the k th iteration. Then, the next estimate is:

$$\hat{\mathbf{q}}_{k+1} = \hat{\mathbf{q}}_k + \left(\mathbf{F}^T \mathbf{F} \right)^{-1} \mathbf{F}^T \left(\mathbf{R} - \mathbf{f}(\hat{\mathbf{q}}_k) \right) \quad (10.4)$$

where \mathbf{F} is the partial derivatives (Jacobian) matrix; that is:

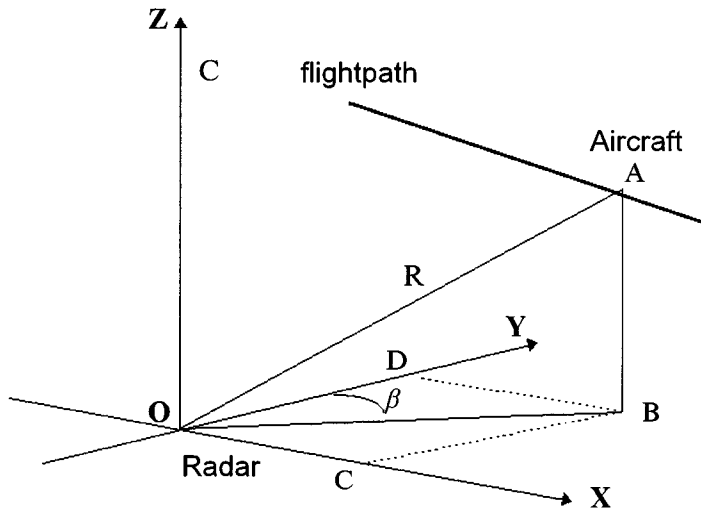

FIGURE 10.2 Geometric configuration of the height measurement system with a single air-traffic control radar. $OC = x$, $OD = y$, $AB = z$, $\beta = \angle BOD$.

$$\mathbf{F} = \frac{\partial \mathbf{f}}{\partial \mathbf{q}} = \begin{bmatrix} \frac{\partial f_0}{\partial x_0} & \frac{\partial f_0}{\partial V_x} & \frac{\partial f_0}{\partial z} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \frac{\partial f_n}{\partial x_0} & \frac{\partial f_n}{\partial V_x} & \frac{\partial f_n}{\partial z} \end{bmatrix} \quad (10.5)$$

Assuming typical aircraft velocities and flight levels, and taking into account the antenna fan beam and rotation rate, it is determined that the observation time is approximately 1 min and the number of measurements is approximately 20. The standard deviation (SD) of the height estimation errors is $\sigma_z = 10$ m when the SD of the measurement errors of range and depression angle are $\sigma_R = 10$ m and $\sigma_\beta = 0.08^\circ$, respectively.

The system has been developed and operates at the Electronic Navigation Institute of Tokyo, Japan. To estimate and anticipate for systematic errors in the depression angle and range measurements, it has been proposed to perform 40 experimental flights above the radar range. The basic assumption of the NAMS system (i.e., that the aircraft flies at constant height) cannot be validated by the NAMS itself. Thus, an SSR is required to confirm that the flight is indeed performed at the same level via the mode C interrogations [3].

Height Estimation with a Single Air-Traffic Control Radar

Nagaoka at the Electronic Navigation Institute of Tokyo investigated the possibility to derive a height estimation with a very simple and inexpensive method [4]. The idea is to use a single radar normally used for air traffic control. The radar antenna rotates around a horizontal axis once every 4 s and measures range R and bearing β , as it is shown in Figure 10.2.

Let (x, y, z) be the 3-D position of the aircraft. The bearing angle is defined as:

$$\beta = \cos^{-1} \left(\frac{y}{\sqrt{x^2 + y^2}} \right) \quad (10.6)$$

FIGURE 10.3 Geometry of the height estimation system with one SSR and one omnidirectional radar (SSROR). The distance x_a of the radars typically ranges from 80 km up to 160 km. $M_1M = z$.

Thus, the relation between the measurements and the unknown quantities is:

$$R = \left(z^2 + x^2 + y^2 \right)^{1/2} = \left(z^2 + \frac{y^2}{\cos^2 \beta} \right)^{1/2} \quad (10.7)$$

The measurement principle is the same as that of the NAMS system, i.e., that during the time the aircraft passes through the data acquisition area, the range varies as a function of both the horizontal position and the height. When straight and level flight is assumed, the unknown quantities are the height z , the y -axis initial position y_0 , and the velocity V_y . The expression relating the measurements R_i , and β_i and the unknown quantities vector $\mathbf{q} = [y_0, V_y, z]^T$ at time t_i is:

$$R_i = \left(z^2 + \frac{\left(y_0 + V_y (t_i - t_0) \right)^2}{\cos^2 \beta_i} \right)^{1/2} = f(t_i, \beta_i, \mathbf{q}) = f_i(\mathbf{q}) \quad (10.8)$$

The measurements are collected as the aircraft flies close to the radar at a distance of 30 km. Approximately, the data acquisition area is 15 km, the observation time is 1 min and the total number of scans is 15. The total set of measurements is expressed as a nonlinear matrix function in the form of Equation 10.3; that is, $\mathbf{R} = \mathbf{f}(\mathbf{q})$ where \mathbf{R} denotes the measurement vector. The unknown vector is estimated using a nonlinear least squares method like that of the NAMS system expressed by Equation 10.4.

The system performance is evaluated with Monte Carlo simulations. The best accuracy achieved is $\sigma_z = 100$ m under the assumption that the SD errors of range and bearing measurements are $\sigma_R = 100$ m and $\sigma_\beta = 0.06^\circ$. The method can use either primary or secondary radar. However, in the latter case, the method has to include systematic delays by the transponder.

Height Estimation with one SSR and One Omni Radar (SSROR)

Manolakis et al. investigated the possibility to estimate the aircraft flight height with a system that consists of one standard SSR plus a secondary radar equipped with an omnidirectional antenna located far away from the SSR; hence, this system could be referred to as SSROR [5]. Figure 10.3 shows a typical geometric configuration of the system. The SSR measures bearing θ and slant range R_s , which is transformed to horizontal range R with correcting look-up tables. The omni radar measures range R_a . Let (x, y, z) , (x_a, y_a, z_a) and $(0, 0, 0)$ be the coordinates of aircraft, omni radar, and SSR, respectively. Then, from Figure 10.3 it follows that the theoretical height function is:

$$z = f(R_a, x, y) = z_a + \left[R_a^2 - (x - x_a)^2 - (y - y_a)^2 \right]^{1/2} \quad (10.9)$$

$$x = R \sin \theta \quad (10.10)$$

$$y = R \cos \theta \quad (10.11)$$

However, the height measurement obtained through the above formula will be biased because of the transponder delay systematic deviation from its nominal value that affects the range measurements. Since this bias cannot be removed by calibration, a suitable algorithm has to be applied to anticipate for it. The approach proposed is to augment the unknown vector by incorporating the bias term. Let b denote the bias in range measurements. The biased measurements R_b and R_{ab} of R and R_a , respectively, are expressed as:

$$R_b = R + b \cos \varphi \quad (10.12)$$

$$R_{ab} = R_a + b \quad (10.13)$$

where φ is the elevation angle. Let s denote the squared height:

$$s = (z - z_a)^2 \quad (10.14)$$

and s_b denote the corresponding quantity derived from (biased) range measurements. Then, after some manipulations of the above equations, the following relation is obtained:

$$s_b = s + b a \quad (10.15)$$

$$a = 2 \left[R_a - \cos \varphi (R - x_a \sin \theta - y_a \cos \theta) \right] \quad (10.16)$$

The term a is the bias multiplying factor determined by the relative geometry of the system. Equation 10.15 is a linear relation between measurement s_b and the unknown quantities s and b . [Figure 10.4](#) shows that the effect of the bias varies as the aircraft passes through the surveillance area. Its form is mainly determined by the flight height. Consequently, it is possible to estimate both the height and the bias by collecting data during the period the aircraft remains in the surveillance area. The measurement equation at time t_i is:

$$s_{bi} = s_i + b a_i + e_i \quad (10.17)$$

where e_i represents the effect of the random measurement errors; hence, it could be referred to as the equation error. Assuming level flight, $s_i = s$, and the set of collected data is expressed with the following linear matrix equation:

$$\mathbf{s}_b = \mathbf{A} \mathbf{q} + \mathbf{e} \quad (10.18)$$

$$\mathbf{s}_b = \begin{bmatrix} s_{b0} \\ s_{b1} \\ \cdot \\ s_{bn} \end{bmatrix} \quad \mathbf{A} = \begin{bmatrix} 1 & a_0 \\ 1 & a_1 \\ \cdot & \cdot \\ 1 & a_n \end{bmatrix} \quad \mathbf{e} = \begin{bmatrix} e_0 \\ e_1 \\ \cdot \\ e_n \end{bmatrix} \quad \mathbf{q} = \begin{bmatrix} s \\ b \end{bmatrix}$$

FIGURE 10.4 Range bias multiplier in squared height measurements as a function of the aircraft distance from the omniradar. Three different flight heights are examined. The omniradar is at position (150 km, 0, 0).

The best estimate $\hat{\mathbf{q}}$ of \mathbf{q} , minimizing the weighted sum of the squared errors $\mathbf{e}^T \mathbf{W} \mathbf{e}$, is:

$$\hat{\mathbf{q}} = (\mathbf{A}^T \mathbf{W} \mathbf{A})^{-1} \mathbf{A}^T \mathbf{W} \mathbf{s}_b \quad (10.19)$$

where \mathbf{W} is the weighting matrix defined as the inverse of the equation error covariance matrix:

$$\mathbf{W}^{-1} = E \{ \mathbf{e} \mathbf{e}^T \} \quad (10.20)$$

where the notation $E\{ \}$ stands for the expected value operation. Thus, the estimate of the geometric height is:

$$\hat{z} = \sqrt{\hat{q}_1} = \sqrt{\hat{s}} \quad (10.21)$$

In the case of nonlevel flights, an augmented unknown vector is used that comprises bias b , initial height z_0 , and vertical velocity V_z [6]. In this case, however, the measurement equation is nonlinear in terms of the unknown quantities; hence, a nonlinear least squares iterative algorithm must be employed.

The system performance is a function of: (1) the range and bearing measurement standard deviation errors, σ_R and σ_θ , respectively; (2) the aircraft velocity, which affects the number of scans; (3) the omniradar scan rate; and (4) geometric terms such as the flight level and the distance between the radars. By assuming that $\sigma_R = 70$ m, $\sigma_\theta = 0.08^\circ$, the SD of the height estimation error will be between 50 m and 100 m when the values of the other factors lie in reasonable ranges.

Dual Synchronized Autonomous Monitoring System (DAMS)

The research has been conducted in the National Aerospace Laboratory NLR, the Netherlands [7]. The system is composed of two primary marine radars. Each radar has a rotating antenna. The antennas scan, with different directions, the same volume — that is an area $3 \text{ km} \times 10 \text{ km}$ above the location site. The primary surveillance area is $3 \text{ km} \times 3 \text{ km}$. The two antennas (A and B) are separated by 2.5 m, are mechanically synchronized, and scan once every 2.5 s. Their data extractors produce measurements of slant ranges and elevation angles, (R_A, φ_A) and (R_B, φ_B) , respectively, for each radar. The tracking software derives estimation of aircraft position and trajectory in off-line mode. At each scan, a combination of four measurements $(R_A, \varphi_A, R_B, \varphi_B)$ is available for use in the estimation of the unknown vector $\mathbf{q} = [x_0, y_0, z_0, V_x, V_y, V_z]^T$. A local Cartesian frame is used to perform the calculations. Finally, 16 equations are available to be solved for the 6 unknowns with a weighted least squares method. The weight of each measurement is the measured amplitude of the radar pulse. The maths of the tracker are not presented in [7]. However, one approach could be the following. If a coordinate system is defined such that radar A is at the origin $(0, 0, 0)$ and radar B is at $(x_B, 0, 0)$, then the measurements obtained at scan time t_i can be expressed as:

$$R_{Ai} = \sqrt{x_i^2 + y_i^2 + z_i^2} = \sqrt{\left(x_0 + V_x(t_i - t_0)\right)^2 + \left(y_0 + V_y(t_i - t_0)\right)^2 + \left(z_0 + V_z(t_i - t_0)\right)^2} \quad (10.22a)$$

$$\varphi_{Ai} = \tan^{-1}\left(\frac{z_i}{\sqrt{x_i^2 + y_i^2}}\right) = \tan^{-1}\left(\frac{z_0 + V_z(t - t_i)}{\sqrt{\left(x_0 + V_x(t - t_i)\right)^2 + \left(y_0 + V_y(t - t_i)\right)^2}}\right) \quad (10.22b)$$

$$\begin{aligned} R_{Bi} &= \sqrt{\left(x_i - x_B\right)^2 + y_i^2 + z_i^2} \\ &= \sqrt{\left(x_0 + V_x(t_i - t_0) - x_B\right)^2 + \left(y_0 + V_y(t_i - t_0)\right)^2 + \left(z_0 + V_z(t_i - t_0)\right)^2} \end{aligned} \quad (10.22c)$$

$$\varphi_{Bi} = \tan^{-1}\left(\frac{z_i}{\sqrt{\left(x_i - x_B\right)^2 + y_i^2}}\right) = \tan^{-1}\left(\frac{z_0 + V_z(t - t_i)}{\sqrt{\left(x_0 + V_x(t - t_i) - x_B\right)^2 + \left(y_0 + V_y(t - t_i)\right)^2}}\right) \quad (10.22d)$$

Notice that x_B has a small value (2.5 m) compared to the magnitude of the other quantities; consequently, it can be neglected. The above set of equations at four different times yields 16 equations that can be solved with a nonlinear least squares method such as the Gauss–Newton iterative method presented in Equation 10.4.

The SD of the height estimation error will be less than 15 m in the primary surveillance area, and 30 m at the edges of the area when the SD of range and elevation angle measurements are smaller than 10 m and 0.1° , respectively.

Height Measurement by Quadrilateration

Rice proposed a system consisting of four synchronized receiving SSR stations S_i , $i = 0, 1, 2, 3$ that use SSR transmissions from the aircraft transponder and estimate the height by quadrilateration [8]. Figure 10.5 shows a typical configuration of systems composed of N SSRs. One of them is an active station, which means that this station has both an interrogator and a receiver. Let (x, y, z) and (x_i, y_i, z_i) denote the Cartesian coordinates of aircraft and station S_i , respectively. Also let R_i denote the range from station S_i to aircraft, c denote the velocity of the light, and T_s denote the time of signal transmission from aircraft transponder. The stations measure the time of arrival (TOA) T_i , $i = 0, 1, 2, 3$, of the aircraft transponder signal at each site. The following relations hold:

FIGURE 10.5 Typical configuration of the height estimation systems that are based on N SSR stations. One of the stations is active, i.e., it both transmits the interrogations and receives the replies, whereas the other stations are receivers only.

$$T_i = T_s + \frac{R_i}{c} \quad i = 0, 1, 2, 3 \quad (10.23)$$

$$R_i^2 = (x - x_i)^2 + (y - y_i)^2 + (z - z_i)^2, \quad i = 0, 1, 2, 3 \quad (10.24)$$

The above system of eight equations can be solved for the unknown quantities. The unknown quantities used by Rice are $(R_0, R_1, R_2, R_3, x, y, z, T_s)^T$. However, an equivalent approach is to substitute for R_i in Equation 10.23, which becomes:

$$T_i = T_s + \frac{1}{c} \sqrt{(x - x_i)^2 + (y - y_i)^2 + (z - z_i)^2} = f_i(\mathbf{q}) \quad i = 0, 1, 2, 3 \quad (10.25)$$

where $\mathbf{q} = [x, y, z, T_s]^T$ is the unknown vector. Thus, there are four nonlinear equations to be solved for \mathbf{q} . One suitable method, for example, is the Newton–Raphson method, which iteratively approximates the solution via the following formula:

$$\mathbf{q}_{k+1} = \mathbf{q}_k + \mathbf{F}(\mathbf{q}_k)^{-1} (\mathbf{T} - \mathbf{f}(\mathbf{q}_k)) \quad (10.26)$$

where $\mathbf{T} = [T_0, T_1, T_2, T_3]^T$ is the measurement vector and \mathbf{F} is the Jacobian matrix:

$$\mathbf{F} = \frac{\partial \mathbf{f}}{\partial \mathbf{q}} = \begin{bmatrix} \frac{\partial f_0}{\partial x} & \frac{\partial f_0}{\partial y} & \frac{\partial f_0}{\partial z} & \frac{\partial f_0}{\partial T_s} \\ \cdot & \cdot & \cdot & \cdot \\ \frac{\partial f_3}{\partial x} & \frac{\partial f_3}{\partial y} & \frac{\partial f_3}{\partial z} & \frac{\partial f_3}{\partial T_s} \end{bmatrix} \quad (10.27)$$

Notice that the time of interrogation transmission, as well as the transponder nominal delay time, are not involved in the measurements. The measured quantities are only the TOAs at the station sites. Thus, the height estimate is not affected by any transponder bias.

The theoretical and experimental research has been conducted at the GEC Marconi Research Center, U.K. The optimum station arrangement is to locate the three of them equispaced on a circle and the fourth in the middle. The typical circle radius is 35 km. The same magnitude holds for the measurement range. The method may be implemented in on-line or off-line mode. In the first case, there must be transmitters at the stations to transmit their measurements of TOA to the height monitoring center. The Vertical Dilution Of Precision (VDOP) is a performance index defined by the ratio:

$$VDOP = \frac{\sigma_z}{\sigma_{rte}} \quad (10.28)$$

where σ_{rte} is the SD of the relative timing errors. The VDOP expresses the effect of the relative geometry to system performance. The VDOP of this system achieves a typical value of 3.

Height Estimation with SSRs and Pseudoranges

This approach has been investigated by Nagaoka at Electronic Navigation Institute of Tokyo [9]. The system consists of N SSR receiving stations; see Figure 10.5. One of them, say S_0 , must be active to transmit interrogations to aircraft. The time of interrogation transmission, T_i , and the times of signal arrival at the receiving stations T_i , $i = 0, 1, \dots, N-1$, are measured. Thus, N pseudorange measurements r_i are obtained where $r_i = c(T_i - T_i)$. Let T_D denote the transponder delay and D denote the distance corresponding to this delay, $D = cT_D$. Then, for each pseudorange measurement r_i , the following relation holds:

$$\begin{aligned} r_i &= D + R_i + R_0 = D + \sqrt{(x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2} + \sqrt{(x-x_0)^2 + (y-y_0)^2 + (z-z_0)^2} \\ &= f_i(\mathbf{q}) \quad i = 0, 1, \dots, N-1 \end{aligned} \quad (10.29)$$

where $\mathbf{q} = [x, y, z, D]^T$ is the unknown vector. The set of N measurements $\rho = [\rho_0, \rho_1, \dots, \rho_{N-1}]^T$, $N \geq 4$, and the unknown vector are related through Equation 10.30.

$$\mathbf{r} = \mathbf{f}(\mathbf{q}) \quad (10.30)$$

The unknown vector \mathbf{q} can be obtained from the solution of Equation 10.30 with a nonlinear weighted least squares method. Thus, the best estimate of \mathbf{q} is iteratively calculated as:

$$\hat{\mathbf{q}}_{k+1} = \hat{\mathbf{q}}_k + (\mathbf{F}^T \mathbf{F})^{-1} \mathbf{F}^T (\mathbf{r} - \mathbf{f}(\hat{\mathbf{q}}_k)) \quad (10.31)$$

where \mathbf{F} is the Jacobian matrix

$$\mathbf{F} = \frac{\partial \mathbf{f}}{\partial \mathbf{q}} = \begin{bmatrix} \frac{\partial f_0}{\partial x} & \frac{\partial f_0}{\partial y} & \frac{\partial f_0}{\partial z} & \frac{\partial f_0}{\partial D} \\ \cdot & \cdot & \cdot & \cdot \\ \frac{\partial f_{N-1}}{\partial x} & \frac{\partial f_{N-1}}{\partial y} & \frac{\partial f_{N-1}}{\partial z} & \frac{\partial f_{N-1}}{\partial D} \end{bmatrix} \quad (10.32)$$

The estimate of \mathbf{q} is free of the transponder delay systematic error because the estimation is based not on the nominal delay, but on the actual delay time, which is one of the parameters to be estimated, whereas the rest of the parameters are the aircraft 3-D position coordinates x, y, z .

The station arrangement proposed by Nagaoka, when there are four stations, is an equilateral triangle formed by the three stations, whereas the fourth station is located in the center. The VDOP, defined as the ratio σ_z/σ_R (where σ_R is the observation error) has a typical value of 4 when the aircraft is above the center at a height equal to the baseline radius. The VDOP increases as the aircraft flies higher and longer and as the baseline radius becomes smaller.

Height Measurement with SSRs and Range Differences

This approach has been proposed by Manolakis and Lefas [10, 11]. The system consists of $N-1$ receiving SSR stations S_i , $i = 1, N-1$, and one station, say S_0 , which is both receiver and interrogator, see Figure 10.5. The stations receive the reply and the time difference of arrival (TDOA) between a reference station, say S_0 , and station S_i is measured. A set of $N-1$ TDOA or equivalently range difference (RD) measurements is collected at each time the transponder sends a reply signal. The height estimation derived from this set of measurements is not affected by any transponder delay systematic error since this error is inherently subtracted from the measurements used. This system could be referred to as RD height monitoring unit (RDHMU). The systems that derive the position fix based on this kind of measurement are known as TDOA or RD or hyperbolic systems.

Let τ_i denote the TDOA between stations S_i and S_0 , and d_i denote the corresponding RD measurement, $d_i = c \tau_i$. The following relation holds:

$$\begin{aligned} d_i &= R_i - R_0 = \sqrt{(x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2} - \sqrt{(x-x_0)^2 + (y-y_0)^2 + (z-z_0)^2} \\ &= f_i(\mathbf{q}) \quad i = 1, 2, \dots, N-1 \end{aligned} \quad (10.33)$$

where $\mathbf{q} = [x, y, z]^T$ is the unknown aircraft position vector. The vector of RD measurements $\mathbf{d} = [d_1, d_2, \dots, d_{N-1}]$ is expressed as:

$$\mathbf{d} = \mathbf{f}(\mathbf{q}) \quad (10.34)$$

A commonly employed method to solve for \mathbf{q} in this nonlinear equation is the Taylor series method or equivalently the Gauss-Newton iterative method. The best estimate of \mathbf{q} is iteratively approximated as:

$$\hat{\mathbf{q}}_{k+1} = \hat{\mathbf{q}}_k + (\mathbf{F}^T \mathbf{F})^{-1} \mathbf{F}^T (\mathbf{d} - \mathbf{f}(\hat{\mathbf{q}}_k)) \quad (10.35)$$

where \mathbf{F} is the Jacobian matrix:

$$\mathbf{F} = \frac{\partial \mathbf{f}}{\partial \mathbf{q}} = \begin{bmatrix} \frac{\partial f_1}{\partial x} & \frac{\partial f_1}{\partial y} & \frac{\partial f_1}{\partial z} \\ \vdots & \vdots & \vdots \\ \frac{\partial f_{N-1}}{\partial x} & \frac{\partial f_{N-1}}{\partial y} & \frac{\partial f_{N-1}}{\partial z} \end{bmatrix} \quad (10.36)$$

In the case of four stations the best arrangement is an equilateral triangle with the fourth station in the center. The SD of height estimation error σ_z will be 15 m when the baseline radius is 6 km, the flying height is 9 km, and σ_{TDOA} is 10 ns.

Work on proof of principles and system development of a HMU based on the concept of TDOA measurement of SSR signals has been conducted by Roke Manor Research Ltd., U.K. [12].

FIGURE 10.6 Configuration of the on-board height estimation system that utilizes the distance measurements derived from the DME equipment.

Onboard Derived Height Estimation

Height Measurement with Distance Measuring Equipment (DME)

This approach for deriving the geometric height onboard the aircraft using DME equipment was first reported by Rekkas et al. [13], whereas more efficient and general techniques have been proposed by Manolakis [14, 15]. Using the DME interrogation equipment, the distance from three DME ground stations is measured onboard (see Figure 10.6). The three stations are located under an airway. The height is then computed from the range measurement vector $\mathbf{R} = [R_1, R_2, R_3]^T$ by trilateration. An exact and efficient solution of the nonlinear measurement equation was derived in [15]. Specifically, the height is computed from the closed form:

$$z = g(\mathbf{R}) = \frac{-b(\mathbf{R}) + \sqrt{d(\mathbf{R})}}{2a} \quad (10.37)$$

where $b(\mathbf{R})$ and $d(\mathbf{R})$ are the following simple polynomial-type functions

$$b(\mathbf{R}) = b_0 + b_1 R_1^2 + b_2 R_2^2 + b_3 R_3^2 \quad (10.38)$$

$$d(\mathbf{R}) = d_{00} + d_{01} R_1^2 + d_{02} R_2^2 + d_{03} R_3^2 + d_{11} R_1^4 + d_{22} R_2^4 + d_{33} R_3^4 + d_{12} R_1^2 R_2^2 + d_{13} R_1^2 R_3^2 + d_{23} R_2^2 R_3^2 \quad (10.39)$$

The coefficients a , b_i , d_{ij} are analytically defined in the Appendix of [15]. An important aspect of these coefficients is that they are completely defined by the ground stations' coordinates (x_i, y_i, z_i) , which are fixed. Thus, the coefficients are calculated only once at the moment the aircraft enters the data acquisition area. Then, every time a new set of range measurements is available, the height is computed from the above equations using the range measurements and the stored coefficients. Define the ratio σ_z/σ_R as the VDOP of this technique, where σ_R is the SD of the ranging error. The VDOP is 1 in the case where the stations form an equilateral triangle inscribed in a circle with 10 km radius and the aircraft is above the triangle center at a height of 8 km.

Estimation of Vertical Position with the Global Positioning System (GPS)

The research and development of the GPS has been coordinated by the U.S. Department of Defense. Another similar system is the Global Navigation Satellite System (GLONASS) developed by the former Soviet Union. The GPS is a satellite system providing users with accurate timing and ranging information. The system is available with reduced accuracy to civilian users. Many companies, mainly from the U.S., produce GPS receivers. Let (x, y, z) and (x_i, y_i, z_i) be the coordinates of the user and satellite s_i . The GPS receiver of the user derives the pseudorange measurement D_i , and the corresponding measurement equation is:

$$D_i = R_i + cT_b = \sqrt{(x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2} + b = f_i(\mathbf{q}) \quad (10.40)$$

where T_b is the user clock bias, and $\mathbf{q} = [x, y, z, b]^T$ is the unknown vector that incorporates the bias term b . Thus, in order to estimate the 3-D position of the aircraft, four pseudorange measurements are required at least; consequently, four satellites must be visible from the receiver. The set of N pseudorange measurements $\mathbf{D} = [D_1, D_2, \dots, D_N]^T$ defines the following matrix measurement equation:

$$\mathbf{D} = \mathbf{f}(\mathbf{q}) \quad (10.41)$$

which is solved for \mathbf{q} with the Gauss–Newton least squares iterative method, that is:

$$\hat{\mathbf{q}}_{k+1} = \hat{\mathbf{q}}_k + (\mathbf{A}^T \mathbf{W} \mathbf{A})^{-1} \mathbf{A}^T \mathbf{W} (\mathbf{D} - \mathbf{f}(\hat{\mathbf{q}}_k)) \quad (10.42)$$

where \mathbf{A} is the partial derivatives matrix:

$$\mathbf{A} = \frac{\partial \mathbf{f}}{\partial \mathbf{q}} = \begin{bmatrix} \frac{\partial f_1}{\partial x} & \frac{\partial f_1}{\partial y} & \frac{\partial f_1}{\partial z} & \frac{\partial f_1}{\partial b} \\ \cdot & \cdot & \cdot & \cdot \\ \frac{\partial f_N}{\partial x} & \frac{\partial f_N}{\partial y} & \frac{\partial f_N}{\partial z} & \frac{\partial f_N}{\partial b} \end{bmatrix} = \begin{bmatrix} \mathbf{a}_{x1} & \mathbf{a}_{y1} & \mathbf{a}_{z1} & 1 \\ \cdot & \cdot & \cdot & \cdot \\ \mathbf{a}_{xN} & \mathbf{a}_{yN} & \mathbf{a}_{zN} & 1 \end{bmatrix} \quad (10.43)$$

The elements a_{xi} , a_{yi} , a_{zi} , of the partial derivatives matrix \mathbf{A} are the direction cosines from the receiver to the satellite s_i . The weighting matrix is the inverse of the covariance matrix of the pseudorange measurement errors, $\mathbf{W}^{-1} = \mathbf{E}(\delta \mathbf{D} \delta \mathbf{D}^T)$. The weighting is generally used to take into account the possible different performances of each satellite, although usually the same performance is assumed for all satellites; that is, $\mathbf{W} = \mathbf{I}$. The VDOP, defined as σ_z / σ_D , depends on the geometry which varies continuously, even in the case of a fixed receiver, because the satellites are not geostationary but move in such orbits as to complete a rotation in 12 h. The world mean value of VDOP is about 2 [16]. Typical VDOP values range from 1.5 to 7, depending on the area of the receiver and on the time of day. The ranging error for the precision positioning service (available only to U.S. military users) has been specified to be less than 6 m (SD). For the standard positioning service, normally available to civilian users, the specified ranging error is double (12 m, SD), whereas it will be about 40 m when selective availability is activated by the Department of Defense. The corresponding measured ranging errors found to be smaller than the specified ones. Namely, for the three operating conditions mentioned, the corresponding values for ranging errors were found to be 2.3 m, 6 m, and 20 m, respectively [17]. The multiplication of the ranging SD error by the VDOP yields the standard deviation of the height estimation error.

To anticipate for the error intentionally induced by the Department of Defense, the Differential GPS (DGPS) method has been developed. A station located at a precisely known position receives the satellite signals, computes its own position on the basis of pseudorange measurements, compares this position with the known position in order to estimate the included error in satellite signals, and finally transmits the appropriate corrections to the receivers in its neighborhood. The achieved accuracy is in the order of a few meters.

Special Topics

The performance analysis of the various parameter estimation systems is usually restricted to the variance analysis, and the estimation error is usually assumed to have zero mean value. However, it is proven that in all of the above systems, the estimation error does not have zero mean value due to the nonlinearity of the measurement equation. Another important aspect is that there are cases where it is not possible to obtain a solution due to the relative geometry of aircraft vs. stations that leads to large errors. In these cases, the successive iterations applied to solve the system of nonlinear equations may not converge. Also, even after convergence, the solutions need not necessarily be “the best” or the “correct ones.”

Inherent Bias

The nonlinearity of the systems, joined with the measurement random errors, causes inherently biased estimations although the measured quantities are unbiased. For example, take the case of height estimation with DME measurements. The function $g(\mathbf{R})$ in Equation 10.37, which determines that the height z is nonlinear. In addition, the range measurements will be contaminated by additive zero mean value random errors. Let \mathbf{R}_m denote the noisy measurement vector and z_m denote the height measurement derived from $g(\mathbf{R}_m)$, i.e., from the measurement function when it is fed with noisy measurements. Extending $g(\mathbf{R}_m)$ in a Taylor series around the actual values of ranges R_1, R_2, R_3 up to second-order terms and taking the expected values, it is derived that the expected value of z_m will not be the actual value z , but it will differ by an amount b_z , which is called inherent bias. Specifically, for the DME case, the inherent bias is evaluated as:

$$b_z = E[z_m] - z = \frac{1}{2} \left(\frac{\partial^2 g}{\partial R_1^2} \sigma_{R_1}^2 + \frac{\partial^2 g}{\partial R_2^2} \sigma_{R_2}^2 + \frac{\partial^2 g}{\partial R_3^2} \sigma_{R_3}^2 \right) \quad (10.44)$$

Figure 10.7 shows the inherent bias generated in the DME system. The inherent bias becomes larger as the magnitude of the measurement errors and the system nonlinearity becomes stronger. This bias error is inherently generated in all position estimation algorithms and must be taken into account when precise position estimation is required. Biased height estimates have also been reported in [18] for the SSROR system, in [10] for the RDHMU, and in [3] for the NAMS system.

Existence and Uniqueness of Position Fix

In some systems, there are singular cases for which it is not possible to achieve a position fix. This fact has been reported by Abel and Chafee for the GPS system in [19], where it is shown that for some satellites/aircraft relative geometries, it is not possible to solve the relevant equation or there is more than one solution. Also, for the RDHMU, it has been shown by Manolakis and Lefas that there are some station arrangements for which it is not possible to derive height estimation when the aircraft is at specific areas [11]. For example, in the case of four stations, when the quadrilateral defined by the stations is inscribed in a circle, it is not possible to estimate the height when the aircraft is above the center. Also, when the quadrilateral is a rectangle or symmetric trapezoid, it is not possible to derive a position fix when the aircraft is above the line that passes from the middle of the parallel sides. From a mathematical point of view, this singularity is expressed by the singularity of the Jacobian matrix; consequently, this matrix cannot be inverted as is required by the relevant position estimation algorithm. The algorithm in this case diverges from the actual height and finally collapses. Notice that height estimation is achieved everywhere except at this singular point. However, when the aircraft is close to the singular region,

FIGURE 10.7 Bias inherently generated by the height estimation algorithm of the system based on DME measurements. The stations' sites form an equilateral triangle. The inherent bias is shown as function of the horizontal distance from the center for various magnitudes of the triangle side. The flight height is $z = 9$ km, and the SD of the distance measurement error is $\sigma_R = 90$ m.

although a position fix is achieved, it is not actually reliable since it is affected by large errors; for example, the VDOP could be larger than 600 in regions close to the singular region.

Table 10.1 presents the institutes and companies that either investigate and develop prototype height monitoring units or provide relevant systems in the market.

10.2 Attitude Measurement

Mark A. Stedham, Partha P. Banerjee, Seiji Nishifuji, and Shogo Tanaka

In many practical situations, it is important to determine and measure the attitude of a particular vehicle, such as a ship, an airplane, a piece of mechanical equipment such as a crane lifter, or a spacecraft. For this reason, many attitude sensors have been developed with advanced computer and semiconductor technologies. This section first introduces the various attitude sensors with an explanation of their operating principles and then presents several methodologies for attitude measurement and determination, including ships and crane lifters, aircraft, and spacecraft applications.

Attitude Sensors for Ships, Aircraft, and Crane Lifters

There are many types of gyroscopes that, corresponding to the physical measurement mechanisms used, may be classified as two-axes *freedom gyro* and single-axis freedom gyro using precession, *vibratory gyro* using Coriolis' force, and *optic gyro* using Sagnac's effect. Among them, the two-axes freedom gyro has the longest history. It consists of a high-speed rotating rotor around a spin axis supported by two orthogonal axes. This type of gyro is generally classified as either a *free gyro*, a *vertical gyro* (VG), or a *directional gyro* (DG).

The single-axis freedom gyro has only one output axis in addition to the spin axis. Depending on the specifications (in which) the gyro is designed, there are two types of gyros, the *rate gyro* and the *rate integrating gyro*. Related to these rotating-type gyros is another type of gyro known as the *electrostatic gyro*, which makes use of a high-speed rotating sphere in a vacuum cavity. Because of its resistance-free property, the electrostatic gyro has the highest accuracy among existing gyros. There are also rotorless gyros. The first one is a vibratory gyro that uses Coriolis' force as the measurement principle. The second type is an optical one. Among optical gyros, there are two types: the *ring laser gyro* and the *fiber optic gyro*. Both rely on the Sagnac effect in their measurement mechanisms. The performance of gyros is evaluated by their drift rates, and the performance of various gyros is shown in [Table 10.2](#), for reference, with their primary usages.

Recently, with the development of computer technology, many types of three-axes gyros have been developed that can measure not only the tilt angles but also the angular velocities and the accelerations along the three axes by combining several gyros and accelerometers. Accelerometers are often coupled with gyros to provide flight and ship navigation systems as well as attitude sensors for dynamic objects such as crane lifters. Examples include the *attitude and heading reference system* (AHRS), *inertial navigation system* (INS), *inertial measurement unit* (IMU), and *gyro compass* (GC), as well as the VGs and DGs discussed above [1].

TABLE 10.2 Performance of Different Types of Gyros

Type of the gyro	Degrees of freedom	Quantities to be detected	Accuracy ($^{\circ} \text{h}^{-1}$)
Free gyro	2	Angle	1
Vertical gyro	2	Declination from horizontal plane	1
Directional gyro	2	Shift from reference direction	1
Rate gyro	1	Angular velocity	10
Rate integrating gyro	1	Angle	0.001–1
Ring laser gyro	1	Angular velocity	0.003
Fiber optic gyro	1	Angular velocity	0.01
Electrostatic gyro	2	Angle	0.00001–0.01

The principle of a servo-type accelerometer is explained below (see Figure 10.8). As soon as the shift of the beam caused by the acceleration α is detected by the deflection pickup, the current i is generated by the servo-amplifier, which produces a torque to keep the beam at the principle axis of the sensor. Since the torque and the current that generates the torque are proportional to α , the acceleration can be measured using the current. The measurement process forms a closed-loop system, so that the sensor is not only robust to disturbances, but also achieves a high measurement accuracy (see Table 10.3).

Similarly, an inclinometer is another inertial sensor that measures tilt angle to provide attitude information (see Figure 10.9). The principle of servo-type inclinometers is the same as that of the servo-type accelerometer, except that the beam in the accelerometer is replaced by a pendulum suspended from the supporting point in the sensor. When the sensor is placed on the inclined static surface of tilt angle β , the pendulum takes the angle β against the principle axis of the sensor, assuming the sensor has no force other than gravity acting on it. The sensor can, however, generate a torque $T_c = mg_l \sin\beta \cong mg_l \beta$ to keep the pendulum at the principle axis, then the tilt angle β can be accurately measured using the torque (and consequently the current producing the torque), where m and l are the pendulum mass and length of the pendulum to its mass center, respectively. One must note, however, that such a sensor is essentially designed to measure the tilt angles of static inclined surfaces. Thus, when applied to dynamic inclined surfaces, the accelerations will affect the torque, making the sensor unreliable. An intelligent attitude

TABLE 10.3 Specification of a Servo-Type Accelerometer

Measurement range	± 5 g
Resolution	Less than $5 \mu\text{g}$ (dc)
Sensitivity	2 V g^{-1}
Output resistance	560Ω
Torquer current	3.5 mA g^{-1}
Case alignment	Less than $\pm 1^\circ$
Frequency response	450 Hz (± 3 dB)
Temperature range	-25 to $+70^\circ\text{C}$
Power source	$\pm 15 \text{ V}$ (dc)
Consumption current	Less than 15 mA
Size	$28.4 \text{ mm} \times 24.5 \text{ mm}$
Mass	46 g (including the cable 10 g)

Note: g: gravitational acceleration (according to the type TA-25D-05 by TOKIMEC).

sensing system that overcomes such difficulty will be introduced later. Although application is limited to static inclined surfaces with minute tilt angles, a dielectric-type inclinometer employing electrodes and a bubble kept in an electrolyte can achieve high accuracies on the order of 10^{-40} .

Attitude Sensors for Spacecraft Applications

Attitude measurement for spacecraft usually requires two or more sensors for detecting the reference sources needed to satisfy attitude requirements. The choice of which sensors to employ is primarily influenced by the direction the spacecraft is usually pointing as well as the accuracy requirements for attitude determination [2]. Table 10.4 summarizes some performance parameters for these sensors as well as typical manufacturers.

Inertial measurement units generally consist of gyroscopes coupled with accelerometers, which together measure both rotational and translational motion. These IMUs may be either gimbal mounted (movement about a gimbal point, independent of the spacecraft) or a strapdown system (rigidly mounted to the spacecraft body), where expansive software is used to convert sensor outputs into reference frame measurements. IMUs tend to suffer gyro drift and other bias errors and, when used for spacecraft attitude measurements, are often used with one or more of the sensors discussed below.

Sun sensors detect the visible light from the sun, measuring the angle between the sun's radiation and the detector's photocell. The sun is a commonly chosen attitude reference source since it is by far the

FIGURE 10.9 Dielectric-type inclinometer (front view).

TABLE 10.4 Spacecraft Attitude Determination Sensors

Sensor	Accuracy	Mass (kg)	Typical vendors
IMU	$1 \text{ to } 5 \times 10^{-6} \text{ g}$	3 to 25	Northrop Grumman, Bendix, Kearfott, Honeywell, Hamilton, Standard, Litton, Teledyne
Sun Sensor	$10^{-2} \text{ to } 3^\circ$	0.5 to 2	Adcole, TRW, Ball Aerospace
Horizon Sensor	$10^{-1} \text{ to } 1^\circ$	2 to 5	Barnes, Ithaco, Lockheed Martin, Lockheed Barnes
Star Sensor	$10^{-3} \text{ to } 10^{-2^\circ}$	3 to 7	Ball Aerospace, Bendix, Honeywell, Hughes
Magnetometer	$0.5 \text{ to } 3^\circ$	~ 1	Schonstedt, Develco

visually brightest object in the sky, having a total radiation per unit area of 1353 W m^{-2} at Earth distances [3]. Also, it is generally accepted as a valid point source for most attitude applications, having an angular radius of 0.25° at Earth distances. Increased measurement accuracy can be obtained by determining its centroid. Even though sun sensors are quite accurate (0.01° to 3.0°), they do require clear fields of view, and sometimes suffer periods of eclipse from both the Earth and the moon [4]. Also, sensitive equipment (such as imaging devices) must be protected from the powerful radiation of direct sunlight. When the sun is available, the angle between it and the sensor's primary axis is referred to as the *sun angle*.

For spacecraft in near-Earth orbits, the Earth is the second brightest object in the sky and covers as much as 40% of the sky. Earth *horizon sensors* detect the interface between the Earth's edge (or limb) and the space background. Horizon sensors can detect either of the Earth's visible limb (albedo sensor), infrared limb, or air glow. The infrared limb is the edge between the warm Earth and the cold space background. The air glow is a region of the atmosphere around the Earth that is visible to the spacecraft when it is on the night side of the Earth. Accuracies for horizon sensors are in the 0.1° to 1.0° range. Increased accuracy requires Earth oblate spheroid modeling [4]. Some problems associated with albedo detection include the distortion effects of the Earth's atmosphere, falsely identifying the day/night terminator crossing as the true Earth limb, and the considerable variability of the Earth's albedo in the visible spectrum (varies from land, sea, ice).

Most sensors used to detect the Earth's horizon are scanning sensors with narrow fields of view that measure the time between horizon crossings. In general, two horizon crossings occur per sensor scan period: one crossing when the sensor scans from the space background onto the Earth, followed by a second crossing when the sensor scans from the Earth back to space. The combination of horizon crossing times, scan rate, and spacecraft altitude allows for the computation of the Earth's apparent *angular radius*. The apparent angular radius will be smaller than the real (or physical) angular radius if the spacecraft is tilted away from the Earth nadir vector. The nadir vector is defined as the vector connecting the center of the spacecraft to the center of the Earth. To see this effect, one needs to compute the Earth's physical radius ρ , which for a given spacecraft altitude h (in kilometers), is given by $\rho = \sin^{-1}[(6371)/(6371 + h)]$.

If the spacecraft horizon sensor is pointing exactly *nadir*, then the apparent angular radius as measured by the sensor will agree with the physical radius given by the above relation for ρ . However, if the horizon sensor is pointed away from nadir, the horizon crossing times will be smaller than when pointing exactly nadir. This results in an apparent angular radius that is smaller than the physical radius by an amount proportional to the angle between the sensor axis and the nadir vector. This angle is referred to as the *nadir angle*.

Star sensors are used when extreme accuracy requirements are necessary. This high degree of sensor accuracy (0.003° to 0.01°) can be attributed mainly to the point source nature and precise fixed location of stars in space. Star sensors may be categorized as either star trackers or star mappers. A star tracker utilizes a wide field of view in order to search for a given star of specific brightness. A star mapper is similar to a tracker, except that it scans over many stars, recording their relative positions and angular separations. By comparing the recorded data with that from a *star catalog* (database), exact spacecraft

orientation can be obtained. The angle between the star line-of-sight and the sensor's primary axis is referred to as the *star angle*.

The accuracy of star sensors is obtained with higher costs, however. Star sensors are generally heavier and consume more power than other types of attitude sensors. In addition, star sensors are quite sensitive to stray light sources such as sunlight reflected from the spacecraft or the Earth and sunlight scattered from dust particles and jet exhausts [4]. Most rely on optical shielding to reduce the effects of stray light.

Magnetic sensors (called *magnetometers*) measure both the magnitude and direction of the Earth's magnetic field. The difference in orientation between the measured field and the true field translates into attitude determination. Magnetometer accuracies (0.5° to 3.0°) are usually less than the other sensor types because of the uncertainty in the Earth's true field, which tends to change or shift over time. In addition, the Earth's magnetic field decreases with increasing altitude, and magnetometers are generally limited to altitudes of about 6000 km. For this reason, magnetometers are often used with one of the other sensor types already discussed for improved measurement accuracy [2].

Automatic On-Line Attitude Measurement for Ships and Crane Lifters

For on-line attitude measurement for ships and crane lifters, the first thing that comes to mind is to use gyros. However, because they often suffer from drifts, accurate attitude measurements might not be achieved using the gyros. Accordingly, one uses attitude on-line measurement systems that do not utilize gyros but servo-type accelerometers and inclinometers. The philosophy of the measurement systems introduced here is to make the best use of the system dynamics of the object and the sensors and to apply Kalman filters or adaptive filters to achieve high measurement accuracy.

Attitude Measurement for Ships

On-line accurate measurement of a ship's attitude is extremely important in exact search of the seabed patterns with sonars [5, 6]. It is also required by high-performance ships like hovercrafts from the viewpoint of suppressing swings by the waves. The measurement of a ship's attitude can usually be reduced to that of the heaving, rolling, and pitching of the ship. For such a measurement, a heave sensor has been used, whose output is given by double integration of the output of an accelerometer vertically directed with a gyroscope. However, since the initial values of heaving displacement and its velocity are unknown, the output will contain a bias that increases with time, and the accuracy of the sensor deteriorates considerably. From this viewpoint, one introduces a strapdown-type on-line measurement system that adequately processes the outputs of the two servo-type inclinometers and one accelerometer mounted on the ship [7].

Location of Sensors and Outputs

The two servo-type inclinometers and one servo-type accelerometer are located on the deck (at the point A) of vertical distance L from O, the intersection of rolling and pitching axes (see [Figure 10.10](#)). The two inclinometers are set in such a way that the rolling and the pitching angles are measured respectively. The accelerometer is set upward to the deck to obtain the information on the heaving. Because inclinometers were originally developed for the measurement of the tilt angles of static inclined surfaces, the rigid pendulum inside the sensor is considerably affected by the ship's acceleration other than the gravitational one. Applying Lagrange's equations of motion [8, 9] to rigid pendulums and calculating the torques to keep their deflections from the principal axes almost zero yields the sensor outputs [7]:

$$z_1(t) = \theta(t) - \frac{L}{g} \ddot{\theta}(t) + v_1(t) \quad (10.45)$$

$$z_2(t) = p(t) - \frac{L}{g} \ddot{p}(t) + v_2(t) \quad (10.46)$$

FIGURE 10.10 Location of sensors.

where $z_1(t)$, $z_2(t)$, $\theta(t)$, $p(t)$, and g denote, respectively, the outputs of the two inclinometers, the rolling and the pitching angles, and the gravitational acceleration ($v_1(t)$ and $v_2(t)$: noises of the outputs, including the approximation errors in deriving the outputs).

On the other hand, the accelerometer output is expressed as:

$$z_3(t) = (g + \alpha(t)) \cos \theta(t) \cos p(t) + v_3(t) \quad (10.47)$$

where $\alpha(t)$ and $v_3(t)$ represent, respectively, the heaving acceleration and the accelerometer noise.

Dynamics of Attitude Signals

It is well known that each of the heaving, rolling, and pitching in inshore seas has two dominant waves in a short interval. That is, a sinusoidal wave of long periodic length (in the range of 6 s to 10 s) and a sinusoidal wave of short periodic length (in the range of 2 s to 3 s) [10–12]. Thus, one model each of the signals in a short interval by a composite wave of the two dominant sinusoidal waves. For the heaving (in a short interval), the displacement is modeled by:

$$x(t) = a_1 \sin(\omega_1 t + \varphi_1) + a_2 \sin(\omega_2 t + \varphi_2) \quad (10.48)$$

with the parameters $\{a_i\}$, $\{\varphi_i\}$, and $\{\omega_i\}$ unknown. From the 4th-order differential equation satisfied by the $x(t)$, we obtain the linear dynamic equation [7]:

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t), \quad \mathbf{A} \equiv \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -\omega_1^2 \omega_2^2 & 0 & -(\omega_1^2 + \omega_2^2) & 0 \end{bmatrix} \quad (10.49)$$

where $\mathbf{x}(t) \equiv (x_1, x_2, x_3, x_4)^T$ ($x_n = d^{n-1}x/dt^{n-1}$ ($n = 1, \dots, 4$)). On the other hand, the rolling and pitching angles can be modeled by:

$$x(t) = a_1 \sin(\omega_1 t + \varphi_1) + a_2 \sin(\omega_2 t + \varphi_2) + b \quad (10.50)$$

because there are usually some biases associated with them. From the 5th-order differential equation which Equation 10.50 satisfies, we get the similar state variable representation of the model as

Equation 10.49. In practice, the heaving, rolling, and pitching signals have many nondominant sinusoidal waves in addition to the dominant ones. Therefore, Equation 10.49 is modified by introducing a white Gaussian noise $w(t)$ with zero mean and adequate variance σ^2 as follows:

$$\dot{\mathbf{x}}(t) = A\mathbf{x}(t) + \Gamma w(t) \quad (10.51)$$

where $\Gamma = (0,1,0,0)^T$ for the heaving and $\Gamma = (0,1,0,0,0)^T$ for the rolling and pitching. The higher the order of the models, the better the measurement accuracy will be. If we consider the on-line measurement of the signals, Equation 10.51 will be sufficient.

On-Line Attitude Measurement

The observation Equations 10.45 and 10.46 are expressed using their own state vector $\mathbf{x}(t)$. The observation equations in a discretized form are:

$$y_k = H\mathbf{x}_k + v_k \quad (10.52)$$

where $H = [1,0,-L/g,0,0]$ and y_k , \mathbf{x}_k , and v_k , respectively, denote $y(t)$, $\mathbf{x}(t)$, and $v(t)$ of the corresponding signals at the k -th sampling instant [7, 9]. The discretized form of the dynamic Equation 10.51 is:

$$\mathbf{x}_{k+1} = F\mathbf{x}_k + \mathbf{w}_k \quad (10.53)$$

where

$$F \equiv \Phi(t) \Big|_{t=\Delta T}, \quad \Phi(t) \equiv L^{-1} \left\{ (sI - A)^{-1} \right\}. \quad (10.54)$$

Here, L^{-1} and ΔT , respectively, denote the inverse Laplace transformation and the sampling period. The discretized transition noise \mathbf{w}_k becomes a white Gaussian noise with zero mean and covariance:

$$W = \sigma^2 \int_0^{\Delta T} \Phi(\Delta T - \tau) \Gamma \Gamma^T \Phi^T(\Delta T - \tau) d\tau \quad (10.55)$$

The measurement of the rolling and pitching can thus be reduced to the state estimation of the linear discrete dynamic systems (Equations 10.52 and 10.53), if the angular frequencies ω_1 and ω_2 are given and v_k is assumed to have a white Gaussian property. The state estimation is achieved by a Kalman filter [7, 13]. However, difficulties in implementing the filter are that the exact values of the two angular frequencies are a priori unknown and also time variant. To overcome the difficulty, adequate candidates $\{(\omega_1^i, \omega_2^i); 1 \leq i \leq M\}$ for the parameters $\{\omega_1, \omega_2\}$ are set and a bank of Kalman filters is used. Then, the final estimate is obtained as the conditional expectation of the state estimate as follows:

$$\hat{\mathbf{x}}_{k/k}^0 \equiv \sum_{i=1}^M p_k^i \hat{\mathbf{x}}_{k/k}^i \quad (10.56)$$

where $\hat{\mathbf{x}}_{k/k}^i$ represents the state estimate $\hat{\mathbf{x}}_{k/k}$ for the i -th candidate $\Omega_i = (\omega_1^i, \omega_2^i)$, and p_k^i denotes the conditional posteriori probability of the i -th candidate calculated based on the Bayesian theorem:

$$p_k^i = \frac{p(y_k / \Omega_i, Y^{k-1}) p_{k-1}^i}{\sum_{j=1}^M p_{k-1}^j p(y_k / \Omega_j, Y^{k-1})} \quad (10.57)$$

Here, $p(y_k/\Omega_i, Y^{k-1})$ represents the conditional Gaussian probability density function of y_k under Ω_i and $Y^{k-1} \equiv \{y_j; j \leq k-1\}$, whose mean and variance are calculated recursively [7].

The proposed measurement system can adaptively and automatically select the most appropriate candidate versus time. It thus enables an accurate on-line measurement of the rolling and pitching whose dominant angular frequencies vary with time. The first, second, and third components of the final estimate $\hat{\mathbf{x}}_{k/k}^o$ represent, respectively, the estimates of the displacement, velocity, and acceleration. The proposed system thus has an advantage in that it can measure not only the displacements, but also the velocities and the accelerations of the three signals. In order to improve the measurement accuracy of the rolling and pitching, one should place the inclinometers near the intersection O of the rolling and the pitching axes.

Finally, the dynamics of the heaving is given by Equation 10.51 similar to that of the rolling and pitching. Substituting the estimates $\hat{\theta}(t)$ and $\hat{p}(t)$ obtained above into Equation 10.47 and subtracting the effect of the gravitational acceleration, one can derive a linear observation equation for $\alpha(t)$:

$$\begin{aligned} y_k &= \left[z_3(t) - g \cos \hat{\theta}(t) \cos \hat{p}(t) \right]_{t=k\Delta T} \\ &= H_k \mathbf{x}_k + v_k \end{aligned} \quad (10.58)$$

where $H_k = [0, 0, \cos \hat{\theta}(t) \cos \hat{p}(t), 0]_{t=k\Delta T}$

$$v_k = v_3(k\Delta T)$$

Thus, the on-line measurement of the heaving is also realized by executing the same procedure as described before. The location of the rolling and pitching axes were assumed to be known; however, even when they are unknown, the attitude measurement system described above is effective, if we introduce the candidates on the location of the axes adding to the angular frequencies.

Attitude Measurement for Crane Lifters

Dynamics of Attitude Signals

An illustrative diagram of a crane lifter system is shown in [Figure 10.11](#). One of the easiest ways to measure the attitude of the lifter is to set up a high-resolution camera on the bottom of the trolley and to track a mark on the top of the lifter. However, it increases the cost and also the difficulty in maintenance. Furthermore, sometimes the scheme does not work because of shadows and light reflection. As previously mentioned, for gyros not offering sufficiently accurate measurement, a high-sensitivity servo-type accelerometer is used to extract the attitude signals. When setting up the sensor on the lifter, however, there is a secondary swing signal adding to the primary one, due to the free suspension of the lifter and the structure of the lifter. Despite its small amplitude, the secondary one has a higher frequency and for this reason has a large magnitude on the sensor output. The important signal for practical applications, such as the attitude control of the lifter, is the primary one, which has a larger amplitude with a lower angular frequency of $\omega = \sqrt{g/\ell}$ (g : the gravitational acceleration; ℓ : the wire length from the primary supporting point to the center of gravity of the pulley). If we try to attenuate the secondary swing signal by passing the output through a low-pass filter, the phase lag is also introduced into the primary swing signal and the signal can no longer be used for the accurate attitude control of the lifter.

For the above reasons, we introduce an autonomous measurement system that measures both the primary and the secondary swings by modeling the lifter system with a double pendulum and applying a Kalman filter to it [14]. The dynamics of the trolley-lifter system is derived using Lagrange's equations of motion [8, 9].

$$\frac{d}{dt} \left(\frac{\partial T}{\partial \dot{x}} \right) - \frac{\partial T}{\partial x} + \frac{\partial V}{\partial x} = u - z\dot{x} \quad (10.59)$$

FIGURE 10.11 A crane lifter system.

$$\frac{d}{dt} \left(\frac{\partial T}{\partial \dot{\theta}_i} \right) - \frac{\partial T}{\partial \theta_i} + \frac{\partial V}{\partial \theta_i} = 0 \quad (i=1, 2) \quad (10.60)$$

where T and V represent, respectively, the kinetic and the potential energies of the trolley-lifter system, and θ_1, θ_2 denote, respectively, the angles that the primary and the secondary pendulums take against the vertical line. The other variables x, u , and a represent, respectively, the location of the trolley, the driving force, and the coefficient of friction between the trolley and the rail. Considering that $\theta, \dot{\theta}$ ($1 \leq i \leq 2$) are small, the dynamic equation of the trolley-lifter system can be expressed as [14]:

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{b}u(t) \quad (10.61)$$

where $\mathbf{x}(t)$ is the state vector $\mathbf{x}(t) = x, \dot{x}, \theta_1, \dot{\theta}_1, \theta_2, \dot{\theta}_2)^T$. Taking into account the approximation errors in deriving Equation 10.61, air resistance, friction in the wires, and microscopic swings at the other connection points, it is reasonable to introduce white Gaussian noises $w(t)$ ($1 \leq i \leq 3$) with zero mean and appropriate variances to the dynamic Equation 10.61 as in Equation 10.49 as follows [14]:

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{b}u(t) + \Gamma \mathbf{w}(t) \quad (10.62)$$

where

$$\Gamma = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}^T, \quad \omega(t) = [\omega_1(t), \omega_2(t), \omega_3(t)]^T \quad (10.62a)$$

FIGURE 10.12 Dynamics of a trolley lifter system.

Sensor Outputs and On-Line Attitude Measurement

When a servo-type accelerometer is set up on the lifter (in the direction of the swing) at the place of the distance ℓ'_2 from the secondary supporting point, the output of the sensor becomes [14]:

$$y(t) \cong -\ddot{x} - \ell'_1 \ddot{\theta}_1 - \ell'_2 \ddot{\theta}_2 - g\theta_2 \quad (10.63)$$

where ℓ'_1 is the distance between the primary and the secondary supporting points (see Figure 10.12). Substitution of Equation 10.61 into Equation 10.63 yields an output expressed in terms of the state vector $\mathbf{x}(t)$, as in Equation 10.52. Using a rotary-encoder to measure the location and the velocity of the trolley, and then combining these three sensor outputs with the dynamic Equation 10.62 and applying a Kalman filter enables the state vector to be estimated on-line. Using this approach, both angular displacement and velocity of the deflections θ_1, θ_2 of the two pendulums can be measured exactly.

Aircraft Attitude Determination

The determination of aircraft attitude requires the measurement of angles about three independent body axes. These angles are the roll, pitch, and yaw angles. There are two primary means employed today for measuring these angles; the first method uses VGs to measure the roll and pitch angles, and a DG to measure the yaw angle. The second method, more commonly used today, employs an IMU for full three-axis attitude determination coupled with a baro-altimeter to correct for vertical drift errors in the IMU. Both methods are described below.

Vertical and Directional Gyro Analysis

A VG is a two degree-of-freedom gyro with its spin axis mounted nominally vertical. It employs two specific force sensors mounted nominally horizontal on the inner gimbal. The two angles measured by the VG — roll and pitch — require nearly identical analyses [1]. Consider the situation shown in

FIGURE 10.13 Vertical gyro analysis.

Figure 10.13, depicting an aircraft with a roll angle of ϕ with respect to the local vertical. The sensed roll angle ϕ_s is given by the difference in the actual roll angle and the gyro roll drift error ϕ_Δ :

$$\phi_s = \phi - \phi_\Delta \quad (10.64)$$

In order to compensate for this drift error, gyros employ a specific force sensor such as an electrolytic bubble device, which senses drift error. This correction device senses the angular difference between the specific force vector \mathbf{f} acting on the aircraft roll axis and the gyro axis, as shown in Figure 10.13. Thus,

$$\phi_B = \tan^{-1}\left[\left(f_\phi/f_v\right) - \phi_\Delta\right] \cong \left(f_\phi/f_v\right) - \phi_\Delta \quad (10.65)$$

where f_ϕ is the side horizontal component of \mathbf{f} and $f_v =$ force of gravity is the vertical component. A similar analysis for the pitch angle θ yields:

$$\theta_s = \theta - \theta_\Delta \quad (10.66)$$

$$\theta_B = \tan^{-1}\left[f_\theta/f_v - \theta_\Delta\right] \cong f_\theta/f_v - \theta_\Delta \quad (10.67)$$

where f_θ is the back horizontal component of \mathbf{f} . Next, define the gyro angular momentum vector by:

$$\mathbf{H}_{VG} = \left[J_x \dot{\phi}_\Delta, J_y \dot{\theta}_\Delta, -h \right] \quad (10.68)$$

where J_x and J_y are the sensor moments of inertia and h is the gyro spin angular momentum. In addition, define the inner gimbal axes angular velocity vector as:

$$\boldsymbol{\omega}_{VG} = \left[\dot{\phi}_\Delta, \dot{\theta}_\Delta, 0 \right] \quad (10.69)$$

Finally, define the gimbal torque vector by:

$$\mathbf{Q}_{VG} = \left[Q_{c_x} + Q_{d_x}, Q_{c_y} + Q_{d_y}, 0 \right] \quad (10.70)$$

where

$$Q_{c_x} = \text{gimbal roll control torque} = -k_c \theta_B \quad (10.71a)$$

$$Q_{cy} = \text{gimbal pitch control torque} = k_c \phi_B \quad (10.71b)$$

$$Q_{dx} = \text{gimbal roll disturbance torque} = -k_d (\dot{\phi}_\Delta - \dot{\phi}) + \text{random torques} \quad (10.71c)$$

$$Q_{dy} = \text{gimbal pitch disturbance torque} = -k_d (\dot{\theta}_\Delta - \dot{\theta}) + \text{random torques} \quad (10.71d)$$

and the k_c and k_d are constant scaling factors related to each torque component.

Using the vectors defined in Equations 10.68 through 10.70, the gyro equations of motion are given by:

$$\frac{\partial}{\partial t} (\mathbf{H}_{VG}) + (\boldsymbol{\omega}_{VG} \times \mathbf{H}_{VG}) = \mathbf{Q}_{VG} \quad (10.72)$$

Taking the Laplace transform of the expansion of Equation 10.72, with the assumption that $J_x \cong J_y = J$, yields the following gyro equations of motion in the Laplace domain:

$$\begin{bmatrix} J_x s^2 + k_d s & -(hs + k_c) \\ hs + k_c & J_y s^2 + k_d s \end{bmatrix} \begin{bmatrix} \phi_\Delta(s) \\ \theta_\Delta(s) \end{bmatrix} \cong \begin{bmatrix} -k_c \theta_B + k_d s \phi(s) + \text{random torques} \\ (k_c/g) f_\phi(s) + k_d s \theta(s) + \text{random torques} \end{bmatrix} \quad (10.73)$$

For normal gyro operation, $J_x \cong J_y \cong 0$ and $k_d/h \ll 1$; so these factors may be ignored in Equation 10.73. Thus, solving for the desired roll and pitch angles under these assumptions gives [1]:

$$\phi_s = \begin{cases} \phi & \omega \gg k_c/h \\ \phi - f_\phi/g & \omega \ll k_c/h \end{cases} \quad (10.74)$$

$$\theta_s = \begin{cases} \theta & \omega \gg k_c/h \\ \theta - f_\theta/g & \omega \ll k_c/h \end{cases} \quad (10.75)$$

A DG is a two degree-of-freedom gyro with its spin axis mounted nominally horizontal and pointing in the direction of magnetic north. It employs a single specific force sensor mounted on the inner gimbal [1]. The DG measures the third required aircraft angle, yaw, generally denoted by ψ . The sensed yaw angle ψ_s is given by the difference in the actual yaw angle ψ (angle between the aircraft z-axis and true north) and the gyro heading angle drift error ψ_Δ (angle between the gyro axis and true north):

$$\psi_s = \psi - \psi_\Delta \quad (10.76)$$

Define the gyro angular momentum vector by:

$$\mathbf{H}_{DG} = [J_y \dot{\theta}_\Delta, J_z \dot{\psi}_\Delta, -h] \quad (10.77)$$

and the inner gimbal axes angular velocity vector as:

$$\boldsymbol{\omega}_{DG} = [\dot{\theta}_\Delta, \dot{\psi}_\Delta, 0] \quad (10.78)$$

and the gimbal torque vector as

$$Q_{DG} = [Q_{cy} + Q_{dy}, Q_{cz} + Q_{dz}, 0] \quad (10.79)$$

Here, the torque vector components are given by:

$$Q_{cy} = k_c (M_\Delta - \Psi_\Delta) \quad (10.80a)$$

$$Q_{cz} = -k_c \theta_B \quad (10.80b)$$

$$Q_{dy} = -k_d (\dot{\theta}_\Delta - \dot{\theta}) + \text{random torques} \quad (10.80c)$$

$$Q_{dz} = -k_d (\dot{\Psi}_\Delta - \dot{\Psi}) + \text{random torques} \quad (10.80d)$$

where M_Δ = magnetic compass heading error (from true north). Therefore, the DG equations of motion are given in Laplace domain as:

$$\begin{bmatrix} J_y s^2 + k_d s & -(hs + k_c) \\ hs + k_c & J_z s^2 + k_d s \end{bmatrix} \begin{bmatrix} \theta_\Delta(s) \\ \Psi_\Delta(s) \end{bmatrix} \equiv \begin{bmatrix} k_c M_\Delta(s) + k_d s \theta(s) + \text{random torques} \\ -k_c \theta_B + k_d s \Psi(s) + \text{random torques} \end{bmatrix} \quad (10.81)$$

The desired yaw angle measurement for the DG is thus given as [1]:

$$\Psi_s = \begin{cases} \Psi & \omega \gg k_c/h \\ \Psi - M_\Delta & \omega \ll k_c/h \end{cases} \quad (10.82)$$

As indicated in Table 10.2, the accuracies of both VGs and DGs are approximately 1°. An improvement of over 2 orders of magnitude can be obtained through the use of inertial measurement units, which are described next.

Inertial Measurement Units (IMUs)

Inertial measurement units consist of gyroscopes and accelerometers that together provide full three-axis attitude measurements. Most are mounted on stable gimballed platforms that remain locally horizontal via torquing devices. An IMU aboard an aircraft cannot measure exactly the local vertical due to the fact that the specific force acting on the aircraft has a horizontal component due to vehicle motion. In addition, since the vehicle is moving with respect to the inertial reference frame, the Earth's magnetic pole cannot be determined precisely [1].

These problems (errors) are minimized by aligning the IMU to be exactly horizontal and north pointing while the aircraft is stationary. Once platform motion begins, the IMU may be constantly realigned by sensing changes in the direction of vertical and north, and then applying appropriate torques to the platform to keep it properly aligned. This realignment is accomplished by integrating the two orthogonal accelerometer outputs to determine the components of horizontal velocity. This data, combined with the Earth's rotation rate, yields the desired rates of change in local vertical and true north at the vehicle's current latitude and longitude. Performing a second integration of the sensor outputs yields an estimate of relative position.

Analysis in Bryson et al. [1], has shown that the pitch angle (variation in platform horizontal position) is given by the IMU sensor output as:

$$\theta(t) = \frac{-\varepsilon}{\omega_s} \sin(\omega_s t) - \frac{b}{g} \quad (10.83)$$

where ε = gyro drift rate error, b = specific force sensor error, and $\omega_s \equiv$ Schuler frequency = $\sqrt{g/R}$, [g = force of gravity, R = Earth's radius]. Thus, the platform root-mean-square pitch angle becomes:

$$\theta_{\text{rms}} = \left[\frac{1}{2} \left(\frac{\varepsilon}{\omega_s} \right)^2 + \left(\frac{b}{g} \right)^2 \right]^{\frac{1}{2}} \quad (10.84)$$

Using typical values for ε ($\cong 0.015^\circ \text{ h}^{-1}$), ω_s ($\cong 0.71^\circ \text{ h}^{-1}$), and b ($\cong 0.01$) yields an rms pitch angle error of $\theta_{\text{rms}} = 0.01^\circ$. Thus, it is apparent that under normal operating conditions the IMU provides a two orders-of-magnitude improvement in sensor accuracy when compared to the VG and DG.

Spacecraft Attitude Determination

Most spacecraft attitude determination techniques rely upon finding the orientation of a single axis in space (e.g., the spacecraft z -axis) plus the spacecraft rotation about this axis. This provides a full three-axis attitude solution. In order to achieve this, reference sources that are external to the spacecraft must be used. Specifically, full three-axis spacecraft attitude determination requires at least two external vector measurements. Commonly used reference sources for these external vector measurements include the sun, Earth, moon, stars, planets, and the Earth's magnetic field. In addition, IMUs are also used to provide the necessary attitude measurements.

Attitude Determination Methodology

The first step in attitude determination is to determine the angles between the spacecraft's primary axis and the two (or more) attitude reference sources. For example, suppose a particular spacecraft is using the sun and the Earth for attitude reference. The two angles in this case are referred to as the sun angle β_s and the nadir angle Γ_N . Since the orientation of even a single spacecraft axis is unknown at this point, these angles establish two *cones* along which the attitude vector \mathbf{A} must lie. Since the attitude vector must lie on both cones, it must lie along the intersection between the two cones [4] (See [Figure 10.14](#)). The two vectors, notably \mathbf{A}_1 and \mathbf{A}_2 , resulting from the intersection of these two cones may be determined by the following method derived by Grubin [15]. Let \mathbf{S} represent the sun vector, \mathbf{E} the spacecraft nadir vector, and \mathbf{A} the desired attitude vector, each defined in Cartesian space as follows:

$$\mathbf{S} = (S_x, S_y, S_z) \quad (10.85)$$

$$\mathbf{E} = (E_x, E_y, E_z) \quad (10.86)$$

$$\mathbf{A} = (A_x, A_y, A_z) \quad (10.87)$$

Let the vectors \mathbf{S} , \mathbf{E} , and \mathbf{N} define a set of base unit vectors with:

$$\mathbf{N} = \frac{\mathbf{S} \times \mathbf{E}}{|\mathbf{S} \times \mathbf{E}|} = (N_x, N_y, N_z) \quad (10.88)$$

FIGURE 10.14 Relationship between reference vectors and single-axis attitude cones.

If we introduce a proper set of scaling factors as follows:

$$I_x = \frac{[\cos\beta_s - (\mathbf{S} \cdot \mathbf{E})\cos\Gamma_N]}{1 - (\mathbf{S} \cdot \mathbf{E})^2} \quad (10.89a)$$

$$I_y = \frac{[\cos\Gamma_N - (\mathbf{S} \cdot \mathbf{E})\cos\beta_s]}{1 - (\mathbf{S} \cdot \mathbf{E})^2} \quad (10.89b)$$

$$I_z = \sqrt{1 - I_x \cos\beta_s - I_y \cos\Gamma_N} \quad (10.89c)$$

then the two possible attitude vectors \mathbf{A}_1 and \mathbf{A}_2 are found to be:

$$\mathbf{A}_{1,2} = \left[\left(I_x S_x + I_y E_y \pm I_z N_x \right), \left(I_x S_y + I_y E_y \pm I_z N_y \right), \left(I_x S_z + I_y E_z \pm I_z N_z \right) \right] \quad (10.90)$$

In Equations 10.88 through 10.90, $\mathbf{S} \times \mathbf{E}$ represents the Cartesian vector product, and $\mathbf{S} \cdot \mathbf{E}$ represents the Cartesian scalar product. The radicand in Equation 10.89c may be negative, thus producing imaginary

FIGURE 10.15 Method of trace averaging for resolving ambiguous attitude solutions.

values for I_z whenever the two cones do not intersect. Such occurrences are usually attributed to sensor error or random noise fluctuations. In this case, one can add a predetermined sensor bias to both sensors in order to “broaden” the cone angles, thus forcing the cones to intersect.

It should be noted that for most applications involving spacecraft attitude determination, the principle coordinate system used is the *celestial sphere* coordinate system. This coordinate system has the z -axis aligned with the Earth’s polar axis, and the x -axis aligned with the intersection of the Earth’s equatorial plane and the Earth’s orbital plane around the sun (i.e., aligned with the *vernal equinox*). In this coordinate system, all vectors are considered unit vectors and the two principle measurements describing a vector’s position are the *right-ascension* and *declination angles*, denoted Ω and Δ , respectively. Thus, the sun vector \mathbf{S} and the Earth nadir vector \mathbf{E} used in Equations 10.85 and 10.86 will, in general, be given as right-ascension and declination angles that can be converted to Cartesian coordinates via the following set of transformations:

$$x = \cos(\Omega)\cos(\Delta); \quad y = \sin(\Omega)\cos(\Delta); \quad z = \sin(\Delta) \quad (10.91a)$$

$$\Omega = \tan^{-1}(y/x); \quad \Delta = \sin^{-1}(z) \quad (10.91b)$$

The final step in measuring three-axis attitude is to determine which attitude solution is correct, \mathbf{A}_1 or \mathbf{A}_2 , and then measure the rotation about this axis. The two ambiguous attitude solutions may be resolved by comparison with a priori attitude information, if available, or through the use of *trace averaging* [4]. Trace averaging is a method of plotting each attitude solution on a right-ascension versus declination plot and choosing the area of greatest concentration as the correct solution, as demonstrated in Figure 10.15. Since the attitude is assumed to change more slowly than the attitude sensor’s sample rate, over short time intervals the data for the correct solution usually form a “cluster” near the correct attitude; the data for the incorrect solution are usually much more scattered.

Once the correct attitude vector has been obtained, the orientation of the remaining two orthogonal axes may be found by measuring the rotation, or phase angle, of the spacecraft about the preferred axis. Any sensor measurement that provides this phase angle may be used. An example of this technique is provided by the panoramic annular lens attitude determination system (PALADS), described in the next section. This imaging system uses a unique “three-dimensional” lens that provides simultaneous detection of two (or more) reference sources [16]. This information, combined with the orientation of the single axis, uniquely determines three-axis attitude.

FIGURE 10.16 Panoramic annular lens ray diagram.

The three angles derived above, which are commonly referred to as *Euler angles*, define the orientation of the three spacecraft axes with respect to the chosen reference frame. A more formal treatment of the attitude solution usually requires specifying the components of the 3×3 attitude matrix \mathbf{A} . Each component of the attitude matrix defines the angular relationship between a given spacecraft axis and a reference frame axis. Various methods exist for computing the attitude matrix \mathbf{A} (see [4]); the preferred method depends on the particular application at hand.

PALADS

The primary component of PALADS is the panoramic annular lens (PAL), a single-element lens made from a high index of refraction glass with certain portions of the lens coated with a mirrored surface. Hence, it relies on both refraction and reflection in forming an image (Figure 10.16). The lens is unique in that it images a three-dimensional object field onto a two-dimensional image plane, whereas a “normal” lens is capable of only imaging two-dimensional object space onto an image plane. The combination of high index of refraction glass and mirrored surfaces provides the PAL with a field of view extending from approximately 65° to 110° from the optical axis. This 45° field of view covers the entire 360° surrounding the optical axis [17]. Any ray originating from outside the 45° field of view will not form a part of the image. The PAL may be attached to any high-quality imaging system using an appropriate *transfer lens*. As currently configured, the PALADS imaging system utilizes a Sony XC-73 charged-couple device (CCD), a black and white video camera coupled to the PAL via a Nikon $f/1.4$ transfer lens.

The hemispherical view provided by PALADS allows for single-sensor detection of multiple attitude reference sources, such as the Earth and the sun or moon. The position of each reference source in the image plane translates into a unique azimuth elevation angle between the PAL’s optical axis and the reference source. Since the PAL has a 360° field of view surrounding the optical axis, it may detect several reference sources simultaneously. The data points associated with each source are extracted from the image plane using digital image processing techniques. Thus, it is easy to see how a single image from PALADS (containing two or more reference sources) provides the necessary angle data to determine three-axis spacecraft attitude.

10.3 Inertial Navigation

Halit Eren and C. C. Fung

The Principles

The original meaning of the word *navigation* is “ship driving.” In ancient times when sailing boats were used, navigation was a process of steering the ship in accordance with some means of directional information, and adjusting the sails to control the speed of the boat. The objective was to bring the vessel from location A to location B safely. At present, navigation is a combination of science and technology. No longer is the term limited to the control of a ship on the sea surface; it is applied to land, air, sea surface, underwater, and space.

The concept of inertial-navigator mechanization was first suggested by Schuler in Germany in 1923. His suggested navigation system was based on an Earth-radius pendulum. However, the first inertial guidance system based on acceleration was suggested by Boykow in 1938. The German A-4 rocket, toward the end of World War II, used an inertial guidance system based on flight-instrument type gyroscopes for attitude control and stabilization. In this system, body-mounted gyro-pendulum-integrating accelerometers were used to determine the velocity along the trajectory. The first fully operational inertial auto-navigator system in the U.S. was the XN-1 developed in 1950 to guide C-47 rocket. Presently, inertial navigation systems are well developed theoretically and technologically. They find diverse applications,

FIGURE 10.17 In inertial navigation, the movement of a vehicle, rocket, ship, aircraft, robot, etc. with respect to a reference axis is monitored. On the Earth's surface, the conventional reference is the Earth's fixed axes — North, East, and Down. A vehicle such as an aircraft or a marine vessel will have its own local axes, known as roll, pitch, and yaw.

allowing the choice of appropriate navigation devices, depending on cost, accuracy, human interface, global coverage, time delay, autonomy, etc.

Inertial navigation is a technique using a self-contained system to measure a vehicle's movement and determine how far it has moved from its starting point. Acceleration is a vector quantity involving magnitude and direction. A single accelerometer measures magnitude but not direction. Typically, it measures the component of acceleration along a predetermined line or direction. The direction information is usually supplied by gyroscopes that provide a reference frame for the accelerometers. Unlike other positional methods that rely on external references, an *inertial navigation system* (INS) is compact and self-contained, as it is not required to communicate to any other stations or other references. This property enables the craft to navigate in an unknown territory.

Inertial navigation can be described as a process of directing the movement of a vehicle, rocket, ship, aircraft, robot, etc., from one point to another with respect to a reference axis. The vehicle's current position can be determined from "dead reckoning" with respect to a known initial starting reference position. On the Earth's surface, the conventional reference will be North, East, and Down. This is referred to as the *Earth's fixed axes*. A vehicle such as an aircraft or a marine vessel will have its own *local axes*: roll, pitch, and yaw, as shown in [Figure 10.17](#).

The inertial sensors of the INS can be mounted in such a way that they stay leveled and pointing in a fixed direction. This system relies on a set of gimbals and sensors attached on three axes to monitor the angles at all times. This type of INS is based on a *navigational platform*. A sketch of a three-axis platform is shown in [Figure 10.18](#). Another type of INS is the *strapdown system* that eliminates the use of gimbals. In this case, the gyros and accelerometers are mounted to the structure of the vehicle. The measurements received are made in reference to the local axes of roll, pitch, and yaw. The gyros measure the movement of angles in the three axes in a short time interval (e.g., 100 samples per second). The computer then uses this information to resolve the accelerometer outputs into the navigation axes. A schematic block diagram of the strapdown system is shown in [Figure 10.19](#).

The controlling action is based on the sensing components of acceleration of the vehicle in known spatial directions, by instruments which mechanize Newtonian laws of motion. The first and second integration of the sensed acceleration determine velocity and position, respectively. A typical INS includes

FIGURE 10.18 Some Inertial Navigation Systems, INS, are based on a navigational platform. The inertial sensors are mounted in such a way they can stay leveled at all times, pointing in a fixed direction. This system uses a set of gimbals and sensors attached on three axis in the x , y , and z directions to monitor the angles and accelerations constantly. The navigation computer makes corrections for coriolis, gravity, and other effects.

a set of gyros, a set of accelerometers, and appropriate signal processing units. Although the principle of the systems may be simple, the fabrication of a practical system demands a sophisticated technological base. The system accuracy is independent of altitude, terrain, and other physical variables, but is limited almost purely by the accuracy of its own components. Traditional INSs mainly relied on mechanical gyros and accelerometers, but today there are many different types available, such as optical gyroscopes, piezoelectric vibrating gyroscopes, active and passive resonating gyroscopes, etc. Also, micromachined gyroscopes and accelerometers are making an important impact on modern inertia navigation systems. A brief description and operational principles of gyroscopes and accelerometers suitable for inertial navigation are given below.

Major advances in INS over the years include the development of the *electrostatic gyro* (ESG) and the laser gyro. In ESG, the rotor spins at a speed above 200×10^3 rpm in a near-vacuum environment. The rotor is suspended by an electrostatic field; thus, it is free from bearing friction and other random torques due to mechanical supports. Hence, its operation results in a superior performance compared to others, closely resembling the performance of a theoretical gyro. Although no system can claim to reach perfection, an ESG requires less frequent updates as compared to other mechanical gyros.

Gyroscopes

There are two broad categories: (1) mechanical gyroscopes and (2) optical gyroscopes. Within both of these categories, there are many different types available. Only the few basic types will be described to

FIGURE 10.19 The use of a strapdown system eliminates the need for gimbals. The gyros and accelerometers are mounted rigidly on the structure of the vehicle, and the measurements are referenced to the local axes of roll, pitch, and yaw. The gyros measure the movement of angles in the three axes in short time intervals to be processed by the computer. This information is used, together with the accelerometer outputs, for predicting navigation axes.

illustrate the operating principles; detailed information may be found in the references listed at the end of this chapter.

Mechanical gyroscopes: The first mechanical gyroscope was built by Foucault in 1852, as a gimbaled wheel that stayed fixed in space due to angular momentum while the platform rotated around it. They operate on the basis of *conservation of angular momentum* by sensing the change in direction of an angular momentum. There are many different types, which are:

1. *Single degree of freedom gyroscopes:* include the rate, rate integrating, spinning rotor flywheel, electron, and particle gyros.
2. *Two degree of freedom gyroscopes:* incorporate the external gimbal types, two-axis floated, spherical free-rotor, electrically suspended, gas-bearing free-rotor gyros.
3. *Vibrating gyroscopes:* include the tuning fork, vibrating string, vibrating shell, hemispherical resonating, and vibrating cylinder gyros.
4. *Continuous linear momentum gyroscopes:* incorporate a steady stream of fluid, plasma, or electrons, which tends to maintain its established velocity vector as the platform turns. One typical example is based on a differential pair of hot-wire anemometers to detect the apparent lateral displacement of the flowing air column.

The operating principle of all mechanical gyroscopes is based on the conservation of angular momentum, as shown in [Figure 10.20](#). The angular momentum is important since it provides an axis of reference. From Newton's second law, the angular momentum of a body will remain unchanged unless it is acted upon by a torque. The rate of change of angular momentum is equal to the magnitude of the torque, in vectorial form as:

$$T = dH/dt \quad (10.92)$$

where H = angular momentum (= inertia \times angular velocity, $I\omega$).

FIGURE 10.20 The operation principle of gyroscopes is based on the angular momentum of a carefully constructed rotating body. The angular momentum stabilizes the system. The angular momentum of a body will remain unchanged unless it is acted upon by a torque. If the torque is orthogonal to the spin axis, it cannot change the velocity, but it can change the direction in the same direction as the torque. The spin axis always tries to align with the external torque.

If a torque acts about the axis of rotation, it changes the angular velocity by:

$$T = I \, d\omega / dt = I\alpha \quad (10.93)$$

where I = inertia about the spin axis
 α = angular acceleration

If the torque is orthogonal to the spinning axis, it cannot change the magnitude of the angular velocity vector, but it can change direction in the same direction as torque T ; then:

$$dH = H \, d\theta \quad (10.94)$$

where θ = angle of rotation.

Therefore, from Equations 10.94 and 10.92:

$$T = dH / dt = H \, d\theta / dt = H \, \Omega \quad (10.95)$$

where Ω is the precession rate or the angular velocity of the spinning wheel about the axis normal to the plane of the spin and the input torque. Generally, the spin axis tries to align with the external input torque.

These equations can be elaborated to describe the operating principles of mechanical gyros by taking into account the angular momentum in x , y , and z directions, nutation, coriolis accelerations, directions of other influencing torques and linear forces, etc. Here, the operation of the well-known *flywheel gyroscope* will be described as the basis for further discussions on inertial navigation systems.

An example of a double-axis flywheel gyro is shown in [Figure 10.21](#). In this type of gyroscope, an electrically driven rotor is suspended in a pair of precision low-friction bearings at both ends of the rotor axle. The rotor bearings are supported by a circular ring known as an *inner gimbal ring*, which in turn pivots on a second set of bearings that is attached to the *outer gimbal ring*. The pivoting action of the inner gimbal defines the horizontal axis of the gyro, which is perpendicular to the spin axis of the rotor. The outer gimbal ring is attached to the instrument frame by a third set of bearings that defines the vertical axis of the gyro that is perpendicular to both the horizontal axis and the spin axis. This type of

FIGURE 10.21 In a double-axis flywheel gyro, an electrically driven rotor is suspended by a pair of precision low-friction bearings at the rotor axle. The rotor bearings are supported by a circular inner gimbal ring. The inner gimbal ring in turn pivots on a second set of bearings attached to an outer gimbal ring. The pivoting action of the inner gimbal defines the horizontal axis of the gyro, which is perpendicular to the spin axis of the rotor. The outer gimbal ring is attached to the instrument frame by a third set of bearings. This arrangement always preserves the predetermined spin-axis direction in inertial space.

suspension has the property of always preserving the predetermined spin-axis direction in inertial space. Equations governing the two degrees of freedom gyroscope can be written using Equations 10.92 to 10.95. The torque with respect to an inertial reference frame can be expressed as:

$$T = \dot{H}_I \tag{10.96}$$

If the Earth is taken as a moving reference frame, then:

$$\dot{H}_I = \dot{H}_E + \omega_{IE} H \tag{10.97}$$

If the gyroscope itself is mounted on a vehicle (e.g., aircraft) that is moving with respect to the Earth, then:

$$\dot{H}_E = \dot{H}_B + \omega_{EB} H \tag{10.98}$$

The case of the gyroscope can be mounted on a platform so that it can rotate relative to the platform; then:

$$\dot{H}_B = \dot{H}_C + \omega_{BC} H \tag{10.99}$$

Finally, the inner gimbal can rotate relative to the case, hence:

$$\dot{H}_C = \dot{H}_G + \omega_{GC} H \tag{10.100}$$

Substituting Equations 10.97 to 10.100 into Equation 10.96 yields:

$$T = \dot{H}_G \left(\omega_{GC} + \omega_{BC} + \omega_{EB} + \omega_{IE} \right) H \tag{10.101}$$

But:

$$\left(\omega_{GC} + \omega_{BC} + \omega_{EB} + \omega_{IE}\right) = \omega_{IG} \quad (10.102)$$

Therefore,

$$T = \dot{H}_G + \omega_{IG} H \quad (10.103)$$

By carefully constructing the gyroscope and maintaining the spin velocity of the rotor constant, H_G can be made to be zero. Thus, the law of gyroscopes can be written as:

$$T = \omega_{IG} H \quad (10.104)$$

This means that if an external torque T is applied to the gyroscope, the inner gimbal will precess with respect to the inertial frame with a velocity ω such that Equation 10.104 is satisfied.

In most designs (e.g., rate gyros), the gimbal is hermetically sealed in a liquid and liquid is floated in the case, to unload the gimbal bearings and to provide viscous damping. A pick-off senses gimbal deflection by means of position transducers and it controls a servo system, with a servomotor driving the case to maintain pick-off null.

Optical gyroscopes are based on the inertial properties of light instead of Newton's law of motion. They operate on the Sagnac effect, which produces interferometer fringe shift against the rotation rate. In this case, two light waves circulate in opposite directions around a path of radius R , beginning at source S . A typical arrangement for the illustration of operation principles is shown in [Figure 10.22](#). When the gyro is stationary, the two beams arrive at the detector at the same time and no phase difference will be recorded. Assume that the source is rotating with a velocity ω so that light traveling in the opposite direction to rotation returns to the source sooner than that traveling in the same direction. Thus, any rotation of the system about the spin axis causes the distance covered by the beam traveling in the direction of rotation to lengthen, and the distance traveled by the beam in the opposite direction to shorten. The two beams interfere to form a fringe pattern and the fringe position may be recorded, or the phase differences of the two beams may be sensed. This phase difference is directional and proportional to the angular velocity. Usually, photodetectors are used to measure the phase shift.

Two different types of optical gyros can be categorized: either passive or active, and resonant or nonresonant. In passive gyrosensors, the Sagnac phase is measured by some external means; whereas in active gyros, the Sagnac phase causes a frequency change internal to the gyro that is directly proportional to the rotation rate.

The Sagnac interferometer is the basis of the *interferometric fiber-optic gyro* (IFOG). A typical fiber-optic gyroscope is shown in [Figure 10.22](#). However, the most widely used gyro is the active resonant *ring laser gyro* (RLG), which is applied extensively in aircraft navigation. Two different types of resonant passive gyros, the *resonant fiber-optic gyro* (RFOG) and the *micro-optic gyro* (MOG), are lower cost devices commonly used and comparable to RLGs.

Accelerometers

In inertial navigation, the absolute acceleration is measured in terms of three mutually perpendicular components of the total acceleration vector. Integrating these acceleration signals twice gives the displacement from an initial known starting location. Details of the acceleration and accelerometers are given elsewhere in this book (see Acceleration, Vibration, and Shock). Accelerometers are made from three basic elements: proof mass, suspension mechanism, and pick-off mechanism. Some accelerometers require electric or magnetic force generators and appropriate servo loops. Accelerometers measure not only real vehicular acceleration, but also respond to gravitational reaction forces. Acceleration due to gravity is a function of position — in particular, latitude and altitude — and is compensated by computers.

FIGURE 10.22 A typical fiber-optic gyroscope. This gyroscope is based on the inertial properties of light, making use of the Sagnac effect. The Sagnac effect describes interferometer fringe shift against rotation rate. Two light waves circulate in opposite directions around a path of radius R , beginning at source S . When the gyro is stationary, the two beams arrive at the detector at the same time and no phase difference is recorded. If the optical path is rotating with a velocity, the light traveling in the opposite direction to rotation returns to the source sooner than that traveling in the same direction. The two beams interfere to form a fringe pattern and the fringe position may be recorded, or the phase differences of the two beams may be sensed by photodetectors.

The most commonly used accelerometer in navigation systems is based on pendulous types. These accelerometers can be classified as:

1. Generic pendulous accelerometer
2. Q-flex type accelerometers
3. Micromachined accelerometers (A typical example of a modern micromachined accelerometer is given in [Figure 10.23](#).)

Accelerations in the three axes are measured by suitably positioned accelerometers. Since accelerometers contain errors, the readings must be compensated by removing fixed biases or by applying scaling factors. The errors may be functions of operating temperature, vibration, or shock. Measurement of time must be precise as it is squared within the integration process for position determination. The Earth's rotation must also be considered and gravitational effects must be compensated appropriately.

Errors and Stabilization

Errors

In general, inertial navigation is an initial value process in which the location of the navigating object is determined by adding distances moved in known directions. Any errors in the system cause misrepresentation of the desired location by being off-target. The major disadvantage of an inertial guidance system is that its errors tend to grow with time. These errors in the deduced location are due to a number of reasons, including: imperfect knowledge of the starting conditions, errors in computation, and mainly errors generated by gyros and accelerometers.

FIGURE 10.23 A typical example of a modern micromachined accelerometer. Multiple accelerometers can be mounted on a single chip, sensing accelerations in the x , y , and z directions. The primary signal conditioning is also provided in the same chip. The output from the chip is usually read in digital form.

If the error build-up with time becomes too large, external aids (e.g., LORAN, OMEGA) may be used to reset or update the system. Optimal use of the data from external aids must account for the geometry of the update and also for the accuracy of the update relative to the accuracy of the inertial system. The Kalman filter, for example, is one of the computational procedures frequently applied for optimally combining data from different sources.

Errors can broadly be classified as:

1. *System heading error:* A misalignment angle in the heading of an object traveling with a velocity can cause serious errors. For example, a vehicle traveling with velocity of 500 km h^{-1} in the same direction with 0.1° initial heading error will be off the target by approximately 873 m at the end of 1 h travel.
2. *Scale error:* Error in scaling can accumulate. In order to minimize scale errors, a scale factor is used. The scale factor is the ratio between changes in the input and output signals. It simply translates the gyro output (counts per second in the case of RLG) into a corresponding angle rotation. Some instruments may have different scale factors for positive and negative inputs, known as *scale factor asymmetry*. (Scale factors are measured in $^\circ \text{ h}^{-1} \text{ mA}^{-1}$, $^\circ \text{ h}^{-1} \text{ Hz}^{-1}$, or $g \text{ Hz}^{-1}$.)
3. *Nonlinearity and composite errors:* In most cases, scale factors are not constant, but they can have second- or higher-order terms relating the output signals to the input. Statistical techniques can be employed to minimize these errors.
4. *Bias errors:* Zero offset or bias error is due to existence of some level of output signal for a zero input. Bias errors exist in accelerometers, gyros, tilt misalignments, etc.
5. *Random drift and random walk errors:* In some cases, the outputs of the devices can change due to disturbances inside the sensors, such as ball bearing noise in mechanical gyros. These disturbances may be related to temperature changes, aging, etc. White noise in optical gyros can cause a long-term accumulation in angle error known as the *random walk*.
6. *Dead band, threshold, resolution, and hysteresis errors:* These errors can be related to inherent operation of accelerometers and gyros. They can be due to stiction, minimum input required for an output, minimum measurable outputs, and nonrepeatability of variations in the output versus variations in the input.

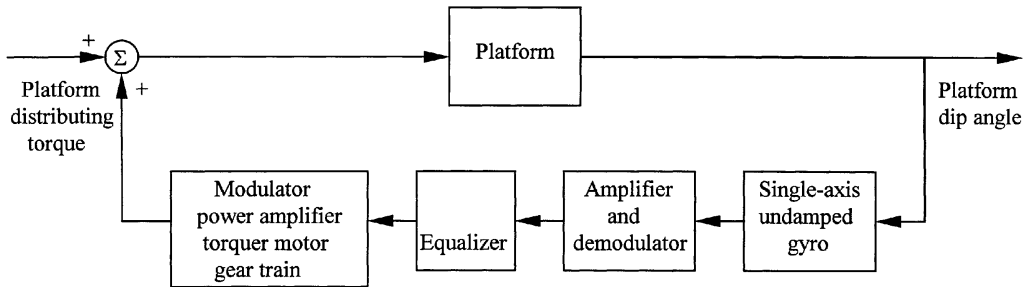

FIGURE 10.24 Stabilization is obtained using platforms designed to accurately maintain accelerometers and gyros leveled and oriented in the azimuth direction. In some cases, the platform is driven around its axis by servo amplifiers and electric motors. Sensitive pick-offs on the gyroscopes fed error signals are used to maintain a desired stability of the platform in the presence of disturbing torques.

It should be pointed out that this list is by no means exhaustive. Detailed error analysis can be found in the references cited.

Stabilization

The inertial navigation sensors must maintain angles within specified limits in spite of the disturbances imposed by the moving object. Accuracy requirements demand that the system must provide reliable and stable information in spite vibrations and other disturbing factors. One way of achieving stabilization is by using a stabilized platform. These platforms are designed to maintain accelerometers and gyros accurately leveled and oriented in the azimuth direction. In some cases, the platform is driven around its axis by servo amplifiers and electric motors. Usually, outputs of doubly integrating accelerometers are used directly to control the level-axis gyroscope precession rates. Sensitive pick-offs on the gyroscopes fed error signals are used to maintain a desired stable platform in the face of disturbing torques. The operation of a typical system, in block diagram form, is shown in [Figure 10.24](#).

Unlike platform models, in a strapped-down system, gyroscopes and accelerometers are rigidly mounted to the vehicle structure so that they move with the vehicle. The accelerometers and gyroscopes are manufactured to measure accelerations and angles up to the maximum expected values. As the vehicle travels, the measured values are frequently transmitted to a computer. The computer uses these values to resolve the readings into the navigation axis sets and make deductions on the body axis sets.

Vehicular Inertial Navigation

In modern vehicular navigation, computerized maps and mobile communication equipment are integrated together with inertial and/or other electronic navigation systems. In recent years, in the wake of low-cost GPS systems, the vehicular navigation system has attracted much attention due to its large potential markets for consumer as well as business vehicles.

Automobile navigation systems are based on dead-reckoning, map matching, satellite positioning, and other navigational technologies. Map intelligent systems achieve high relative accuracy by matching dead-reckoned paths with road geometry encoded in a computerized map. This is also used to perform other functions such as vehicle routing and geocoding. Satellite-based navigation systems achieve high absolute accuracy with the support of dead-reckoning augmentation.

The capabilities and functions of automobile navigation systems depend on:

- Choosing the necessary technology
- Integrating the overall system
- Resolving driver interface
- Providing map data basis
- Coordinating mobile communications

Digital maps and mobile data communications combine together for full usefulness and effectiveness. The navigation systems are greatly enhanced in conjunction with stored digital maps combined with effective communications.

The usefulness of a navigation system is related to the accuracy in position determination. There are a number of methods available with varying accuracy; these include the following:

Dead-reckoning

Dead-reckoning is the process of determining vehicle location relative to an initial position by integrating measured increments and directions of travel. The devices include the odometer, the differential odometer, and a magnetic compass. Gyros and inertial systems prove to have limited applications in harsh automotive environments. Although, dead-reckoning systems suffer from error accumulation, they are widely used inertial navigation systems, particularly in robotics and vehicular applications. Even the most precise navigation system requires periodic reinitialization and continuous calibrations by computers.

Radiolocation

In radiolocation, the global positioning system (GPS) is used extensively. Nevertheless, LORAN is gaining popularity as means of tracking land vehicle location from a central location. But its modest accuracy limits its global application in automotive navigation.

Map Matching

Artificial intelligence concepts are applied to match dead-reckoned vehicle paths, which are stored in computers. In map matching, sensed mathematical features of the vehicle paths are continuously associated with those encoded in a map database. Thus, a vehicle's dead-reckoned location can be initialized automatically at every turn to prevent accumulation of dead-reckoning errors.

The first application of map matching technology was in the Automatic Route Control System (ARCS), which used a differential odometer for dead-reckoning. In another system, the Etak map matching system, a solid-state flux gate compass is used as well as a differential odometer to dead-reckon paths for matching with digitized maps and aerial photographs. Further details on these technologies can be found in the references given at the end of this chapter.

In a map matching system, as long as the streets and road connectivities are accurately defined, the process identifies position relative to the road network as visually perceived by the vehicle driver.

Most of the dead-reckoning equipment commercially available is sufficiently robust to support map matching when operating in a defined road network. However, a good dead-reckoning accuracy is required to achieve reinitialization through map matching upon returning to the road network after off-road operations.

Proximity Beacon

This approach uses strategically located short-range transmitters, and reception of their location coded signal infers the receiving vehicle's instantaneous location. There are several variations of the proximity approach; some versions involve two-way communications with the equipped vehicle. Typically, the driver enters the destination code on the vehicle panel, for automatic transmission to the roadside unit, as the vehicle approaches an instrumented intersection. The roadside unit, which can be networked with a traffic management system, analyzes the destination code and transmits route instructions to the display on the vehicle panel. Proximity beacon systems are being tested in Germany and Japan. One of the most popular system is the ALI-SCOUT (see references) proximity beacon system, which uses dead-reckoning and map matching techniques between beacons to download updated map and traffic data in Berlin.

The approach to the interface between an on-board navigation system and a vehicle operator must take into account ergonomics and safety considerations as well as functional requirements. As a result of intensive research, especially in the aerospace industry, display of information for the operator is a well-developed area. In a well-known European system, Philips' CARIN, a color CRT map display is used to show vehicle location relative to the surroundings. Many other systems use short visual messages, symbolic graphics, and voice.

FIGURE 10.25 In many commercial aircraft, suitably located gyroscopes and accelerometers give signals for controlling the stability of the aircraft. Due to various instrumental errors and in-flight random disturbances such as gyro drift, scale factor errors, and accelerometer bias errors, the errors in the desired orientation increase with time. These accumulated errors need to be compensated periodically by external information such as Omega navigation systems.

Major potential roles for data communications in future automobile navigation need to provide current updates (road additions, closures, detours, etc.) for on-board map databases, and also provide real-time information on traffic conditions for on-board route generation.

Aircraft

The primary navigation aid for civil aircraft flying in the airspace of most of the developed countries is the VOR/DME system. The VOR (Very high frequency Omni Range) and the DME (Distance Measuring Equipment) enable on-board determination of an aircraft's bearing relative to North at the fixed ground station and slant range from the station, respectively. Further details can be found in references given at the end of this chapter.

Many commercial aircraft are equipped with precision Inertial Navigation Systems (INS) not only for navigation purposes, but also for stabilization of the aircraft at all times. Suitably located gyroscopes and accelerometers give signals to control the stability of the aircraft, as shown in Figure 10.25. Many aircraft INS utilize a gyro-stabilized platform on which the accelerometers are mounted. The platform is aligned before take-off to the desired orientation. Due to alignment errors and in-flight random disturbances such as gyro drift, scale factor errors, and accelerometer bias errors, the errors in the desired orientation increase with time. The errors need to be compensated periodically by external information such as Omega navigation systems.

Omega is a 10 kHz to 14 kHz navigation system that was primarily intended for updating submarine inertial navigators because of its very low frequencies penetrating beneath the ocean surface. It is also used by many general-aviation and military aircraft because of its worldwide coverage. Some airlines (e.g., American Airlines) have equipped their entire fleet with Omega receivers. The U.S. Coast Guard maintains two Omega stations and other countries maintain six more. Each station transmits eight consecutive sinusoidal tones with a 10 s repetition rate. Four are navigation tones common to all stations;

the other four tones uniquely identify the station. Each station has a cesium clock that is calibrated within 1 μ s by exchanging portable atomic clocks with other Omega stations and with the U.S. Naval Observatory.

GPS systems give all vehicles on or near the Earth unprecedented navigation accuracy. A number of international airlines are equipped with confined GPS-Glonass receivers. Many experiments are now in progress to balance the cost versus accuracy of various combinations of inertial, Omega, Loran, GPS, and Transit equipment. Airborne receivers are designed that combine nav aids operating in a common radio band (e.g., GPS, DME, JTID, and IFF).

INMARSAT's "Marec" communication satellites serve ship traffic but are configured to serve air traffic by directly communicating with aircraft for approximately \$10 per call.

Underwater

The Ship's Inertial Navigational System (SINS) was originally developed for precision position-finding required by ballistic missile submarines in the late 1950s and early 1960s. The first deployment was on-board U.S. George Washington in 1960, and SINS are used today in submarines, aircraft carriers, and other surface warships. As the cost and size are continually decreasing, the system is also deployed in naval as well as merchant vessels. Another development of INS for underwater application is in the area of the autonomous underwater vehicle (AUV). In this section, a number of such products are described.

AUVs are used extensively for military and civilian purposes. Application examples are mapping, surveillance, ocean exploration, survey, and mining, all of which require precise position determination. The desired features of such systems are: low power, high accuracy, small volume, light weight, and low cost. Two typical examples are the LN family produced by Litton Guidance and Control Systems, and the system developed by the Harbor Branch Oceanographic Institution Inc. (HBOI). The specifications of some of these systems are briefly described below to give examples of underwater INS.

The Litton LN-100 System

Litton's LN-100 is an example of the strapdown INS. The LN-100 system consists of three Litton Zero-Lock Gyros (ZLG), a Litton A4 accelerometer triad, power supply, supporting electronics, and a JIWAG standard 80960 computer. The single-board computer performs all the control, navigation, and interface functions.

The HBOI System

The HBOI system was developed with Kearfott Guidance and Navigation (KGN) and utilizes a Monolithic Ring Laser Gyroscope (MRLG), motion sensors, GPS input, and control unit. The inertial measurement unit is based on the Kearfott's T16-B three-axis ring laser gyro and three accelerometers.

Robotics

Closely related to the autonomous underwater vehicles, autonomous mobile robots also use INS extensively as a self-contained, independent navigation system. Typical applications are mining, unknown terrain exploration, and off-line path planning. There are many commercially available inertial navigation systems suitable for cost-effective utilization in the navigation of robots. Some of these are: gyrocompasses, rate gyros, gyrochip, piezoelectric vibrating gyros, ring laser gyros, interferometric, and other types of fiber-optic gyros. Three popular systems will be explained here.

The Honeywell Modular Azimuth Position System (MAPS)

Honeywell's H-726 Modular Azimuth Position System (MAPS) is a typical example of an inertial navigation system for land-based vehicles. It consists of a Dynamic Reference Unit (DRU) that provides processed information from the inertial sensor assembly, a Control Display Unit (CDU) that is used for human-machine interface, and a Vehicle Motion Sensor (VMS) that monitors the vehicle's directional and distance information. The inertial sensor assembly comprises three Honeywell GG1342 ring-laser

gyros and three Sundstrand QA2000 accelerometers mounted to measure movements in three local axes. The inertial processor translates the information to the navigation processor that resolves the vehicle movement information from the VMS. The CDU provides mode selection, data display, waypoint information, and general operator interface.

Hitachi Fiber-Optic Gyroscopes

The Hitachi products are significant as they are relatively inexpensive and were designed for automotive applications. The open-loop Interferometric Fiber-Optic Gyros (IFOG) HOFG-4FT received the “Most Technologically Significant New Products of the Year” award in 1993, and is now installed in one of the production models from Toyota. The subsequent models of IFOG are HOFG-X, HOFG-1, and HGA-D. The HOFG-1 has been employed extensively in industrial mobile robots. The output of the system can be in serial form in RS-232 standard or as analog signals. Specifications of HOFG-1 include a range of $\pm 60^\circ \text{ s}^{-1}$, an update rate of 15 ms, and linearity of $\pm 0.5\%$. The power requirement is 10 to 16 V dc and 0.5 A.

10.4 Satellite Navigation and Radiolocation

Halit Eren and C. C. Fung

Modern electronic navigation systems can be classified by range, scope, error, and cost. The range classifications are short, medium, and long ranges, within which exact limits are rather indefinite. The scope classifications can be either self-contained or externally supported, and active (transmitting) or passive (not transmitting) mode of operation.

Short-range systems include radiobeacons, radar, and Decca. Medium-range systems include Decca and certain types of extended-range radars. The long-range systems include Loran-C, Consol, and Omega. All these systems depend on active radio frequency (RF) transmissions, and all are externally supported with respect to the object being navigated, with the exception of the radar. In addition to these, there is another category of systems which are called *advanced navigation systems*; the transit satellite navigation systems, Glonass, and the Global Positioning Systems (GPS) are typical examples.

Utilization of electromagnetic radio waves is common to all navigation systems discussed here. Understanding of their behavior in the Earth's atmosphere is very important in the design, construction, and use of all kinds of navigation equipment — from satellites to simple hand-held receivers.

When an FM radio wave is generated within the Earth's atmosphere, the wave travels outward. The waves may be absorbed or reflected from surfaces of materials they encounter. The absorption and scattering of electromagnetic waves take place for many reasons, one of which is caused by excitation of electrons within the molecules in the propagation media. The behavior of an electromagnetic wave is dependent on its frequency and corresponding wavelength. [Figure 10.26](#) shows the frequency spectrum of electromagnetic waves. They are classified as *audible waves* at the lower end of the spectrum, *radio waves* from 5 kHz to 300 GHz, and *visible light* and various other types of rays at the upper end of the spectrum.

For practical purposes, the radio wave spectrum is broken into eight bands of frequencies; these are: *very low frequency* (VFL) less than 30 kHz, *low frequency* (LF) 30 kHz to 300 kHz, *medium frequency* (MF) 300 kHz to 3 MHz, *high frequency* (HF) 3 MHz to 30 MHz, *very high frequency* (VHF) 30 MHz to 300 MHz, *ultra high frequency* (UHF) 300 MHz to 3 GHz, *super high frequency* (SHF) 3 GHz to 30 GHz, and *extremely high frequency* (EHF) 30 GHz to 300 GHz.

For easy identification, the frequencies above 1 GHz are further broken down by letter designators, as: L-band (1–2 GHz), S-band (2–4 GHz), C-band (4–8 GHz), X-band (8–12.5 GHz), and K-band (12.5–40 GHz). Since severe absorption of radar waves occurs near the resonant frequency of water vapor at 22.2 GHz, the K-band is subdivided into lower K-band (12.5–18 GHz) and upper K-band (26.5–40 GHz). Most navigation radars operate in the X- and S-bands, and many weapons fire control radars operate in the K-band range.

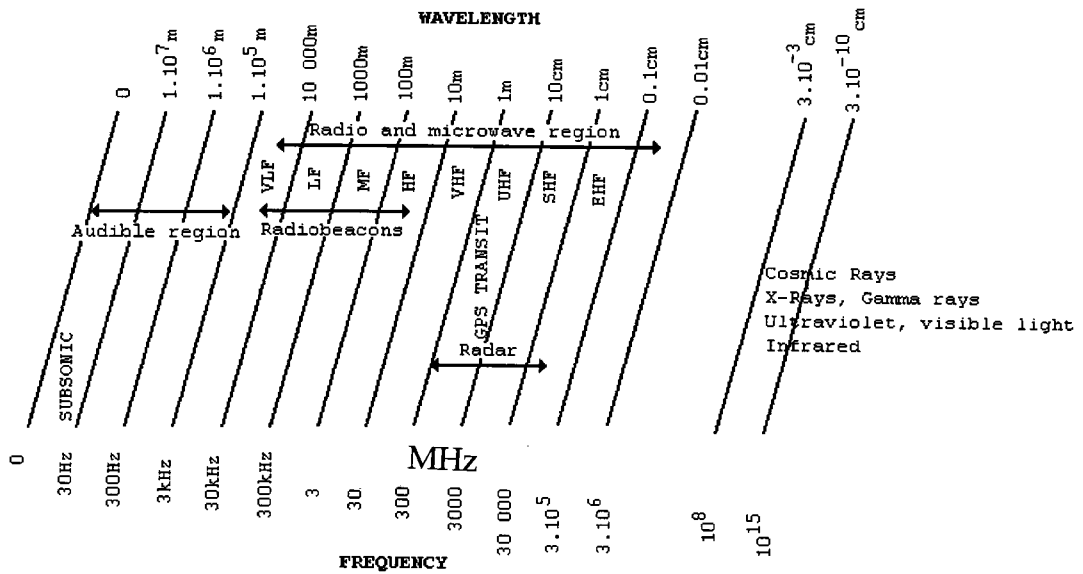

FIGURE 10.26 Electromagnetic wave frequency spectrum. Audible range can be heard if converted to sound waves. Radiobeacons operate in the VLF, LF, and MF ranges. Omega operating at VLF covers the entire world with only eight transmission stations. GPS, Transit, and Glonass use UHF frequencies. Wavelengths less than 10 cm are not suitable for satellite systems, but they are used in radars.

FIGURE 10.27 Amplitude, frequency, and pulse modulation of RF carrier waves. Amplitude modulation is suitable for broadcasting radio stations. Frequency modulation is used in commercial radio broadcasts. The pulse modulation is used in satellite systems, radars, and long-range navigation aids.

The radio waves are transmitted as continuous or modulated waves. A carrier wave (CW) is *modulated* to convey information in three basic forms: amplitude, frequency, and pulse modulation, as shown in [Figure 10.27](#). The amplitude modulation (AM) modifies the amplitude of the carrier wave with a modulating signal. In frequency modulation (FM), the frequency of the carrier wave is altered in accordance with the frequency of the modulating wave. FM is used in commercial radio broadcasts and the sound

FIGURE 10.28 The four layers of the ionosphere and its effect on radio propagation. The four layers are produced by the ionization of molecules of particles in the atmosphere by ultraviolet rays of sun. The effect of ionosphere on the radio waves is shown by reflections, also termed hops. The frequency of the electromagnetic wave is important in its behavior through ionosphere.

portion of the television broadcast. Pulse modulation is different from AM and FM in that there is usually no impressed modulation wave employed. In this modulation, the continuous wave is broken up into very short bursts or “pulses,” separated by periods of silence during which no wave is transmitted. This is used in satellite navigation systems, surface search radars, and long-range radio navigation aids such as Loran.

When an electromagnetic wave encounters an obstruction, *diffraction* takes place marked by a weak reception of the signal within the “shadow” zone. Two waves acting on the same point will also result in *interference*. The degree of interference depends on the phase and frequency relationship. For example, two waves of the same frequency with a 180° phase difference will result in a null at that point. Also, under certain conditions, a portion of the electromagnetic energy in radio waves may reflect back toward the Earth’s surface to form the *ionosphere*. The ionosphere is a layer of charged particles located about 90 to 400 km high from Earth’s surface; such reflected waves are called *sky waves*.

In the study of radio wave propagation, there are four *ionosphere layers* of importance, as shown in [Figure 10.28](#). The D-layer is located about 60 km to 90 km and is formed during daylight. The E-layer is about 110 km. It persists through the night with decreased intensity. The F₁-layer is between 175 km and 200 km; it occurs only during daylight. The F₂-layer is between 250 km and 400 km; its strength is greatest in the day but it combines with the F₁-layer later to form a weak F-layer after dark. The layers in the ionosphere are variable, with the pattern seeming to have diurnal, seasonal, and sun spot periods. The layers may be highly conductive or may entirely hinder transmissions, depending on the frequency of the wave, its angle of incidence, height, and intensity on various layers at the time of transmission. In general, frequencies in the MF and HF bands are most suitable for ionosphere reflections during both day and night.

FIGURE 10.29 The rms radius circle that encompasses 68% of all measured positions. The variations in the measurements are due to a number of factors, including: ionosphere conditions, precise location of satellites, and inefficiencies in electronic circuits. (2 rms encompasses 95% of all indicated positions.)

Because of the higher resistance of the Earth's crust as compared to the atmosphere, the lower portions of radio waves parallel to the Earth's surface are slowed down, causing the waves to bend toward Earth. A wave of this type is termed a *ground wave*. The ground waves exist because they use the Earth's surface as a conductor. They occur at low frequency since LF causes more bending in conformity to Earth's shape. The ultimate range of such ground waves depends on the absorption effects. Sometimes, in the lower atmosphere, *surface ducting* occurs by multiple hopping, thus extending the range of a ground wave well beyond its normal limits. It is associated with higher radio and radar frequencies. This phenomenon is common in tropical latitudes. Behavior patterns of waves transmitted at various angles are illustrated in Figure 10.28.

Accuracy of Electronic Fix

There are a number of random effects that influence the accuracy of an electronic position determination; atmospheric disturbances along the transmission path, errors in transmitters and receivers, clocks, inaccuracy in electronic circuitry, gyro errors, etc. As a result, a series of positions determined at a given time and location usually results in a cluster of points near the true position. There are two measures commonly used to describe the accuracy: the first is the *circular error probable* (CEP) — a circle drawn on the true position whose circumference encompasses 50% of all indicated positions, and the second technique, more common, is the *root mean square* (rms), where:

$$\text{rms} = \sqrt{\sum_{n=1}^N (E_n)^2 / N} \quad (10.105)$$

where E = the distance between actual and predicted positions
 N = the number of predicted positions

A circle, shown in Figure 10.29, with one rms value is expected to contain 68% of all the indicated positions. Another circle of radius equal to 2 rms should contain 95% of all the indicated positions, for isotropic scattering, or errors.

In electronic navigation systems, three types of accuracy are important: (1) *predictable* or *absolute accuracy*—the accuracy of a position with respect to the geographic coordinates of the Earth; (2) *repeatable accuracy*—the accuracy with which the user can return to a position whose coordinates have been determined at a previous time with the same navigation system; and (3) *relative accuracy*—the accuracy with which a user can measure position relative to that of another user of the same system at the same time.

Radionavigation Systems

In the 1930s, improved radio direction-finding techniques and better equipment led to the establishment of systems called *radiobeacons*. These systems consisted of small radio transmitters located in fixed places to provide radio bearings that could be used in all weather conditions. Position findings by these beacons became known as *radionavigation*. Continued refinements in the state-of-the-art electronics technology and a better understanding of electromagnetic wave propagation led to the subsequent development of radar and longer-range radionavigation systems.

Essentially, radiobeacons are single transmitters, transmitting a continuous wave at low power, usually modulated by audible Morse code characters for identification. The transmitted signal is received by an on-board receiver incorporating a radio direction finder (RDF) to be processed further.

Short- and Medium-Range Radiolocation Systems

Most short- to medium-range navigation systems are designed to provide either a bearing to a fixed transmitter site, as in the case of radiobeacons, or a range and bearing from the transmitter to a natural or manufactured navigation aid, as in the case of radar.

Long-Range Hyperbolic Navigation Systems

Long-range electronic navigation systems are based on *hyperbolic systems*. In these systems, the lines of positions yield in segments of hyperbolas rather than as radial lines. The line connecting the master and secondary stations transmitting the same signal simultaneously is called the *baseline*. Hyperbola lines represent the locus of all points of the arrival of master and secondary pulses at specified time differences. This is illustrated in [Figure 10.30](#). Any change in the position of the receiver near the baseline corresponds to a relatively large change in time difference of reception of pulses.

In practice, the secondary stations transmit pulses at fixed intervals, called *coding delays*, after having received a pulse from the master station. Currently, hyperbolic systems employ atomic time standards to regulate both master and secondary station transmissions to increase the system accuracy by eliminating random time errors due to atmospheric conditions.

In some systems, as an alternative to short pulses, continuous waves are propagated with the leading edges of each cycle representing a given time and distance interval. The corresponding hyperbolas then represent loci of constant phase differences, called *isophase lines*. The space between the hyperbolas are referred to as *lanes*. The position of the receiver within a lane is determined by the phase difference between the master and secondary signals. A disadvantage of this system is that it is not possible to distinguish one lane from another by the use of phase comparison alone. Hence, the lanes must be either counted as they are traversed from some fixed position, or they must be identified by some other means. For good accuracy, the user's distance from the stations can seldom exceed about six times the length of the baseline.

Radiobeacons

Most radiobeacon signals are limited to less than 320 km (200 miles), with a majority not receivable beyond about 32 km (20 miles). Often, radiobeacons located in a given area are grouped on a common frequency, such that each transmitter transmits only during a segment of a time-sharing plan. Radio bearings to the site of transmitter are determined by the use of a radio receiver equipped with a Radio Direction Finder (RDF). There are moderately priced, manually operated RDF receivers, and several more expensive fully automated models are also available. As a general rule, RDF bearings are normally

FIGURE 10.30 Hyperbolic patterns of two interacting radio waves propagated in opposite directions. These lines represent the locus of all points of a specified time difference between master and secondary pulses. The straight line MS is called the baseline. The maximum distance of the target object should not exceed 6 times the length of the baseline.

considered accurate only to within $\pm 2^\circ$; for example, under 200 km (120 miles) to the transmitter in favorable conditions and $\pm 5^\circ$ to 10° when conditions are unfavorable.

Information on the locations, ranges, and using procedures of radio beacons are given in a number of publications such as DMAHTC Publication No. 117 *The Radio Navigation Aids*. Correct radiobeacon bearings are plotted on Mercator charts for position estimation. Because of possible inaccuracies, radiobeacons are not used universally. Navigators such as small boats and merchant ships not equipped with other systems use radiobeacons.

Loran-C

Loran was developed in the 1940s to be one of the first systems implementing a long-range hyperbolic system for both ships and aircraft. The system used master and slave stations transmitting sequential radio waves in the upper MF band with frequencies between 1850 kHz and 1950 kHz. Loran-A featured ground wave coverage out to between 700 km and 1250 km from the baseline by day, and up to 2200 km by night. It was the most widely used electronic navigation system until 1970. Later, a system employing synchronized pulses for both time-difference and phase comparison measurements was developed, known as Loran-C. Loran-C was configured to operate in a *chain* form consisting of more than one slave station usually located in triangles.

All stations in the system transmit a signal on a common carrier frequency in mid-LF band of $100 \text{ kHz} \pm 10 \text{ kHz}$. The ground wave range is about 1900 km. One-hop sky waves have a range of about 3600 km, and two-hop signals were noted to have been received about 6250 km from the ground station. One-hop sky waves are produced both by day and by night, while two-hop sky waves are formed only at night. Present Loran-C chains have baseline distances between 1500 km and 2300 km. The accuracy of the system varies from about $\pm 200 \text{ m rms}$ near the baseline to $\pm 600 \text{ m rms}$ near the extreme ranges

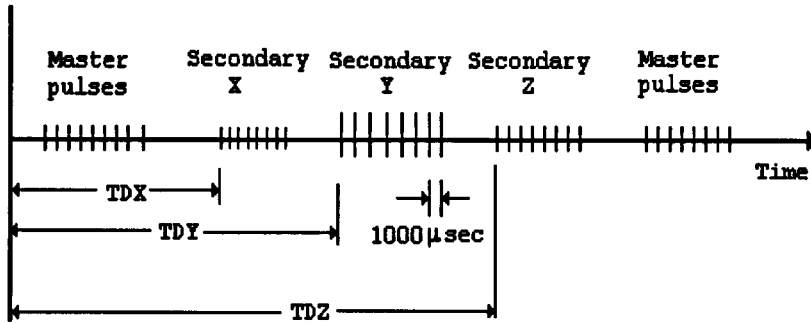

FIGURE 10.31 Loran-C pulse sequence. The nine pulses from the master station are separated by 1 ms intervals, except the ninth one, which has a 2 ms interval. The secondary stations X, Y, and Z transmit pulses some time after they receive the information from the master station. The receivers picking up these pulses provide direct latitude and longitude information, usually by a digital readout.

of the system. Differential techniques employed in recent years have increased the accuracy. The low frequency and high-power transmitters allow ground waves to penetrate the surface layer of the sea water, enabling submerged submarines to receive them.

To lessen the large power requirements, *multipulsed* signals are used. The multipulsed signals of each master station and its associated secondary stations are transmitted in a predetermined sequence, as shown in [Figure 10.31](#). Eight of the nine pulses are separated by 1 ms intervals and the ninth one by a 2-ms interval. Integrated master and secondary pulses are compared at a sampling point at exactly 30 μ s from their leading edges.

Loran-C receivers are fully automatic, suitable to be employed for marine, land vehicle, and aircraft applications. Most receivers provide direct lat/long digital readout, precise to a tenth of a minute of arc. They also provide auxiliary features such as destination selection, course and speed overground, etc. Once initialized, they automatically select the best chain and the most suitable master/secondary pulses.

There are 13 Loran-C chains worldwide. Each chain uses a different basic pulse repetition rate (PRR) and pulse repetition interval (PRI). The specific PRI used in a given chain is referred to as group repetition interval (GRI), often called *rate*. This system has enjoyed great expansion since 1970s, attracting many users. It has found applications in ships, aircraft, as well as land vehicles. Land vehicles are equipped with automatic vehicle location systems (AVLS). In one application in the U.S., the AVLS system is integrated with the city's emergency telephone system, a computer-aided dispatch system to control the position of emergency vehicles such as ambulances and fire trucks.

Nevertheless, the progress made in satellite-based global positioning systems (GPS) calls for termination of Loran-C in the very near future. However, complete system shut-down may not occur immediately, due to the vast number of current users of the system.

Decca

Decca is similar to Loran-C in that each chain is composed of one master and three slave stations arranged in *star* pattern, at an angle of about 120° between the baselines. It uses unmodulated continuous waves rather than the pulsed waves of Loran. The characteristic hyperbolic grid pattern is formed by phase comparisons of master and slave signals. All stations transmit in the LF-band between 70 kHz and 130 kHz. The nominal range is about 400 km both by day and by night. The system is extremely accurate within the operating range. The signals transmitted by each of the stations are all harmonics of a single fundamental frequency.

There are a wide variety of receivers available for Decca system, including automatic flight logs for aircraft. In general, the systems consist of four separate receivers, each of which can be set to receive one of the four signals transmitted by a given chain. The lane identification is accomplished by a signal transmitted by each master and slave station, transmitted once every 20 s for a duration of 0.6 s. By some

FIGURE 10.32 Three successive phase comparisons for lane resolution in Omega systems. Phase differences are compared in three stages with respect to three different signals transmitted by each station for accurate position finding. One wavelength is 25 km, representing two lanes. Accuracy of the Omega system is limited.

short signal interruptions and transmissions of harmonics simultaneously, zones and lanes are identified in a precise manner.

Consol

Consol is limited to the Eastern and Northern Atlantics. It is a hyperbolic system with extremely short baseline lengths, such that a collapsed hyperbolic pattern is formed. It employs three towers located three wavelengths apart. The operational frequencies are in the MF range between 250 kHz and 370 kHz. The system range is about 1900 km by day and 2400 km by night. The minimum range is about 40 km near the stations. One tower transmits a continuous wave, while other towers transmit waves with 180° phase shift by a *keying cycle*. The signals are modulated by dots and dashes such that receivers determine the position by counting them and printing on Consol grid patterns.

Omega

Omega is a hyperbolic navigation system that covers the entire world with only eight transmission stations located 7500 km to 9500 km apart. It transmits on frequencies in the VLF band from 10 kHz to 14 kHz at a power of 10 kW. The signals of at least three and usually four stations can be received at any position on Earth.

The 10 kHz to 14 kHz frequency band was chosen specifically to take advantage of several favorable propagation characteristics, such as: (1) to use the Earth's surface and ionosphere as a waveguide; (2) to enable submerged submarines to receive the signals; and (3) to form long baselines at 7500 km to 9500 km.

The basic frequency at which all eight stations transmit is 10.2 kHz. Each station transmits four navigation signals as well as a timing signal with atomic frequency standards ensuring that all stations are kept exactly in phase. Two continuous waves are in phase but traveling in opposite directions to produce a series of Omega lanes. Within each lane, a phase difference measurement would progress from 0° to 360° as the receiver moves across, as shown in [Figure 10.32](#). Two Omega lanes complete one cycle, giving a wavelength of 25 km and lane of 12 km expanding as the distance from the baseline increases. Lanes are identified by three other signals transmitted by each station on a multiplexed basis. Omega

FIGURE 10.33 A surface search radar beam. High-frequency electromagnetic waves are formed by parabolic antenna. The receiving antenna is rotated 360° to scan the entire surrounding area. The location of the target is determined by the reflected back signals and the orientation of the antenna.

fixes have been accurate to within ± 1.5 km rms by day and ± 3 km rms by night. Differential techniques can greatly reduce this error.

Omega receivers are fully automated sets that provide direct lat/long readout for a cost of around U.S. \$1,000 for marine and aviation use. Nevertheless, since the precision of the system is not as good as others, they are mainly used as back-up systems.

Radar

The word is derived from *radio detection* and *ranging*. It works on the basic principle of reflection, which determines the time required for an RF pulse to travel from a reference source to a target and return as an echo. Most surface search and navigation radar high-frequency electromagnetic waves are formed by a parabolic antenna into a beam form, as shown in Figure 10.33. The receiving antenna is rotated to scan the entire surrounding area, and the bearings to the target are determined by the orientation of the antenna at the moment the echo returns. A standard radar is made up of five components: transmitter, modulator, antenna, receiver, and indicator. They operate on pulse modulation.

Radars are extremely important devices for air control applications. Nowadays, airborne beacon radar systems are well developed in traffic alert and collision avoidance systems (TCAS). In this system, each plane constantly emits an interrogation signal, which is received by all nearby aircraft that are equipped appropriately. The signal triggers a transponder in the target aircraft, which then transmits some information concerning 3-D location and identification.

Satellite Relay Systems

The use of satellites is a highly developed technology utilized extensively throughout the world. In the past 2 decades, it has progressed from quasi-experimental in nature to one with routine provisions of new services. They take advantage of the unique characteristics of *geostationary satellite orbits* (GSO). The design of satellite systems is well understood, but the technology is still dynamic. The satellites are useful for long-distance communication services, for services across oceans or difficult terrain, and point-to-multipoint services such as television distribution.

Frequency allocation for satellites is controlled by the International Telecommunication Union (ITU). In the U.S., the Federal Communications Commission (FCC) makes the frequency allocations and assignments for nongovernment satellite usage. The FCC imposes a number of conditions regarding construction and maintenance of in-orbit satellites.

There are many satellite systems operated by different organizations and different countries mainly developed for communications and data transmissions; these include: Iridium of Motorola, Globalstar of Loral Corporation, Intelsat, CS-series of Japan, Turksat of Turkey, Aussat of Australia, Galaxy and Satcom of the U.S., Anik of Canada, TDF of France, etc. Some of the communication satellite systems are suitable for navigation purposes. However, satellite systems specifically designed for navigation are limited in number. The most established and readily accessible by civilian and commercial users are the GPS system of the U.S. and the Glonass of Russia.

The first generation of the satellite system was the *Navy satellite system* (Navsat), which became operational in January 1964, following the successful launch of the first transit satellite into polar orbit.

FIGURE 10.34 Transit satellite Doppler curve. As the satellite approaches the receiver, the frequency of the received signal increases due to Doppler shift. At the time of closest approach, the transmitted and received frequencies are the same. The frequencies received from a receding satellite result in lower values. This is also applicable in other position sensing satellites such as GPS, Glonass, Starfix, etc.

The system was declared open for private and commercial use in 1967. Civil designation of the name of the system is *Transit Navigation Satellite System*, or simply *Transit*. Later, this system evolved to become the modern Navsat GPS system, which will be discussed in detail. Most of the operational principles discussed here are inherited by the GPS system.

The Transit system consists of operational satellites, plus several orbiting spares, a network of ground tracking stations, a computing center, an injection station, naval observatory time signals, and receiver-computer combinations. The transit satellites are in circular polar orbits about 1075 km above ground with periods of revolution of about 107 min. Because of the rotation of the Earth beneath the satellites, every position on Earth comes within range of each satellite at least twice a day, at 12 h intervals. As originally intended, if at least five satellites are operational at any given time, the average time between fix opportunities would vary from about 95 min near the equator to about 35 min or less above 70° North and South.

The Transit system is based on the Doppler shift of two frequencies, 150 MHz and 400 MHz, transmitted simultaneously by each satellite moving its orbit at a tangential velocity of about 7.5 km s^{-1} . Two frequencies are used so that the effects of the ionosphere and atmospheric refraction on the incoming satellite transmission can be compensated for by the receivers. Each frequency is modulated by a repeating data signal lasting 2 min, conveying the current satellite time and its orbital parameters and other information. Within the receiver, a single Doppler signal is created by processing the two signals transmitted by the satellite. By plotting the frequency of this signal versus time, a characteristic curve of the type shown in Figure 10.34 is obtained. Since the frequency of the transmitted signal is compressed as the satellite approaches, according to what proportion of the velocity vector is seen by the user receiver, the curve begins at time T_1 at a frequency several cycles higher than the transmitted frequency.

Tracking stations record Doppler observations and memory readout received during each satellite pass to relay them to a computer center. Updated orbital position and time data communications are relayed to an “injection” station from the computer center for transmission to satellite in a burst once each 12 h. Enough data is supplied in this 15 s injection message to last for 16 h of consecutive 2 min broadcasts describing the current orbital positions of the satellite.

The system accuracy depends on the accuracy of the satellite orbit computation, the effect of ionosphere refraction, the precision of the receiver speed, and heading determination. Under optimal conditions, the system is capable of producing fixes with a maximum rms error of about 35 m for the stationary receivers anywhere on Earth. Nevertheless, if a site is occupied for several weeks, an accuracy better than 1 m can be achieved. The time signal transmitted as a “beep” at the end of each 2 min transmission cycle coincides with even minutes of Coordinated Universal Time, which can be used as a chronometer check.

There are other satellite systems, either already in existence or in the planning stages, suitable for navigation. Some of these are: Marec satellites operating at VHF and owned by the intergovernment consortium INMARSAT; privately owned Geostar provides services for oil industry; and many other systems offering transcontinental communication and navigation services as well as position sensing; examples include: SATCOM, ARINC's, Avsat, Starfix, etc.

Transponders

Transponders are transducers that respond to incoming signals by generating appropriate reply messages. Recent developments in technology have made the configuration of transponders possible using elaborate and powerful on-board signal processing. This enhanced the capacity by improving the link budgets, by adjusting the antenna patterns and by making the satellite resources available on a demand basis — called the “switch board in the sky concept.”

Increased interest in deep sea exploration has brought acoustic transponders to the forefront as an important navigation tool. They provide three-dimensional position information for subservience vehicles and devices.

Some transponders are based on radar signals that respond to radar illumination. Transponders are programmed to identify friend or foe or, in some cases, simply inform ground stations about the position of aircraft.

Transponders are used for emergency warning. The U.S. and Canadian satellites carry Sarsat transponders, and Russian satellites carry Cospas transponders. They are also used as warning devices in collision avoidance systems in aircraft and land vehicles.

Global Satellite Navigation Systems

The GPS System

The Global Satellite Navigation Systems are second-generation satellites evolved primarily from the Naval Global Positioning System. They provide a continuous three-dimensional position-finding capability (i.e., latitude, longitude, and altitude), in contrast to the periodic two-dimensional information of the Transit system. Twenty-four operational satellites, as shown in [Figure 10.35](#), constitute the system. Each satellite orbit is circular, about 2200 km high, and inclined at angles of 55° with respect to Earth's axis.

The position determination using the GPS system is based on the ability of the receivers to accurately determine the distance to the GPS satellites above the user's horizon at the time of fix. If accurate distances of two such satellites and the heights are known, then the position can be determined. In order to do this, the receiver would need to know the exact time at which the signal was broadcast and the exact time that it was received. If the propagation speeds through the atmosphere are known, the resulting range can be calculated. The measured ranges are called *pseudoranges*. Nowadays, normally, information is received from at least four satellites, leading to accurate calculations of the fix. The time errors plus propagation speed errors result in range errors, common to all GPS receivers. Time is the fourth parameter evaluated by the receiver if at least four satellites can be received at a given time. If a fifth satellite is received, an error matrix can be evaluated additionally.

Each GPS satellite broadcasts simultaneously on two frequencies for the determination and elimination of ionosphere and other atmospheric effects. The Navstar frequencies are at 1575.42 MHz and 1227.6 MHz, designated as L1 and L2 in the L-band of the UHF range. Both signals are modulated by 30 s navigation messages transmitted at 50 bits s^{-1} . The first 18 s of each 30 s frame contain *ephemeris* data for that particular satellite, which defines the position of the satellite as a function of time. The remaining 12 s is the *almanac* data, which define orbits and operational status of all satellites in the system. The GPS receivers store and use the ephemeris data to determine the pseudorange, and the almanac data to help determine the four best satellites to use for positional data at any given time. However, the “best four” philosophy has been overtaken slowly by an all-in-view philosophy.

FIGURE 10.35 Operational GPS satellite coverage for navigation. Four satellites orbit in circular form. There are six such orbits inclined at angles of 60° from each other. In this arrangement, any point on Earth can see at least four satellites at any given time. This yields great accuracy in the position determination of the target, even only with C/A codes received.

The L1 and L2 satellite navigation signals are also modulated by two additional binary sequences called *C/A code* for acquisition of coarse navigation and the other *P-code* for precision ranging. The L1 signal is modulated both by the C/A and P-codes, and the L2 only by the P-code. Positional accuracies of about 20 m rms are usual in using C/A codes alone. The P-code, however, is not available for civilian users. The P-code is redesignated to be a Y-code, decipherable only by high-precision receivers having access to encrypted information in the satellite message. Nevertheless, it is fair to comment that civilians have figured out how to benefit the P/Y signals without actually knowing the codes, but at lower SNR. Further, C/A codes are degraded by insertion of random errors such that positional accuracy is limited to 50 m rms for horizontal values and 70 m for vertical values. These errors are intended to be lifted by the year 2006. Civilian users have access to the so-called *Standard Positioning Services* (SPS) accurate to 50 m rms, while U.S. and NATO military users will use *Precise Positioning Service* (PPS).

In enhancing SPS accuracy, differential techniques may be applied, as shown in [Figure 10.36](#), to the encrypted GPS signals. Since the reference receiver is at a known location, it can calculate the correct ranges of pseudoranges at any time. The differences in the measured and calculated pseudoranges give the correction factors. Accuracy less than 1 m can be obtained in the stationary and moving measurements. Recently, differential receivers became commonly available, giving higher accuracy in sub-centimeter ranges. They are getting cheaper day by day and finding applications in many areas such as airplanes, common transport vehicles, cars, geological surveying, orienteering, farming, etc.

There are currently three basic types of GPS receivers designed and built to address various user communities. These are called *slow sequencing*, *fast sequencing*, and *continuous tracking* receivers. The least complicated and lowest cost receiver for most applications is the slow sequencing type, wherein only one measurement channel is used to receive sequential L1 C/A code from each satellite every 1.2 s,

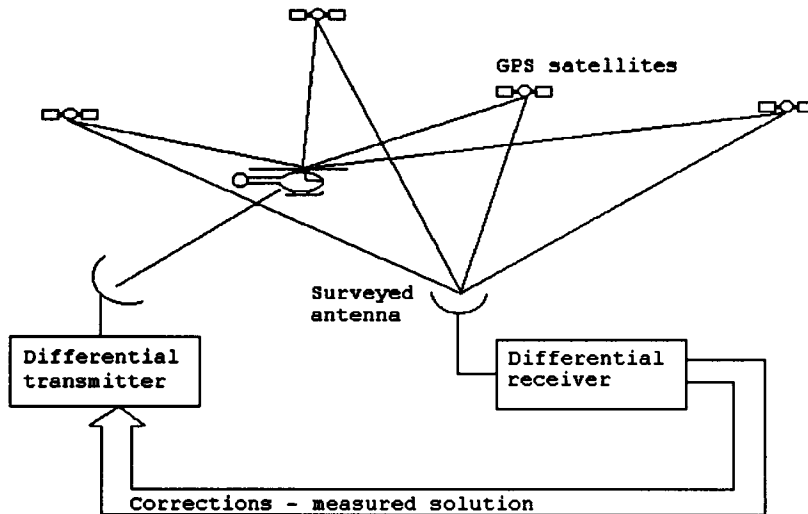

FIGURE 10.36 Differential GPS operation. Satellite and target positions are sensed by ground-fixed receivers or mobile receivers with exact known positions. Errors of the target position due to signals received from the satellites are corrected using the information from the fixed receivers. Using this method, accuracy in submeter range can be obtained.

with occasional interrupts to collect ephemeris and almanac data. Once the data is received, computation is carried out within 5 s, making this system suitable for stationary or near-stationary fixes.

Fast sequencing receivers have two channels: one for making continuous pseudorange measurements, and the other collection of the ephemeris and almanac data. This type is used in medium dynamic applications such as ground vehicles.

Continuous tracking receivers employ multiple channels (at least five) to track, compute, and process the pseudoranges to the various satellites being utilized simultaneously, thus obtaining the highest possible degree of accuracy and making it suitable for high dynamic applications such as aircraft and missiles. The parallel channel receivers are so cost effective nowadays that other types are likely to disappear.

A number of companies produce highly sophisticated GPS receivers. EURONAV GPS receivers operate on two and five channels for military applications. They provide features such as precise time, interfacing with digital flight instruments, RS-422 interface, altimeter input, self initialization, etc.

Software implementation satellite management functions, having different features, are offered by many manufacturers. In the case of DoD NAVSTAR GPS receivers, for example, three functional requirements are implemented: (1) database management of satellite almanac, ephemeris, and deterministic correction data; (2) computation of precise satellite position and velocity for use by navigation software; and (3) using satellite and receiver position data to periodically calculate the constellation of four satellites with optimum geometry for navigation. The DoD receivers are divided for three functions as Satellite Manager (SM), Satellite-Data-Base-Manager (SDBM) SV-Position Velocity Acceleration (SVPVA), and Select-Satellites (SS).

Differential navigation is also applied where one user set is navigating relative to another user set via a data link. In some cases, one user has been at a destination at some prior time and is navigating relative to coordinates measured at that point. The true values of this receiver's navigation fix are compared against the measured values, and the differences become the differential corrections. These corrections are transmitted to area user sets in real-time, or they may be recorded for post-mission use so that position fixes are free of GPS-related biases.

Differential navigation and GPS systems find applications in enroute navigations for commercial and civil aviation, military application, navigation of ships especially in shallow waters, in station keeping of aircraft, seismic geophysical explorations, land surveying, transport vehicles and traffic controls, etc.

The Glonass

There are a number of other satellite navigation systems similar to GPS of the U.S., such as Russian *Glonass*. The Glonass consists of 24 satellites orbiting in circular form 1500 km above the ground. The accuracy of the system is about 10 m rms. Glonass satellites transmit details of their own position and a time reference. The carrier frequencies are in L-band, around 1250 MHz (L2) and 1600 MHz (L1). Only the L1 frequency carries the Civil C/A code. The radio frequency carriers used by Glonass are channelized within bands 1240–1260 MHz and 1597–1617 MHz, the channel spacing being 0.4375 MHz at the lower frequencies and 0.5625 MHz at the higher frequencies. The number of channels is 24. Glonass data message is formatted in frames of 3000 bits, with a duration of 30 s. The ephemeris data are transmitted as a set of position, velocity, and acceleration coordinates in a Cartesian Earth-centered, Earth-fixed (ECEF) coordinate system. The new ephemeris data are available every half hour, valid for the following quarter-hour. The data are sent at a 50 baud rate and superimposed on a pseudorandom noise (PRN) code. The low-precision code has length 511 bits as compared to 1023 bits for Navstar. Glonass accuracy is as good as that for the GPS system. Glonass and GPS have different coordinate frames and different time frames that are being coordinated together.

The Starfix

Another interesting satellite-based system — privately funded, developed, launched, and maintained — is the Starfix positioning system. This system is designed primarily for oil surveying. The system consists of a master site, which generates satellite ephemeris data, and four satellites in geosynchronous orbits. The system said to have a precision of 2.5 m rms.

10.5 Occupancy Detection

Jacob Fraden

Occupancy sensors detect the presence of people in a monitored area. Motion detectors respond only to moving objects. A distinction between the two is that the occupancy sensors produce signals whenever an object is stationary or not, while the motion detectors are selectively sensitive to moving objects. The applications of these sensors include security, surveillance, energy management (electric lights control), personal safety, friendly home appliances, interactive toys, novelty products, etc. Depending on the applications, the presence of humans may be detected through any means that is associated with some kind of a human body's property or actions [1]. For example, a detector may be sensitive to body weight, heat, sounds, dielectric constant, etc. The following types of detectors are presently used for the occupancy and motion sensing of people:

1. *Air pressure sensors*: detect changes in air pressure resulting from opening doors and windows
2. *Capacitive*: detectors of human body capacitance
3. *Acoustic*: detectors of sound produced by people
4. *Photoelectric*: interruption of light beams by moving objects
5. *Optoelectric*: detection of variations in illumination or optical contrast in the protected area
6. *Pressure mat switches*: pressure-sensitive long strips used on floors beneath the carpets to detect the weight of an intruder
7. *Stress detectors*: strain gages embedded into floor beams, staircases, and other structural components
8. *Switch sensors*: electrical contacts connected to doors and windows
9. *Magnetic switches*: a noncontact version of switch sensors
10. *Vibration detectors*: react to the vibration of walls or other building structures; may also be attached to doors or windows to detect movements
11. *Glass breakage detectors*: sensors reacting to specific vibrations produced by shattered glass
12. *Infrared motion detectors*: devices sensitive to heat waves emanating from warm or cold moving objects
13. *Microwave detectors*: active sensors responsive to microwave electromagnetic signals reflected from objects
14. *Ultrasonic detectors*: similar to microwaves, except that instead of electromagnetic radiation, ultrasonic waves are used
15. *Video motion detectors*: video equipment that compares a stationary image stored in memory with the current image from the protected area
16. *Laser system detectors*: similar to photoelectric detectors, except that they use narrow light beams and combinations of reflectors
17. *Triboelectric detectors*: sensors capable of detecting static electric charges carried by moving objects

One of the major aggravations in detecting occupancy or intrusion is a false positive detection. The term "false positive" means that the system indicates an intrusion when there is none. In some noncritical applications where false positive detections occur once in a while, for example, in a toy or a motion switch controlling electric lights in a room, this may be not a serious problem: the lights will be erroneously turned on for a short time, which will unlikely do any harm. In other systems, especially those used for security purposes, the false positive detections, while generally not as dangerous as false negative ones (missing an intrusion), may become a serious problem. While selecting a sensor for critical applications, consideration should be given to its reliability, selectivity, and noise immunity. It is often good practice to form a multiple sensor arrangement with symmetrical interface circuits; this can dramatically improve the reliability of a system, especially in the presence of external transmitted noise. Another efficient way to reduce erroneous detections is to use sensors operating on different physical principles [2]; for example, combining capacitive and infrared detectors is an efficient combination as they are receptive to different kinds of transmitted noise.

Ultrasonic Sensors

Ultrasonic detectors are based on transmission to the object and receiving reflected acoustic waves. Ultrasonic waves are mechanical — they cover frequency range well beyond the capabilities of human ears, i.e., over 20 kHz. However, these frequencies may be quite perceptible by smaller animals, like dogs, cats, rodents, and insects. Indeed, the ultrasonic detectors are the biological ranging devices for bats and dolphins.

When the waves are incident on an object, part of their energy is reflected. In many practical cases, the ultrasonic energy is reflected in a diffuse manner. That is, regardless of the direction where the energy comes from, it is reflected almost uniformly within a wide solid angle, which may approach 180°. If an object moves, the frequency of the reflected waves will differ from the transmitted waves. This is called the Doppler effect (see below). To generate any mechanical waves, including ultrasonic, the movement of a surface is required. This movement creates compression and expansion of the medium, which can be a gas (air), a liquid, or a solid. The most common type of the excitation device that can generate surface movement in the ultrasonic range is a piezoelectric transducer operating in the so-called *motor* mode [3]. The name implies that the piezoelectric device directly converts electrical energy into mechanical energy.

Microwave Motion Detectors

Microwave detectors offer an attractive alternative to other detectors, when it is required to cover large areas and to operate over an extended temperature range under the influence of strong interferences (e.g., wind, acoustic noise, fog, dust, moisture, etc.). The operating principle of the microwave detector is based on radiation of electromagnetic radio frequency (RF) waves toward a protected area. The most common frequencies are 10.525 GHz (X-band) and 24.125 GHz (K-band). These wavelengths are long enough ($\lambda = 3$ cm at X-band) to pass freely through most contaminants, such as airborne dust, and short enough to be reflected by larger objects.

The microwave part of the detector consists of a Gunn oscillator, an antenna, and a mixer diode. The Gunn oscillator is a diode mounted in a small precision cavity that, on application of power, oscillates at microwave frequencies. The oscillator produces electromagnetic waves, part of which is directed through an iris into a waveguide and focusing antenna that directs the radiation toward the object. Focusing characteristics of the antenna are determined by the application. As a general rule, the narrower the directional diagram of the antenna, the more sensitive it is (the antenna has a higher gain). Another general rule is that a narrow beam antenna is much larger, while a wide-angle antenna can be quite small. A typical radiated power of the transmitter is 10 mW to 20 mW.

An antenna transmits the frequency f_0 , which is defined by the wavelength λ_0 as:

$$f_0 = \frac{c_0}{\lambda_0} \quad (10.106)$$

where c_0 is the speed of light. When the target moves toward or away from the transmitting antenna, the frequency of the reflected radiation will change. Thus, if the target is moving away with velocity v , the reflected frequency will decrease, and it will increase for the approaching targets. This is called the *Doppler effect*, after the Austrian scientist Christian Johann Doppler (1803–1853). While the effect was first discovered for sound, it is applicable to electromagnetic radiation as well. However, in contrast to sound waves that may propagate with velocities dependent on movement of the source of the sound, electromagnetic waves propagate with speed of light, which is an absolute constant. The frequency of reflected electromagnetic waves can be predicted by the theory of relativity as:

$$f_r = f_0 \frac{\sqrt{1 - (v/c_0)^2}}{1 + v/c_0} \quad (10.107)$$

For practical purposes, however, the quantity $(v/c_0)^2$ is very small compared with unity; hence, it can be ignored. Then, the equation for the frequency of the reflected waves becomes identical to that for the acoustic waves:

$$f_r = f_0 \frac{1}{1 + v/c_0} \quad (10.108)$$

Due to a Doppler effect, the reflected waves have a different frequency f_r . A mixing diode combines the radiated (reference) and reflected frequencies and, being a nonlinear device, produces a signal that contains multiple harmonics of both frequencies.

The Doppler frequency in the mixer can be found from:

$$\Delta f = f_0 - f_r = f_0 \frac{1}{c_0/v + 1} \quad (10.109)$$

and since $c_0/v \gg 1$, the following holds after substituting Equation 10.106:

$$\Delta f \approx \frac{v}{\lambda_0} \quad (10.110)$$

Therefore, the signal frequency at the output of the mixer is linearly proportional to the velocity of a moving target. For example, if a person walks toward the detectors with a velocity of 0.6 m s^{-1} , a Doppler frequency for the X-band detector is $\Delta f = 0.6/0.03 = 20 \text{ Hz}$.

Equation 10.110 holds true only for movements in the normal direction. When the target moves at angles Θ with respect to the detector, the Doppler frequency is:

$$\Delta f \approx \frac{v}{\lambda_0} \cos \Theta \quad (10.111)$$

Micropower Impulse Radar

In 1993, Lawrence Livermore National Laboratory developed a *micropower impulse radar* (MIR), which is a low-cost, noncontact ranging sensor [3]. The operating principle of the MIR is fundamentally the same as a conventional pulse radar system, but with several significant differences. The MIR consists of a noise generator whose output signal triggers a pulse generator. Each pulse has a fixed short duration, while the repetition of these pulses is random, according to triggering by the noise generator. The pulses are spaced randomly with respect to one another in a Gaussian noise-like pattern. It can be said that the pulses have the pulse frequency modulation (PFM) by white noise with maximum index of 20%. In turn, the square-wave pulses cause amplitude modulation (AM) of a radio transmitter. The radio transmitter produces short bursts of high-frequency radio signal that propagate from the transmitting antenna to the surrounding space. The electromagnetic waves reflect from the objects and propagate back to the radar. The same pulse generator that modulates the transmitter, gates (with a predetermined delay) the radio receiver to enable the output of the MIR only during a specific time window. Another reason for gating the receiver is to reduce its power consumption. The reflected pulses are received, demodulated (the square-wave shape is restored from the radio signal), and the time delay with respect to the transmitted pulses is measured. Since the pulses are spaced randomly, practically any number of identical MIR systems can operate in the same space without a frequency division (i.e., they work at the same carrier frequency within the same bandwidth). There is little chance that bursts from the interfering transmitters overlap and, if they do, the interference level is significantly reduced by the averaging circuit.

FIGURE 10.37 An intruder brings in additional capacitance to a detection circuit.

Capacitive Occupancy Detectors

Being a conductive medium with a high dielectric constant, a human body develops a coupling capacitance to its surroundings. This capacitance greatly depends on such factors as body size, clothing, materials, type of surrounding objects, weather, etc. However wide the coupling range is, the capacitance can vary from a few picofarads to several nanofarads. When a person moves, the coupling capacitance changes, thus making it possible to discriminate static objects from the moving ones. In effect, all objects form some degree of capacitive coupling with respect to one another. If a human (or for that purpose, anything) moves into the vicinity of the objects whose coupling capacitance with each other has been previously established, a new capacitive value arises between the objects as a result of the presence of an intruding body [3]. Figure 10.37 shows that the capacitance between a test plate and Earth is equal to C_1 . When a person moves into the vicinity of the plate, it forms two additional capacitors: one between the plate and its own body C_a , and the other between the body and the Earth, C_b . Then, the resulting capacitance C between the plate and the Earth becomes larger by ΔC .

$$C = C_1 + \Delta C = C_1 + \frac{C_a C_b}{C_a + C_b} \quad (10.112)$$

With the appropriate apparatus, this phenomenon can be used for occupancy detection [3]. What is required is to measure a capacitance between a test plate (the probe) and a reference plate (the Earth).

Figure 10.38 illustrates a circuit diagram for detecting variations in the probe capacitance C_p [4]. That capacitance is charged from a reference voltage source V_{ref} through a gate formed by transistor Q_1 when the output voltage of a control oscillator goes low. When it goes high, transistor Q_1 closes while Q_2 opens. The probe capacitance C_p discharges through a constant-current sink constructed with a transistor Q_3 . A capacitor C_1 filters the voltage spikes across the transistor. The average voltage, e_p , represents a value of the capacitor C_p . When an intruder approaches the probe, the latter's capacitance increases, which results in a voltage rise across C_1 . The voltage change passes through the capacitor C_2 to the input of a comparator with a fixed threshold V_T . The comparator produces the output signal V_{out} when the input voltage exceeds the threshold value.

When a capacitive occupancy (proximity) sensor is used near or on a metal device, its sensitivity can be severely reduced due to capacitive coupling between the electrode and the device's metallic parts. An effective way to reduce that stray capacitance is to use driven shields [3].

Triboelectric Detectors

Any object can accumulate, on its surface, static electricity. These naturally occurring charges arise from the triboelectric effect; that is, a process of charge separation due to object movements, friction of clothing

FIGURE 10.38 Circuit diagram for a capacitive intrusion detector.

fibers, air turbulence, atmosphere electricity, etc. Usually, air contains either positive or negative ions that can be attracted to the human body, thus changing its charge. Under idealized static conditions, an object is not charged — its bulk charge is equal to zero. In reality, any object that, at least temporarily, is isolated from the ground can exhibit some degree of its bulk charge imbalance. In other words, it becomes a carrier of electric charges that become a source of electric field. The field, or rather its changes, can be detected by an electronic circuit having a special pick-up electrode at its input [3, 5]. The electrode increases the capacitive coupling of the circuit's input with the environment, very much like in the capacitive detectors described above. The electrode can be fabricated in the form of a conductive surface that is well isolated from the ground.

If a charge carrier (a human or an animal) changes its position — moves away or a new charge carrying an object enters into the vicinity of the electrode — the static electric field is disturbed. The strength of the field depends on the atmospheric conditions and the nature of the objects. For example, a person in dry man-made clothes walking along a carpet carries a million times stronger charge than a wet intruder who has come from the rain.

It should be noted that contrary to a capacitive motion detector, which is an active sensor, a triboelectric detector is passive; that is, it does not generate or transmit any signal. There are several possible sources of interference that can cause spurious detections by the triboelectric detectors. That is, the detector may be subjected to transmitted noise resulting in false positive detection. Among the noise sources are 60 Hz or 50 Hz power line signals, electromagnetic fields generated by radio stations, power electric equipment, lightnings, etc. Most of these interferences generate electric fields that are distributed around the detector quite uniformly and can be compensated for by employing a differential input circuit with a significant common mode rejection ratio.

Optoelectronic Motion Detectors

Optoelectronic motion detectors rely on electromagnetic radiation in the optical range, specifically having wavelengths from $0.4 \mu\text{m}$ to $20 \mu\text{m}$. This covers visible, near- and part of far-infrared spectral ranges. The detectors are primarily used for the indication of movement of people and animals. They operate over distance ranges up to several hundred meters and, depending on the particular need, can have either a narrow or wide field of view.

FIGURE 10.39 General arrangement of an optoelectronic motion detector. A lens forms an image of a moving object (intruder). When the image crosses the optical axis of the sensor, it superimposes with the sensitive element (A). The element responds with the signal that is amplified and compared with two thresholds in the window comparator (B). (From J. Fraden, *Handbook of Modern Sensors*, 2nd ed., Woodburg, NY: AIP Press, 1997. With permission.)

Most of the objects (apart from very hot) radiate electromagnetic waves only in the mid- and far-infrared spectral ranges. Hence, visible and near-infrared light motion detectors must rely on an additional source of light to illuminate the object. The light is reflected by the object's body toward the focusing device for subsequent detection. Such illumination can be sunlight or the invisible infrared light from an additional near-infrared light source (a projector).

The major application areas for the optoelectronic motion detectors are in security systems (to detect intruders), in energy management (to turn lights on and off), and in the so-called "smart" homes where they can control various appliances such as air conditioners, cooling fans, stereo players, etc. They can also be used in robots, toys, and novelty products. The most important advantage of an optoelectronic motion detector is simplicity and low cost.

Sensor Structures

A general structure of an optoelectronic motion detector is shown in [Figure 10.39\(A\)](#). Regardless what kind of sensing element is employed, the following components are essential: a focusing device (a lens or a focusing mirror), a light detecting element, and a threshold comparator. An optoelectronic motion detector resembles a photographic camera. Its focusing components create an image of its field of view on a focal plane. While there is no mechanical shutter like in a camera, in place of the film, a light sensitive element is used. The element converts the focused light into an electric signal. A focusing lens creates an image of the surroundings on a focal plane where the light sensitive element is positioned. If the area is unoccupied, the image is static and the output signal from the element is steady stable. When an "intruder" enters the room and keeps moving, his/her image on the focal plane also moves. In a certain moment, the intruder's body is displaced for an angle α and the image overlaps with the element. This

FIGURE 10.40 Complex shapes of light sensing element with series (A) and parallel (B) connection of segments. (C) shows use of a grid mask in front of light sensing element. (From J. Fraden, *Handbook of Modern Sensors*, 2nd ed., Woodburg, NY: AIP Press, 1997. With permission.)

is an important point to understand — the detection is produced only at the moment when the object's image either coincides with the detector's surface or clears it. That is, no overlapping — no detection. Assuming that the intruder's body creates an image with a light flux different from that of the static surroundings, the light-sensitive element responds with deflecting voltage V . In other words, to cause detection, a moving image will have a certain degree of optical contrast with its surroundings.

Figure 10.39(B) shows that the output signal is compared with two thresholds in the window comparator. The purpose of the comparator is to convert the analog signal V into two logic levels: \emptyset , no motion detected and 1, motion is detected.

To increase area of coverage, an array of detectors can be placed in the focal plane of a focusing mirror or lens. Each individual detector covers a narrow field of view, while in combination they protect larger areas. All detectors in the array should either be multiplexed or otherwise interconnected to produce a combined detection signal; that is, they can be made into a complex sensor shape. An alternative solution is the use of a multiple-element focusing system.

Complex Sensor Shape

If the detector's surface area is sufficiently large to cover an entire angle of view, it may be optically broken into smaller elements, thus creating an equivalent of a multiple detector array. To break the surface area into several parts, one can shape the sensing element in an odd pattern, like the interdigitized shape shown in Figure 10.40(A) or parallel grid as in Figure 10.40(B). Each part of the sensing element acts as a separate light detector.

The parallel or serially connected detectors generate a combined output signal, for example, voltage v , when the image of the object moves along the element surface crossing alternatively sensitive and nonsensitive areas. This results in an alternate signal v at the detector terminals. Each sensitive and nonsensitive area must be sufficiently large to overlap with most of the object's image. An alternative solution to the complex shape of the sensor is use of the image distortion mask as shown in Figure 10.40(C); however, this solution requires a larger sensor surface area.

Facet Focusing Element

A cost-effective way of broadening the field of view while employing a small-area detector is to use multiple focusing devices. A focusing mirror or a lens may be divided into an array of smaller mirrors or lenses called facets, just like in the eye of a fly. Each facet creates its own image resulting in multiple images, as shown in Figure 10.41. When the object moves, the images also move across the element,

FIGURE 10.41 Facet lens creates multiple images near the sensing element.

resulting in an alternate signal. By combining multiple facets, it is possible to create any desirable detecting pattern in the field of view, in both horizontal and vertical planes. Positioning of the facet lens, focal distances, number, and a pitch of the facets (a distance between the optical axes of two adjacent facets) can be calculated in every case by applying rules of geometrical optics [3]. In the far-infrared spectral range (thermal radiation sensors), the polyethylene facet Fresnel lenses are used almost exclusively, thanks to their low cost and relatively high efficiency.

For the visible portion of the optical spectrum, a simple, very inexpensive, yet efficient motion detector can be developed for nondemanding applications, like light control or interactive toys, using simple photoresistors and pinhole lenses [3, 6, 7].

Far-Infrared Motion Detectors

A motion detector that perceives electromagnetic radiation that is naturally emitted by any object operates in the optical range of thermal radiation, also called far-infrared (FIR). Such detectors are responsive to radiative heat exchange between the sensing element and the moving object. The principle of thermal motion detection is based on the physical theory of emission of electromagnetic radiation from any object whose temperature is above absolute zero (see Chapter 32, Section 6, on *Infrared Thermometers*).

For IR motion detection, it is essential that a surface temperature of an object be different from that of the surrounding objects, so a thermal contrast would exist. All objects emanate thermal radiation from their surfaces and the intensity of that radiation is governed by the Stefan–Boltzmann law. If the object is warmer than the surroundings, its thermal radiation is shifted toward shorter wavelengths and its intensity becomes stronger. Many objects whose movement is to be detected are nonmetals, hence they radiate thermal energy quite uniformly within a hemisphere. Moreover, the dielectric objects generally have a high emissivity. Human skin is one of the best emitters, with emissivity over 90%, while most fabrics also have high emissivities, between 0.74 and 0.95 [3]. Below, two types of far-infrared motion detectors are described. The first utilizes a passive infrared (PIR) sensor, while the second has active far-infrared (AFIR) elements.

PIR Motion Detectors

These detectors became very popular for security and energy management systems. The PIR sensing element must be responsive to far-infrared radiation within a spectral range from $4\ \mu\text{m}$ to $20\ \mu\text{m}$ where most of the thermal power emanated by humans is concentrated. There are three types of sensing elements

FIGURE 10.42 A simplified model of a pyroelectric effect as a secondary effect of piezoelectricity. Initially, the element has a uniform temperature (A); upon exposure to thermal radiation, its front side expands, causing a stress-induced charge (B).

that are potentially useful for that detector: thermistors, thermopiles, and pyroelectrics; however, pyroelectric elements are used almost exclusively for the motion detection thanks to their simplicity, low cost, high responsivity, and broad dynamic range. A pyroelectric effect is described in Chapter 32, Section 7 on *Pyroelectric Thermometers*. How this effect can be used in practical sensor design is discussed here.

A pyroelectric material generates an electric charge in response to thermal energy flow through its body. In a simplified way it may be described as a secondary effect of thermal expansion (Figure 10.42). Since all pyroelectrics are also piezoelectrics, the absorbed heat causes the front side of the sensing element to expand. The resulting thermally induced stress leads to the development of a piezoelectric charge on the element electrodes. This charge is manifested as voltage across the electrodes deposited on the opposite sides of the material. Unfortunately, the piezoelectric properties of the element also have a negative effect. If the sensor is subjected to a minute mechanical stress due to any external force, it also generates a charge that in most cases is indistinguishable from that caused by the infrared heat waves. Sources of such mechanical noise are wind, building vibrations, loud sound, etc.

To separate thermally induced charges from the piezoelectrically induced charges, a pyroelectric sensor is usually fabricated in symmetrical form (Figure 10.43(A)). Two identical elements are positioned inside the sensor's housing. The elements are connected to the electronic circuit in such a manner as to produce the out-of-phase signals when subjected to the same in-phase inputs. The idea is that interferences produced by, for example, the piezoelectric effect or spurious heat signals are applied to both electrodes simultaneously (in phase) and thus will be canceled at the input of the circuit, while the variable thermal radiation to be detected will be absorbed by only one element at a time, thus avoiding a cancellation.

One way to fabricate a differential sensor is to deposit two pairs of electrodes on both sides of a pyroelectric element. Each pair forms a capacitor that can be charged either by heat or by mechanical stress. The electrodes on the upper side of the sensor are connected together forming one continuous electrode, while the two bottom electrodes are separated, thus creating the opposite-serially connected capacitors. Depending on the side where the electrodes are positioned, the output signal will have either a positive or negative polarity for the thermal influx. In some applications, a more complex pattern of the sensing electrodes is required (for example, to form predetermined detection zones), so that more than one pair of electrodes is needed. In such a case, for better rejection of the in-phase signals (common mode rejection), the sensor should still have an even number of pairs where positions of the pairs alternate for better geometrical symmetry. Sometimes, such an alternating connection is called an interdigitized electrode.

A differential sensing element should be mounted in such a way as to ensure that both parts of the sensor generate the same signal if subjected to the same external factors. At any moment, the optical component must focus a thermal image of an object on the surface of one part of the sensor only, which is occupied by a single pair of electrodes. The element generates a charge only across the electrode pair that is subjected to a heat flux. When the thermal image moves from one electrode to another, the current

FIGURE 10.43 Dual pyroelectric sensor. (A) A sensing element with a front (upper) electrode and two bottom electrodes deposited on a common crystalline substrate. (B) A moving thermal image travels from the left part of the sensor to the right, generating an alternating voltage across bias resistor, R .

i flowing from the sensing element to the bias resistor R (Figure 10.43(B)) changes from zero, to positive, then to zero, to negative, and again to zero (Figure 10.43(A) lower portion). A JFET transistor Q is used as an impedance converter. The resistor R value must be very high. For example, a typical alternate current generated by the element in response to a moving person is on the order of 1 pA (10^{-12} A). If a desirable output voltage for a specific distance is $v = 50$ mV, then according to Ohm's law, the resistor value is $R = v/i = 50$ G Ω (5×10^{10} Ω). Such a resistor cannot be directly connected to a regular electronic circuit; hence, transistor Q serves as a voltage follower (the gain is close to unity). Its typical output impedance is on the order of several kilohms.

The output current i from the PIR sensor can be calculated on the basis of the Stefan–Boltzmann law as [3]:

$$i \approx \frac{2P\sigma a\gamma}{\pi hc} bT_s^3 \frac{\Delta T}{L^2} \quad (10.113)$$

where $\Delta T = (T_b - T_a)$ is the temperature gradient between the object and its surroundings, P is the pyroelectric coefficient, σ is the Stefan-Boltzmann constant, a is the lens area, γ is the lens transmission coefficient, h is the thickness, and c is the specific heat of the pyroelectric element, respectively, and L is the distance to the object.

There are several conclusions that can be drawn from Equation 10.113. The first part of the equation (the first ratio) characterizes a detector, while the rest relates to an object. The pyroelectric current i is directly proportional to the temperature difference (thermal contrast) between the object and its surroundings. It is also proportional to the surface area of the object that faces the detector. A contribution of the ambient temperature T_a is not as strong as it might appear from its third power. The ambient temperature must be entered in kelvin, hence its variations become relatively small with respect to the scale. The thinner the sensing element, the more sensitive the detector. The lens area also directly affects signal magnitude. On the other hand, pyroelectric current does not depend on the sensor's area as long as the lens focuses an entire image on a sensing element.

AFIR Motion Detectors

The AFIR motion detector is a new class of thermal sensors whose operating principle is based on balancing thermal power supplied to the sensing element [8, 9]. Contrary to a passive motion detector

that absorbs thermal radiation from a warmer object, an AFIR motion detector is active; that is, it radiates heat waves *toward* the surroundings. The sensor's surface temperature (T_s) is maintained somewhat above ambient. The element is combined with a focusing system, very much like the PIR detector; however, the function of that system is inverse to that of the passive detectors. A focusing part in the AFIR detector projects a thermal image of the warm sensing element into its surroundings. The AFIR sensors have a significant advantage over the PIR: immunity against many interferences (such as RFI and microphonics).

The output voltage from the AFIR motion detector can be described by the following equation [3]:

$$\Delta V \approx -\frac{R}{V_0} \frac{\sigma a \gamma}{\pi} b T_s^3 \frac{\Delta T}{L^2} \quad (10.114)$$

where R is the resistance of the sensor's heater and V_0 is the heating voltage. The minus sign indicates that for warmer moving objects, the output voltage decreases. There is an obvious similarity between Equations 10.113 and 10.114; however, sensitivity (detection range) of the AFIR sensor can be easily controlled by varying R or V_0 . For better sensitivity, the temperature increment above ambient can be maintained on a fairly low level. Practically, the element is heated above ambient by only about 0.2° C.

Krohne Messtechnik GmbH

Level is defined as the filling height of a liquid or bulk material, for example, in a tank or reservoir. Generally, the position of the surface is measured relative to a reference plane, usually the tank bottom. If the product's surface is not flat (e.g., with foam, waves, turbulences, or with coarse-grained bulk material) level usually is defined as the average height of a bounded area.

Various classic and modern methods exist to measure product level in process and storage tanks in the chemical, petrochemical, pharmaceutical, water, and food industries, in mobile tanks on vehicles and ships, but also in natural reservoirs like seas, dams, lakes, and oceans. Typical tank heights are approximately between 0.5 m and 40 m.

Two different tasks can be distinguished: (1) continuous level measurements (level indication, LI), and (2) level switches (LS) (e.g., to detect an alarm limit to prevent overfilling). [Figure 11.1](#) shows the principal operational modes of level measurement. Every continuous system can also be used as a programmable switch. Many level devices are mounted on top of the tank and measure primarily the distance d between their mounting position and the product's surface. The level L is then calculated, defining the tank height h as constant, as shown in [Figure 11.1](#) and expressed as:

$$L = h - d \quad (11.1)$$

The following examples describe primarily the measurement of liquids, but most of the methods can also be applied to solids (bulk material). The emphasis of this chapter will be general information about the measurement principles. The focus of the descriptions is on the methods most commonly practiced; other principles are mentioned less comprehensively. Readers interested in more detailed discussions may refer to [1–5].

FIGURE 11.1 Representation of a tank with a liquid or solid material (hatched area), the product to be measured. The level sensor can be mounted (a) contacting product at the bottom, (b) as a contactless instrument on top, (c) as an intrusive sensor, or (d) at the sides as a level switch.

11.1 Measurements Using the Effects of Density

All methods described in this chapter have in common that the product in the tank has an effect due to its density ρ , (1) producing buoyancy to a solid submerged into the liquid, or (2) executing a force due to its weight.

Displacer

Displacers measure the buoyancy of a solid body that is partially submerged in the liquid. The change in weight is measured. Figure 11.2 illustrates the parameters used for these calculations. The cross section A of the body is assumed to be constant over its length b . The weight of force F_G due to gravity g and mass m is:

$$F_G = g m = g A b \rho_D \quad (11.2)$$

The buoyant force F_B accounts for the partial length L_d that is submerged with the remainder of the body in the atmosphere:

$$F_B = g A L_d \rho_L + g A (b - L_d) \rho_A \quad (11.3)$$

FIGURE 11.2 Quantities of a solid body immersed into a liquid. The forces F can be calculated from Equations 2, 3, and 4. ρ = density; b = length of the body; L_d = dipped length.

Combining Equations 11.2 and 11.3 gives the resulting force to be measured by an appropriate method (see Chapter 23 of this handbook):

$$F_R = F_G - F_B \quad (11.4)$$

The result for level L_d , related to the lower edge of the displacer is:

$$L_d = \frac{b(\rho_D - \rho_A) - \frac{F_R}{gA}}{\rho_L - \rho_A} \quad (11.5)$$

The density of the body should be higher than the density of the liquid; otherwise, the measurement operating range is limited (until the displacer floats on the liquid). In another version, a servo-gage moves the displacer up and down to detect the interface between the atmosphere and a liquid, or between two different liquids, by measuring the change in buoyancy. Figure 11.3 shows a special configuration, in which a small ball with volume V is mounted to a thin wire driven by a stepping motor and put into resonant vibration. The resulting force F can be measured from the resonating frequency f of the wire between points A and B:

$$F = \rho_w A_w 4f^2 l^2 \quad (11.6)$$

where l = length of the wire between the points A and B

ρ_w = density of the wire

A_w = cross-sectional area of the wire

FIGURE 11.3 Level, interface and density sensor using the effects of buoyancy. A stepping motor drives the small ball attached to the thin wire to different heights in the liquid or to the interfaces. The resulting force F as a difference between weight force and buoyant force is measured from the resonant frequency of the wire-ball system. The lever arm excites the wire into oscillation and a sensor coil coupled to the lever arm measures its frequency. The signal converter controls the stepping motor and calculates the measured values [6].

And the surrounding density ρ_L can be calculated:

$$F = gV(\rho_D - \rho_L) \Leftrightarrow \rho_L = \rho_D - \frac{F}{gV} \quad (11.7)$$

Float

Floats are similar to displacers, but are swimming on the liquid's surface due to the buoyancy. Hence, the density of the float must be lower than the density of the liquid. [Figure 11.4\(a\)](#) shows the principle

FIGURE 11.4 Principle of operation for float level meters. (a) A counter weight balances the float that swims on the liquid's surface. Its position represents the level. (b) The float contains a magnet that contacts a reed switch inside a guide tube. Using a bistable relay, this system is used as a level switch. One can also insert multiple relays into the tube to achieve different switching points for quasicontinuous operation.

of operation. The position of the float is (1) observed visually, or (2) transferred to an external display or to an angle transmitter. In general, the float is coupled to the transmitter magnetically. Figure 11.4(b) shows a level switch, using a reed relay magnetically coupled with the float. Also, a magnetostrictive linear sensor may determine the position of the float. For more information about this, refer to Chapter 6, Section 9 of this handbook.

If the float is very flat, it is called a "sensing plate". This plate is mechanically guided, e.g., by a servo control, on the surface until uplift is detected. For solids, specially shaped perpendicular floats are helpful.

Pressure Gages

A hydrostatic pressure p , caused by the weight of the product, is present at the bottom of a tank, in addition to the atmospheric pressure p_0 :

$$p = p_0 + g \rho_L L \Leftrightarrow L = \frac{p - p_0}{g \rho_L} \quad (11.8)$$

Pressure gages at the bottom of the tank measure this pressure. In process tanks with varying atmospheric pressure, a differential pressure measurement is achieved by measuring the difference between the pressure at the bottom and that at the top of the tank, above the liquid. Figure 11.5(a) shows such a configuration with a differential pressure sensor. For techniques of pressure measurement, refer to Chapter 26, Section 1 of this handbook. Because measurement by hydrostatic pressure is proportional to the density, level errors result if density changes; see Equation 11.8. Primary pressure gaging is a mass measurement. Figure 11.5(b) shows a vertical arrangement with three sensors; the measurements of p_1 and p_2 are used to compensate for the influence of density ρ_L , and to calculate the level:

FIGURE 11.5 Level gaging by hydrostatic pressure measurement. The bottom pressure p is proportional to level. (a) The atmospheric pressure p_0 can be taken into consideration by a differential measurement. The low side of the differential pressure sensor is connected via a thin pipe to the top of the tank. (b) A differential measurement within the liquid is called “hydrostatic tank gaging, HTG” and can be used to compensate errors due to density variations of the liquid. The signals from all three sensors are evaluated by a computer. (c) With a so-called “bubble tube,” the sensor can be mounted on the top of the tank: an inert gas is injected into the tube such that bubbles of gas escape from the end of the tube. The flow rate of the gas is constant so the head pressure in the system can be measured at the inlet of the pipe.

$$\rho_L = \frac{p_2 - p_1}{gl} \Rightarrow L = \frac{p_2 - p_0}{p_2 - p_1} l \quad (11.9)$$

A system of this configuration is often called “hydrostatic tank gaging” (HTG). [Figure 11.5\(c\)](#) shows a further arrangement, called “bubble tube,” in which the bottom pressure is transmitted to the top of the tank. This is often used for level gaging if the sensor cannot be mounted at the bottom of the tank. It requires a tank with pressure equalization due to the steady insertion of inert gas.

Balance Method

Here simply the weight F of the complete tank is measured, dependent on the level L :

$$F = F_0 + gAL\rho_L \quad (11.10)$$

where F_0 is the weight of the empty tank and A the cross-sectional area, which is assumed to be constant throughout the tank height. In order to measure the weight force correctly, it is necessary to isolate the complete tank mechanically. For precise measurements, the buoyancy in air must be taken into consideration:

$$F = F_0 + gAL(\rho_L - \rho_A) \Leftrightarrow L = \frac{F - F_0}{gA(\rho_L - \rho_A)} \quad (11.11)$$

For techniques of weight measurement, refer to Chapter 20 of this handbook.

This method has severe disadvantages when the tank is not inside a building. Outside, wind forces and the weight of snow and rain can cause errors.

11.2 Time-of-Flight Measurements

An indirect measurement of level is evaluating the time-of-flight of a wave propagating through the atmosphere above the liquid or solid. This is primarily a distance measurement; the level can then be calculated accordingly. The increasing demand of industry for nonintrusive continuous level gaging systems has been instrumental in accelerating the development of technologies using time-of-flight measurements [7].

Basic Principle

Although different types of physical waves (acoustic or electromagnetic) are applied, the principle of all these methods is the same: a modulated signal is emitted as a wave toward the product, reflected at its surface and received by a sensor, which in many cases is the same, (e.g., the ultrasonic piezoelectric transducer or the radar antenna). Figure 11.6 demonstrates the principle of operation. The measuring system evaluates the time-of-flight t of the signal:

$$t = \frac{2d}{v} \quad (11.12)$$

where v is the propagation velocity of the waves.

One can generate an unmodulated pulse, a modulated burst as in Figure 11.6(b), or special forms. Table 11.1 lists the main properties of the three preferred types of waves, used for time-of-flight level gaging.

The very short time spans of only a few nanoseconds for radar and laser measurement techniques require the use of time expansion by sampling (see Chapter 85 of this handbook) or special evaluation methods (see below).

Ultrasonic

Ultrasonic waves are longitudinal acoustic waves with frequencies above 20 kHz. Ultrasonic waves need a propagation medium, which for level measurements is the atmosphere above the product being measured. Sound propagates with a velocity of about 340 m s^{-1} in air; but this value is highly dependent on temperature and composition of the gas, and also on its pressure (see Chapter 6, Section 7 of this handbook). In vacuum, ultrasonic waves cannot propagate. In practice, the reflection ratio is nearly 100% at the product's surface (e.g., at transitions gas/liquid or gas/solid). Piezoelectric transducers (see Chapter 26, Section 3 of this handbook) are utilized as emitter and detector for ultrasonic waves, a membrane coupling it to the atmosphere. The sensor is installed as in Figure 11.1(b), the signal form is as in Figure 11.6(b). Level gaging is, in principle, also possible with audible sound 16 Hz to 20 kHz or infrasonic waves less than 16 Hz.

Another procedure is to propagate the waves within the liquid by a sensor mounted at the bottom of the tank. The velocity of sound in the liquid must be known, considering the dependence on temperature and type of liquid. This method is similar to an echo sounder on ships for measuring the water depth. For more information about time-of-flight ultrasound evaluation techniques, refer to Chapter 6, Section 7 of this handbook.

Microwaves

Microwaves are generally understood to be electromagnetic waves with frequencies above 2 GHz and wavelengths of less than 15 cm. For technical purposes, microwave frequencies are used up to max. 120 GHz; in practice, the range around 10 GHz (X-band) is preferred.

FIGURE 11.6 (a) Representation of time-of-flight measurements. The emitter couples a wave (ultrasonic or electromagnetic) into the atmosphere that propagates the wave toward the liquid. Its surface reflects the wave and a sensor receives it. (b) Due to the propagation velocity v , a time delay is measured between emission and receipt of the signal. This example is characterized by a modulated burst. The time scale is arbitrary.

TABLE 11.1 Properties of the wave types for time-of-flight measuring.

Principle	Wave Velocity	Avg. Carrier Frequency	Wavelength	Avg. Burst Time
Ultrasonic	340 m s^{-1}	50 kHz	7 mm	1 ms
Radar	$300,000 \text{ km s}^{-1}$	10 GHz	3 cm	1 ns
Laser	$300,000 \text{ km s}^{-1}$	300 THz	$1 \mu\text{m}$	1 ns

FIGURE 11.7 Practical antenna forms used for radar level instruments: (a) conical horn antenna, (b) dielectric rod antenna, and (c) parabolic mirror with a small antenna as primary radiator and an auxiliary reflector giving a very small beam angle (so-called Cassegrain model).

The usually applied time-of-flight measurements with microwaves are RADAR-based [8, 9]. The term “RADAR” is generally understood to mean a method by means of which short electromagnetic waves are used to detect distant objects and determine their location and movement. It is an acronym from RADio Detection And Ranging. Figure 11.7 shows preferred antenna forms. They are usually combined with a compact sensor, as in Figure 11.8. For level measuring systems, a small radiation angle is desirable in order to avoid interfering reflections from the tank wall or tank internals as much as possible. The larger the aperture area, the smaller the radiation angle and the higher the antenna gain. The power balance is given by the general radar equation:

$$P_R = \frac{P_T G_T R G_R}{D^2} \quad (11.13)$$

where P_R = received power
 P_T = transmitted power
 G_T = transmitting antenna gain
 R = reflection factor of target
 G_R = receiving antenna gain
 D^2 = propagation loss to and from the surface, due to power density decrease and atmospheric influences

The reflection factor R of the product’s surface is dependent on the dielectric permittivity ϵ_r of the liquid or bulk material:

$$R = \frac{\left(\sqrt{\epsilon_r} - 1\right)^2}{\left(\sqrt{\epsilon_r} + 1\right)^2} \quad (11.14)$$

FIGURE 11.8 Design of a compact industrial level radar system. The converter above the flange includes the complete microwave circuitry, signal processing stages, microprocessor control, display, power supply, and output signal [6].

In level measurement situations, the reflecting area is so large that it intersects the beam cross section completely; therefore, D^2 is approximately proportional with distance d^2 . Thus also, the received power decreases proportionately with d^2 , as derived in [8]:

$$P_R \propto \frac{1}{d^2} \quad (11.15)$$

FIGURE 11.9 Principle of operation of a wire-conducting high-frequency level measurement system. (a) An electrical pulse is generated (time t_0) and a two-wire line guides the electromagnetic wave. At every position where the surrounding permittivity ϵ changes, a part of the wave is sharply reflected (time t_1) back to the sensor. The wave propagates along the entire line and is reflected a second time (t_2) at the interface between the two liquids, and a third time at the end of the line. (b) The signal delay times ($2t_1$, $2t_2$, and $2t_3$) represent the positions of the interfaces with respect to the end of the line, which can be used as a reference. The signal polarity is inverted due to the reflection from lower to higher permittivity. The time scale is arbitrary.

This is not the case if the waves propagate within an electromagnetic waveguide, like a vertical tube dipping into the liquid, called a stilling well. Here, the propagation is nearly without losses.

An alternative method using electromagnetic waves is to propagate them in a cable. Figure 11.9(a) illustrates the operation with a cable dipped into the liquid or bulk material. Where the dielectric permittivity of the surrounding medium changes, part of the wave is reflected. This method can be applied to interface measurements too. Figure 11.9 shows the signals in an application with a two-phase product. This method is called “time domain reflectometry” (TDR).

Laser/Light

Lasers and light-emitting diodes produce electromagnetic waves of very short wavelength (less than $2\ \mu\text{m}$), which can also be used for time-of-flight measurements, similar to the described microwave methods. Preferred laser signals are (1) short pulses of less than 1 ns duration, or (2) lasers with amplitude-modulated intensity with frequencies of some megahertz. For more details about laser operation and interferometry methods, refer to Chapter 6, Section 5 of this handbook.

FIGURE 11.10 Operation characteristics of FMCW radar. The frequency of the transmitter changes linearly by time in an interval (sweep). The received signal has the same form, but is time-delayed. At every point of the sweep, the differential frequency is constant and proportional to the time delay. Time and frequency scales are arbitrary.

Laser systems are very precise and can achieve accuracies better than 1 mm. Because the laser beam is very narrow, such level measurement systems can be installed without influence of tank internals. Some practical disadvantages of laser level measurement are: (1) it functions as does your eye to see the product's surface and therefore fails if dust, smoke, etc. are present; (2) it is sensitive to dirt on the optical sensors; and (3) the equipment is expensive.

Commonly Used Evaluation Methods

Due to the great benefits of contactless time-of-flight measurement, some typical methods have been evaluated for level gaging within the last few years, mainly in radar techniques [8].

Frequency-Modulated Continuous Wave Radar

Because the flight times in typical level applications are very short (a resolution of 1 mm requires a 7 ps time resolution), it is difficult to evaluate information directly in the time domain. By modulation of the microwave signals, the time delay is transformed into the frequency domain, obtaining low-frequency signals. For general information about modulation, see Chapter 81 of this handbook.

Therefore, Frequency Modulated Continuous Wave (FMCW) radar has been established as the dominant technique. FMCW radar utilizes a linearly frequency-modulated microwave signal; the transmission frequency rises linearly in a time interval T . The frequency difference in this interval is called the frequency sweep F .

Figure 11.10 shows the principle of FMCW radar. Due to the time delay during signal propagation, the transmitted frequency changes such that the difference between the momentary transmitted frequency and the received frequency, a low-frequency signal is obtained. The frequency f of that signal (typically up to a few kilohertz) is proportional to the reflector distance d (see Figure 11.6); in this method, therefore, the delay t is transformed into a frequency f :

$$f = \frac{F}{T}t = \frac{F}{T} \frac{2d}{c} \Leftrightarrow d = \frac{f c T}{2 F} \quad (11.16)$$

In Equation 11.16, c is the speed of light and F/T is the sweep velocity; see Figure 11.10.

Figure 11.11 shows a basic circuit block diagram of an FMCW radar system. Because the resultant signal frequencies are low, further signal processing is technically simple and very accurate. Normally,

FIGURE 11.11 Basic circuit block diagram of an FMCW radar system: a microprocessor controls a voltage-controlled oscillator (VCO), such that the desired frequency sweep is obtained. This signal is amplified and fed into the transmitting antenna. The instantaneous frequency must be measured in order to ensure good sweep linearity. This is accomplished by counting the frequency after it has been mixed with the known frequency of a dielectric resonance oscillator (DRO). A directional coupler decouples the received signal, which is mixed with the transmission signal and processed by the microprocessor.

evaluation is by means of digital signal processing. For more information about signal processing techniques using spectrum analysis, refer to Chapter 83 of this handbook.

Time-of-Flight Through Product

Alternatively, the propagation time of the waves through a weakly absorbing liquid or bulk material of low permittivity ϵ_r can be measured, as well as the propagation through the air. In cases where the reflection from the interface between air and the upper surface of the product is poor, part of the signal travels through the liquid and is reflected a second time at the tank bottom or at an interface between two liquids (e.g., oil on water).

Figure 11.12 demonstrates this technique. The evaluation is done in the following four steps:

1. Where microwaves in the tank atmosphere of height d are propagated at the speed of light c , microwaves in the medium (relative permittivity = ϵ_r , height L) are propagated at a slower velocity v .
2. Hence, the reflection r_2 from the tank bottom appears to be shifted downward, and the apparent tank height h_v is greater than the true height h .
3. The transit time in the medium is $t_1 = L/v$, where for the same distance in an empty tank would be $t_0 = L/c$. The ratio of apparent “thickness layer” ($h_v - d$) to true filling height ($h - d$) therefore corresponds to the ratio of the wave propagation rates:

$$\frac{h_v - d}{h - d} = \frac{c}{v} = \sqrt{\epsilon_r} \quad (11.17)$$

4. When ϵ_r , h , and h_v are known, distance d and, from that, filling height L can be calculated exactly:

$$L = h - d = \frac{h_v - h}{\sqrt{\epsilon_r} - 1} \quad (11.18)$$

By this method, a direct level measurement — not a distance measurement — is attained. It can even be applied when signal r_1 from the surface of the medium is no longer measurable. The evaluation of

FIGURE 11.12 Representation of time-of-flight measurement through liquid: the wave is reflected once (r_1) at the product's surface and a second time (r_2) at the tank bottom. Due to the reduced wave velocity within the liquid, the reflection r_2 appears below the geometric position of the bottom. From that shift, the level can be calculated; see Equations 11.17 and 11.18.

the tank bottom reflection signal is known as “tank bottom tracing,” and is used in the radar level system offered by Krohne in Figure 11.8.

11.3 Level Measurements by Detecting Physical Properties

To measure level, one can detect physical parameters that are significantly different between the atmosphere and the product; for example, conductivity, viscosity, or attenuation of any type of radiation. Two types are possible: (1) continuous measurement with an integral sensor, or (2) switching by a point measurement when the sensor comes in contact with the product.

Electrical Properties

The sensor must be in direct or indirect contact with the product to detect its electrical properties. For continuous measurement, only part of the intrusive sensor must be in contact with the product to detect the difference in dielectric permittivity or conductivity.

Capacitive

In most applications, a rod electrode is arranged vertically in the tank. The electrode can be (1) noninsulated if the liquid is nonconductive, or (2) insulated. The metallic vessel acts as a reference electrode.

FIGURE 11.13 Principle of operation for a capacitance-type level device. (a) An insulated electrode protrudes into the liquid. The capacitance between the inner conductor and the tank walls is measured. (b) As a capacitance level switch, the electrode can be mounted at the appropriate position directly into the tank wall.

The result depends on the permittivity ϵ_2 of the product. Figure 11.13(a) shows an electrode concentrically mounted on a cylindrical tank. For such a rotationally symmetrical configuration, the capacitance C of an insulated electrode changes with level L according to:

$$C = \frac{2\pi\epsilon_0 L}{\frac{1}{\epsilon_1} \ln \frac{d_2}{d_1} + \frac{1}{\epsilon_2} \ln \frac{d_3}{d_2}} \Leftrightarrow L = \frac{C \left(\frac{1}{\epsilon_1} \ln \frac{d_2}{d_1} + \frac{1}{\epsilon_2} \ln \frac{d_3}{d_2} \right)}{2\pi\epsilon_0} \quad (11.19)$$

ϵ_0 is the dielectric constant of vacuum (8.85×10^{-12} As $V^{-1}m^{-1}$); ϵ_1 and ϵ_2 are the relative permittivities of the insulation material and the liquid, respectively.

If the liquid itself is highly conductive, Equation 11.19 simplifies to:

$$C = \frac{2\pi\epsilon_0 \epsilon_1 L}{\ln \frac{d_2}{d_1}} \Leftrightarrow L = \frac{\ln \frac{d_2}{d_1}}{2\pi\epsilon_0 \epsilon_1} \quad (11.20)$$

If the electrode is not insulated, the following equation is valid:

$$C = \frac{2\pi\epsilon_0\epsilon_2 L}{\ln \frac{d_3}{d_1}} \Leftrightarrow L = \frac{\ln \frac{d_3}{d_1}}{2\pi\epsilon_0\epsilon_2} \quad (11.21)$$

When arranged horizontally, as in [Figure 11.13\(b\)](#), a capacitive sensor can act as a level switch.

For the electrical measurement of capacitance, refer to Chapter 6.3 of this handbook. For a more precise measurement of conductive liquids, a method measuring the complex impedance is helpful.

Conductive

The resistance of the liquid between two electrodes is measured with (1) a strip line with two parallel electrodes similar to [Figure 11.9\(a\)](#), or (2) a rod electrode with the metal vessel as the reference electrode, similar to [Figure 11.13\(a\)](#) without insulator.

Radiation Attenuation

All radiation (e.g., gamma rays, ultrasonic waves, electromagnetic waves) is attenuated to some degree in any medium. In general, attenuation in liquids or bulk materials is higher than in gases. This effect is used to measure level or limits, without direct contact of the sensor.

Radiometric

The intensity I of gamma rays is attenuated by the liquid according to its damping factor α :

$$I = I_0 \exp(-\alpha d) \quad (11.22)$$

The source can be a radioactive material Co-60 or Cs-137, having half-lives of 5.23 years and 29.9 years, respectively. Emitter and sensor may take the form of (1) a point emitting the rays radially in all directions, (2) a rod emitting radially from a line, or (3) an array consisting of several point emitters in a row. Any combination of point/rod/array emitter with point/rod/array detector is possible. [Figure 11.14](#) shows two different configurations. Radiation protection regulations must be considered. A real-time clock in the system must compensate for the decrease of intensity (dose rate) I by time t according to the half-life T_H of the applied material:

$$I = I_0 2^{-t/T_H} \quad (11.23)$$

For more information about radiation detection methods, refer to Chapter 66 of this handbook. Plastic scintillators and counting tubes are preferred for radiometric level gaging. The level–intensity characteristic is nonlinear, so the equipment should be calibrated in place. Mengelkamp [10] describes the radiometric techniques in more detail.

Ultrasonic Switch

A short ultrasonic transmission path can be used to detect products that dampen sonar waves. For instance, this method is applicable for the detection of slurries or to determine the interface between two different liquids. When combined with a servo system, the vertical profile of ultrasonic attenuation can be measured. Another application uses a noncontact sensor mounted on the outside of the vessel. It measures the acoustic impedance through the vessel wall that changes if liquid or gas is present behind the wall.

FIGURE 11.14 Representation of a radiometric continuous level gage. The rays are emitted by a radioactive source, propagate through the tank walls, and are damped by the liquid. In (a), a point source is combined with a rod detector (e.g., scintillator rod); (b), a source array is combined with a point detector.

Microwave Switch

Liquids and solids dampen microwaves in many cases, sometimes absorbing them completely. A simple unmodulated microwave source and an accompanying receiver are sufficient for level switching.

Photoelectric Barrier

A photoelectric barrier can act as a level switch for liquids that are not transparent, as well as most solids. But in closed nontransparent tanks, the coupling of the photoelectric components to the tank will not be possible in most cases.

Thermal and Mechanical

For some special applications, level sensors utilize the different heat dissipation properties and viscosities of the media.

Thermal

A self-heated resistor with a high temperature coefficient is immersed into the liquid. Heat dissipation causes the temperature to drop somewhat in the region where the liquid covers the sensor. Therefore, the resistance change is nearly linear with the level. This method is often used in automotive applications. In some applications with heated liquids (e.g., chemical reaction vessels), a simple temperature sensor can be used as a level switch by emitting a signal when the liquid contacts the sensor and heats it.

Viscosity

The effect of viscosity, which is significantly higher for liquids than for gases, dampens the movement of a body. These level sensors measure the degree of damping of a vibrating fork when dipped in a liquid. Normally, it is only used as a point level switch. Figure 11.15 shows such a “tuning fork,” named according to the typical form with two or three vibrating paddles. The integrated electronics evaluate the power loss or the frequency shift of the mechanical resonance system. For solids, a sensor with a rotating paddle that stops when contacting the product is useful.

FIGURE 11.15 Design of a vibrating level switch. The switch reacts to product viscosity changes, which dampens the vibration of the paddles [6].

11.4 Instruments

Table 11.2 lists the most common techniques for level gaging with corresponding application range, accuracy, and average prices. Pricing as shown is for typical industrial applications and can vary widely, depending on materials of construction, measuring range, accuracy, approval requirements, etc. Table 11.3 provides contact information for manufacturers of level instruments. Most of these companies manufacture various instruments, using the different technologies shown in Table 11.2. This list is not comprehensive; additionally, some smaller companies provide equipment for specialized level measurements.

TABLE 11.2 Priority Level Measurement Techniques and Prices for Industrial Applications

Technique	Application Range	Attainable Accuracy	Avg. Price
Displacer/float	Continuous, liquids	1 mm	\$2,000
Float	Switch, liquids	10 mm	\$500
Pressure	Continuous, liquids	10 mm	\$2,000
Ultrasonic	Continuous, liquids, solids	5 mm	\$2,500
Radar	Continuous, liquids, solids	1 mm	\$3,000
TDR	Continuous, liquids, solids	3 mm	\$2,500
Laser	Continuous, liquids, solids	0.1 mm	\$10,000
Radiometric	Continuous, liquids, solids	10 mm	\$5,000
Capacitive	Switch, liquids	10 mm	\$500
Viscosity	Switch, liquids	10 mm	\$500

- 12.1 Theory
 Planimeter • Digitizer • Grid Overlay
- 12.2 Equipment and Experiment
- 12.3 Evaluation

One must often measure the area of enclosed regions on plan-size drawings. These areas might be either regular or irregular in shape and describe one of the following:

- Areas enclosed by map contours
- Cross section of the diastolic and systolic volumes of heart cavities
- Farm or forest land shown in aerial photographs
- Cross sections of proposed and existing roads
- Quantities of materials used in clothing manufacture
- Scientific measurements
- Swimming pools
- Quantities of ground cover

Tools for this type of measurement include planimeters, digitizer-computer setups, digitizers with built-in area measuring capability, and grid overlay transparencies.

12.1 Theory

Planimeter

A planimeter is a mechanical integrator that consists of a bar (tracer arm), a measuring wheel with its axis parallel to the bar, and a mechanism that constrains the movement of one end of the bar to a fixed track, [Figure 12.1](#). The opposite end of the bar is equipped with a pointer for tracing the outline of an area. The measuring wheel, [Figure 12.2](#), is calibrated with 1000 or more equal divisions per revolution. Each division equals one count. It accumulates counts, P , according to:

$$P = \frac{K}{\pi D} \int \sin \phi ds \quad (12.1)$$

where K = number of counts per revolution of the measuring wheel
 D = diameter of the measuring wheel
 ϕ = angle between the measuring wheel axis and the direction of travel
 s = traced path

FIGURE 12.1 The constrained end of a **polar planimeter** (a) follows a circular path; the constrained end of a **linear planimeter** (b) follows a straight line path.

FIGURE 12.2 The rotation of a measuring wheel is proportional to the product of distance moved and the sine of the angle between the wheel axis and direction of travel.

The size of an area, A , traced is:

$$A = \frac{P}{K} \times \pi D \times L \quad (12.2)$$

where L = length of bar

P = accumulated counts (Equation 12.1)

Figure 12.3 shows how a basic wheel and bar mechanism determines the area of a parallelogram. The traced path is along the sloped line; however, the wheel registers an amount that is a function of the product of the distance traveled and the sine of the angle between the direction of travel and the axis of the measuring wheel (Equation 12.1). This is the altitude of the parallelogram. The product of the altitude (wheel reading converted to distance) and base (bar length) is the area.

Figure 12.4(a) illustrates the operation of a planimeter when the area of a four-sided figure is measured. Figures 12.4(b), (c), (d), and (e) show the initial and final positions of the bar as each side of the figure

FIGURE 12.3 The area of this parallelogram is proportional to the product of tracer arm length and measuring wheel revolutions.

FIGURE 12.4 This schematic shows a planimeter pointing to each junction of a four-sided figure being traced in (a) and at the ends of each of the segments in (b) through (e). The constrained end of the tracer arm follows a circle.

is traced. Applying the general expression for the area under a curve, $A = \int f(x) dx$ for each of these partial areas gives:

$$A_a = \left(\int_a^1 + \int_1^2 + \int_2^b + \int_b^a \right) f(x) dx \quad (12.3)$$

$$A_b = \left(\int_b^2 + \int_2^3 + \int_3^c + \int_c^b \right) f(x) dx \quad (12.4)$$

$$A_c = \left(\int_c^3 + \int_3^4 + \int_4^d + \int_d^c \right) f(x) dx \quad (12.5)$$

$$A_d = \left(\int_d^4 + \int_4^1 + \int_1^a + \int_a^d \right) f(x) dx \quad (12.6)$$

where A_a , A_b , A_c , and A_d are the four partial areas.

The total area of the figure is the sum of the four partial areas. Combining the terms of these partial areas and rearranging them so that those defining the area traced by the left end of the bar are in one group, those defining the area traced by the other end of the bar are in a second group, and those remaining are in a third group results in the following:

$$A = \left\{ \left[\int_b^a + \int_c^b + \int_d^c + \int_a^d \right] f(x) dx + \left[\int_a^1 + \int_2^b + \int_3^c + \int_4^d + \int_c^3 + \int_d^4 + \int_d^1 + \int_1^a \right] f(x) dx \right. \\ \left. + \left[\int_1^2 + \int_2^3 + \int_3^4 + \int_4^1 \right] f(x) dx \right\} \quad (12.7)$$

The first four integrals describe the area traced by the left end of the bar. Since this end runs along an arc, it necessarily encloses an area equal to zero. The final four integral describe the area traced by the right end of the bar. This is the four-sided figure. The remaining eight integrals cancel out since $\int_a^1 + \int_1^a = 0$, etc. Thus, the total area equals the area traced by the right end of the bar. Note that the same reasoning applies to figures of any number of sides and of any shape.

Digitizer

A digitizer converts a physical location on a map to digital code representing the (x, y) coordinates of the location. The digital code is normally converted to a standard ASCII or binary format and transmitted to a computer where computations are made to determine such things as area or length. Certain digitizers can also compute areas and lengths without the use of a computer.

Area, A , can be computed using the coordinate pairs that define the area boundary.

$$A = \frac{1}{2}(y_1 + y_2)(x_2 - x_1) + \frac{1}{2}(y_2 + y_3)(x_3 - x_2) + \dots + \frac{1}{2}(y_{n-1} + y_n)(x_n - x_{n-1}) \\ + \frac{1}{2}(y_n + y_1)(x_1 - x_n) \quad (12.8)$$

where x_1, x_2, x_3 , etc. = sequentially measured x coordinates along the boundary.

y_1, y_2, y_3 , etc. = are corresponding y coordinates

All digitized coordinate pairs must be used in the computations since the Δx intervals of this data are typically unequal.

In Equation 12.8, the final term deserves special consideration because it contains both the first and last coordinate pair of the series. When computations are performed from data stored in a computer, information is available for computing the final term so that no special actions are necessary. However, when the computations are performed by an embedded microprocessor with limited memory, normally each term is computed as the coordinates are read. In this case, one of two actions must be taken. First, the first coordinate pair is saved and then, once the measurement has been completed, a key is pressed to initiate computation of the final term. This is called “closing the area.” Second, if the first coordinate pair is not saved, to prevent an error the final point digitized must coincide with the first point digitized so that $x_n = x_1$, $y_n = y_1$ and the final term is zero.

Popular types of digitizers in use today are tablets, sonic digitizers, and arm digitizers. Probably the most popular type is the tablet.

Tablet Digitizer

Tablet digitizers consist of a pointer and a work surface containing embedded wires configured as a grid. The horizontal wires are parallel and spaced by about 12 mm. The vertical wires are also parallel and spaced the same. Different sensing techniques are used to locate the pointer position relative to the grid wires.

One sensing technique employs grid wires made from magnetostrictive material that has the property of changing shape very rapidly when subjected to a magnetic field. Each set of grid wires, the horizontal and vertical, is independently energized by a send wire that lies perpendicular to that set of wires [1]. A pulse transmitted over the send wire has a magnetic field that changes the shape of each magnetostrictive wire, causing a strain wave to propagate down the wire. Coincidentally, the pulse starts a counter. A coil in the pointer senses the strain wave and sends a signal to stop the counter. The counter reading is thus proportional to the propagation time of the strain wave. The product of the propagation time and velocity of the strain wave equals the physical distance between send line and pointer detector. The velocity of the strain waves is slow enough so that any errors in time measurement can be made acceptable.

A second sensing technique uses a grid made of conductive wires and a pointer that emits a signal on the order of 57.6 kHz [2]. The vertical grid wires are sensed to determine the amplitude distribution of signal induced in each wire. The point of maximum signal strength determines the location of the pointer along the horizontal axis. The horizontal grid wires are likewise sensed to find the point of maximum signal strength that determines the pointer location along the vertical axis. Coupling between the pointer and grid can be by either electromagnetic or by electrostatic means [3].

Signals can also be applied to the grid wires and the pointer used as a receiver. In this case, the signal to each grid wire must be coded or else applied sequentially, first to one set of grid wires and then to the other. Amplitude profiles of the signals received by the pointer are determined to locate the pointer along each axis.

Sonic Digitizers

Sonic digitizers consist of a pointer and two or more microphones. The pointer, used to identify the point to be digitized, typically contains a spark gap that periodically emits a pulse of sonic energy [4]. The microphones in certain cases are mounted in a bar that is located along the top of the drawing area. In other cases, they are mounted in an L frame and located along the top and one side of the drawing area.

The microphones receive the sonic pulse emitted by the pointer. The time taken for the pulse to travel from the transmitter to each receiver is measured and the slant distance computed from the product of this elapsed time and the sonic velocity. The x and y coordinates of the pointer are computed from the slant ranges and the locations of the microphones.

Ambiguities exist since a single set of slant ranges describe two points; however, the ambiguities can be resolved either by using additional microphones or by ensuring that the ambiguous points are outside the work area. With the microphones aligned along the top of the work area, the ambiguous points are

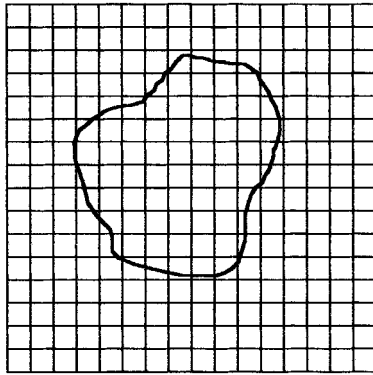

FIGURE 12.5 Grid overlays offer a simple and readily available method for measuring areas.

outside the work area; with them aligned along top and side, the ambiguities have to be resolved with additional microphones.

The sound wave velocity is slow enough so that errors in time measurements can be made acceptable.

Arm Digitizer

An arm digitizer consists of a base, two arms, two rotary encoders, and a pointer. The *base* must be anchored at a point removed from the work area, normally at the top of the user's desk. One end of the arm, called the *base arm*, swivels about a vertical axis at the base. The other end of the base arm hinges to one end of a second arm, called the *tracer arm*, about a vertical axis. On the other end of the tracer arm is the *pointer*. One of the encoders, the *base encoder*, detects the angle between the base and the base arm. The other encoder, the *arm encoder*, detects the angle between the base arm and the tracer arm.

To simplify implementation, each arm is made the same length and, for sufficient accuracy, each encoder provides in excess of 36,000 counts per revolution. The encoder output signals consist of dual square waves with a 90° phase relationship. The leading and trailing edges of each square wave are counted and the 90° phase relationship provides count direction.

Since each encoder is a relative rather than absolute counting device, the count registers of each encoder must be initialized at a known angle. The count register of the arm encoder is set to the angle that results when the pointer is moved to a precisely known location. This location is called "home." The count register for the base encoder is initialized when the rotation of the x - y coordinate system is set. Thereafter, the encoders add to or subtract from their count registers as the pointer is moved.

With the arm lengths and the angles precisely known, the x , y position of the pointer can be computed. However, x and y are relative to a coordinate system whose origin is at the axis of the base and whose rotation is unknown. The user must therefore select an origin, usually near the lower left corner of the drawing area, and the direction of the x -axis, usually parallel to the bottom edge of the drawing area. This information is sufficient for the processor to compute the correct translation and rotation of the coordinate system.

Grid Overlay

A grid overlay is simply a transparent sheet onto which a grid has been drawn. To use it, place it atop the drawing or photo of the area to be measured (Figure 12.5). Then count the number of squares that lie within the boundary of the area. Squares that are at least half enclosed should be counted. The unknown area equals the product of the number of blocks counted and the area of each block. The accuracy achieved is dependent on grid size, precision of the grid dimensions, and counting accuracy.

12.2 Equipment and Experiment

Many different types of planimeters and digitizers are manufactured in the U.S., Europe, and Japan. A representative sample of these instruments are described in this section.

FIGURE 12.6 Mechanical planimeters are normally preferred when occasional use is required.

One of the simplest and least costly area measuring devices is the manual polar planimeter (Figure 12.6). It consists of a weight, two arms, a measuring wheel, and a pointer. The *weight* secures one end of a *pole arm*, allowing the other end to rotate along a fixed arc. The rotating end of the pole arm attaches to one end of a *tracer arm* and constrains its movement to the arc. At the other end of the tracer arm is a *pointer* used for tracing the periphery of an unknown area. The *measuring wheel* is located in the box at one end of the tracer arm. The location of the measuring wheel is not critical; however, its axle must be parallel to the tracer arm.

The length of both arms of the planimeter shown in Figure 12.6 can be adjusted. The length of the pole arm has absolutely no effect on measurement accuracy and is adjustable only for convenience. The effective length of the tracer arm directly affects the reading; a shorter arm results in a larger reading. By adjusting the tracer arm length, one can achieve a very limited range of scaling; however, this is usually not done. Rather, the arm length is adjusted according to the general size of areas to be measured: a shorter arm for smaller areas and a longer arm for larger areas. A shorter arm results in a greater number of counts per unit area, which is needed for smaller areas. Scaling is usually done by multiplying the result by an appropriate value.

One zeros the measuring wheel of the planimeter shown in Figure 12.6 by turning a small knurled wheel attached to the measuring wheel axle. On other models, one pushes a plunger to zero the wheel. The latter method is easier but is sensitive to misalignment.

A planimeter pointer is usually a lens with a small circle engraved in the center, although some planimeter models use a needle as the pointer. The best type of pointer is a matter of personal preference although lens pointers are much more popular.

Figure 12.7 shows two electronic planimeters with digital readouts. With these planimeters, one can measure length as well as area. To measure length, snap out the measuring wheel housing, attach an auxiliary handle, and roll the wheel along the line to be measured. Extremely high accuracy can be achieved.

FIGURE 12.7 Electronic planimeters are easier to use and read, and are preferred especially when frequently used.

The upper planimeter in Figure 12.7 is a polar type. It consists of the same parts as the model in Figure 12.6, except that the measuring wheel is attached to a small optical encoder and the weight is packaged in the digital readout. The encoder provides two square-wave outputs that are in phase quadrature, that is, one is 90° out of phase with the other. Both outputs are fed to a processor that counts the pulses and uses the phase difference to determine count direction.

The processor has an electronic scale feature that translates the planimeter reading to real measurement units such as square feet, square meters, acres, or hectares. One can transmit processor data to a computer using an auxiliary interface unit (not shown).

The planimeter at the bottom of Figure 12.7 is a linear model since the path traveled by the constrained end of the tracer arm is a straight line. The straight line path is maintained by a rigid connection between the two carriage wheels and their axle. Other linear planimeters use an actual rail to guide the constrained end of the tracer arm along a straight line path.

The polar planimeter shown at the top of Figure 12.8 and the linear planimeter shown at the bottom of Figure 12.8 are both compact battery-operated models. The measuring wheel is built into the processor, which is attached to the pole arm of the planimeter. The effective length of the tracer arm for both instruments extends from the axis of the constrained end to the pointer, which for these instruments is a small circle engraved in the center of a lens. These planimeters provide electronic scaling and averaging of multiple readings. They cannot be used to measure length.

Figure 12.9 shows an arm digitizer that can be used either as a stand-alone area and length measuring device or to digitize a map or drawing. When operating as a digitizer, the arm digitizer displays the (x, y) coordinates as well as transmits them to a computer. The digitizer has a built-in interface and can transmit using any of over 24 different ASCII and binary codes, each with a choice of parameters. It can be set to measure x and y coordinates in either English or metric units.

Three other modes, in addition to the digitizer mode, are available for computing and displaying either area and length, area and item count, or item count and length. Measurements can also be made in either English or metric units. Any displayed item can be transmitted to a computer through the built-in interface.

FIGURE 12.8 Battery-operated planimeters have the advantages of electronics planimeters and are portable.

FIGURE 12.9 An arm digitizer lets one measure area, length, and coordinates, and transmit the displayed data to a computer; it requires minimum desk space.

FIGURE 12.10 The popular pad digitizer includes a lightweight puck or pen-type pointer for selecting points whose coordinates are transmitted to a computer for processing.

The arm digitizer has other features that are especially useful when it is used in a nondigitizer mode. It provides independent scaling in each axis, empirical scale factor determination, key-press programming, four-function calculating, unit conversion, and averaging. Also, the arm digitizer can be folded out of the way when not in use.

Arm digitizers can be used on transparent surfaces as well as on normal opaque work surfaces. Thus, they are also useful for digitizing or measuring areas on rear-projected maps or drawings.

Tablet digitizers, like the one shown in [Figure 12.10](#), are popular instruments used for digitizing maps and drawings and as extended keypads for certain software. When used as an extended keypad, a template with figures of key functions is placed somewhere in the work area. Pointing to a function and clicking a cursor key selects it. Tablets feature a built-in interface and one or more binary and ASCII codes. Communication parameters on some tablets are controlled by dip switches and on others by computer software. Pointers are lightweight and include between 1 and 16 cursor keys. Tablets are available in sizes ranging from that of a notebook up to 122 cm by 168 cm (48 in. by 66 in.) or more. Models are available with transparent work surfaces and can be used with rear-projected maps and drawings.

Tablet digitizers have the advantage of lightweight pointers but the larger tablets have the disadvantages of occupying a significant amount of floor space and being relatively difficult to move around. One manufacturer has overcome this disadvantage by designing a digitizer tablet that rolls up.

Sonic digitizers, like tablets, are intended for digitizing maps and drawings and for providing an extended keypad for certain software packages. They feature a built-in computer interface with a number of ASCII and binary codes, with a choice of parameters, that make them suitable for use with many different software packages. A major advantage enjoyed by sonic digitizers is their portability and the fact that they operate well with a transparent work surface required for rear-projected drawings and maps.

[Table 12.1](#) provides a list of manufacturers of planimeters and [Table 12.2](#) lists many of the manufacturers of graphic digitizers.

12.3 Evaluation

Each of the area measuring devices described in this section are excellent and have been thoroughly proven by use. However, some of the devices are more suited to certain tasks and operating environments than others.

To measure an area that is smaller than an equivalent circle of about 2 cm in diameter, a digitizer is probably the best choice. For areas of this magnitude, the **resolution element** of planimeters starts to become a significant portion of the total area. The resolution element of most digitizers is significantly less than that of a planimeter, and any measurement is always plus- or -minus a resolution element.

For measuring areas that are equivalent to a circle between 2 cm and 55 cm in diameter, either a planimeter or a digitizer will provide excellent results.

When measuring areas larger than an equivalent circle of about 55 cm in diameter, one can still use a planimeter; however, one must subdivide the large area into smaller areas and then individually measure each of the smaller areas. A digitizer can measure significantly larger areas, but at some point it too will reach a limit. Then, one can use the same technique of subdividing the large area into smaller areas that the digitizer can handle.

Area measuring instruments of the future will undoubtedly make even greater use of microprocessors to provide more features such as incorporation of slope and tilt correction, statistical operations, and determination of centroids, moment, etc. The instruments should become mechanically simpler and more reliable. Features such as conservation of office space and portability will be emphasized. The

ultimate area measuring device will consist of a detached cursor for pointing and a small calculator-like device for operating on the results, displaying them, storing them, and sending them to a computer.

Scanners and associated software will also impact the field of area measurement, particularly as their coverage increases and their price decreases.

Defining Terms

Planimeter: A mechanical integrator used for measuring the area of enclosed regions on maps, plans, etc.

Pole arm: One of the two bars comprising a polar planimeter. One end of the pole arm is fixed and the other end is free to rotate. The length of the pole arm has no effect on the planimeter reading.

Tracer arm: The bar of a planimeter to which is attached the measuring wheel. One end of the tracer arm is constrained to a fixed path, while the other end traces the perimeter of an enclosed region whose area is being measured. The length of the pole arm is indirectly proportional to the planimeter reading.

Polar planimeter: A planimeter with a tracer arm whose constrained end follows a circle.

Linear planimeter: A planimeter with a tracer arm whose constrained end follows a straight line.

Measuring wheel: The planimeter wheel whose degree of rotation is directly proportional to area.

Digitizer: A device to convert data or an image to digital form. The digitizers discussed here convert images to digital form and are categorized as graphic digitizers.

Pointer: The part of a planimeter or digitizer that is used to follow the line being traced.

Resolution element: The smallest elemental area that can be discerned. When referred to in connection with area measurement, it is an area with a value of 1.

For simple geometric shapes, volume measurements can be performed analytically by measuring the dimensions of the object in question and using the appropriate formula for that shape. Volume formulae are found in geometry and calculus textbooks as well as in reference books such as CRC Press's *Handbook of Mathematical Science* or other references.

Volume can also be measured by fluid displacement. The object whose volume is to be measured is placed in a container filled with fluid and the initial and final volumes are measured. The object's volume is equal to the final volume minus the initial volume. This technique is especially useful for irregularly shaped objects.

Fluids can also be used to measure volume of cavities within objects by filling the cavity entirely with a fluid and then measuring the volume of the fluid after it is removed from the cavity.

The remainder of this chapter is dedicated to the more specific problem of volume measurements in medical applications.

Quantitative volume information can be of importance to the clinician in the diagnosis of a variety of diseases or abnormalities. It can also improve the understanding of the physiology of the patient. Information on volume may be used in various applications such as cardiac monitoring, diagnosis of prostate diseases, follow-up during organ transplantation, surgery for tumor resection, blood flow measurements, plastic surgery, follow-up of preterm infants, sports performance analysis, etc. Because of this wide spectrum of applications, various techniques for volume measurements have been developed, some of which are useful in determining the amount of blood flow to the organ (dynamic), while others are used to obtain the size of the object (static). The techniques can be invasive or noninvasive, and are based on either direct or indirect measurements. Each technique has its own advantages and disadvantages, and the application determines the selection of volume measurement method.

One of the earliest techniques to measure (changes of) body volume was *plethysmography*, originally developed by Glisson (1622) and Swammerdam (1737) to demonstrate isovolumetric contraction of isolated muscle. The measuring technique consists of surrounding the organ or tissue with a rigid box filled with water or air. The displacement of the fluid or the change in air pressure indicates the volume

changes of the tissue due to arterial in-flow. Two major types of plethysmography exist, and these can be distinguished by the technique used to measure the volume change. These are *volume plethysmography* (direct-measurement displacement plethysmography including water and air types), and *electrical plethysmography* (strain-gages, inductive and impedance plethysmographs). The physical condition in which the measurements should be performed determines the plethysmographic method chosen.

Advances in medical imaging have provided new possibilities for noninvasively extracting quantitatively useful diagnostic information. Images are constructed on a grid of small picture elements (pixels) that reflect the intensity of the image in the array occupied by the pixel. Most medical images represent a two-dimensional projection of a three-dimensional object.

Currently, the most commonly used medical imaging modalities are ultrasound, nuclear magnetic resonance imaging, X-rays and X-ray computer tomography. *Ultrasound imaging* is based on the transmission and reflection of high-frequency acoustic waves. Waves whose frequencies lie well above the hearing range can be transmitted through biological tissue and will be reflected if they cross a boundary between media of different acoustic properties. These reflected signals can be reconverted to electrical signals and displayed to obtain a two-dimensional section. *Magnetic resonance imaging* is based on the involvement of the interaction between magnetic moment (or spin) of nuclei and a magnetic field. The proton spins are excited by an external radio frequency signal and the return to an equilibrium distribution is used to construct cross-sectional images. *Computer tomography* or *CT-scanning* uses a rotating source of X-rays. The X-ray source and detector are scanned across a section of the object of interest, and the transmission measurements are used to reconstruct an image of the object.

These imaging techniques display cross-sections of views that can be used to estimate the size of specific components. One way to estimate the volume of internal objects is make certain assumptions concerning the shape and to apply formulae to estimate the volume with dimensions of the object such as length, height, and width. A more accurate technique is *step-section planimetry*, a clinical application of numerical integration. During this procedure, cross-sections of the object are recorded with a certain (fixed) interval. The area of the object is determined in every section, and the total volume is calculated by multiplying the contribution of each section with the interval and summarizing all contributions.

The volume of a fluid-filled region can be calculated if a known quantity of indicator is added to the fluid and the concentration measured after it has been dispersed uniformly throughout the fluid. The selection of the indicator used to measure the volume depends on the application and can be based on temperature, color, or radioactivity.

Finally, volume (changes) can also be performed directly using *water-displacement volumetry*, a sensitive but time-consuming method to measure the volume of an extremity. This method is not suitable for patients in the immediate postoperative period.

13.1 Plethysmography Theory

Fluid in-flow can be measured by blocking the out-flow and then measuring the change in volume due to the in-flow over a defined time interval. Plethysmography enables the volume change to be determined in a reasonably accurate manner. A direct-volume displacement plethysmograph uses a rigid chamber usually filled with water, into which the limb or limb segment is placed. This type of plethysmograph, sometimes called *chamber plethysmography*, can be used in two ways. It can be used to measure the sequence of pulsations proportional to the individual volume changes with each heart beat (arterial plethysmography or rheography). Also, the total amount of blood flowing into the limb or digit can be measured by venous occlusion: by inflating the occluding cuff placed upstream of the limb or digit just above the venous pressure 5 kPa to 8 kPa (40 mm Hg to 60 mm Hg), arterial blood can enter the region but venous blood is unable to leave. The result is that the limb or digit increases its volume with each heart beat by the volume entering during that beat.

FIGURE 13.1 Typical recording from air plethysmograph during venous occlusion, revealing the changes in volume over time caused by arterial in-flow.

Air/Water Plethysmography or Chamber Plethysmography

Air plethysmography uses the relation between the volume change of a gas in a closed system and the corresponding pressure and temperature [1]. The relation between pressure and volume is described by Boyle's law, which can be written as:

$$P_i V_i = P_f V_f \quad (13.1)$$

with P_i and V_i the initial pressure and volume, respectively, and P_f and V_f the final pressure and volume, measured at constant temperature: the displacement of the fluid or the compressing of the air is a direct measure of the blood flow or original volume. The air plethysmograph uses the change in pressure that occurs in a cuff wrapped around the segment of interest due to the change in volume. By inflating the cuff to about 60 mm Hg, the arterial in-flow causes small increases in pressure. These small changes in pressure over the cardiac cycle can be monitored (see [Figure 13.1](#)). The measurement of blood flow is achieved by comparing the pressure changes to changes caused by removing known amounts of air from the system. The second measurement uses volume changes at various pressures between systolic and diastolic pressures, and the peak deflection is compared with the deflection caused by removal of known amounts of air from the system. In segmental plethysmography, two cuffs are used to measure the volume changes in a segment of a limb. Venous occlusion is established by the first cuff, while the second is inflated to a pressure that will exclude blood flow from those parts that should not be included in the measurement.

The technique can also be used for whole-body plethysmography [2], a common technique used to measure residual volume, functional residual capacity (FRC), and total lung volume, the parameters usually determined during pulmonary function testing [3]. In body plethysmography, the patient sits inside an airtight box, and inhales or exhales to a particular volume (usually the functional residual capacity, the volume that remains after a normal exhalation). Then, a shutter closes the breathing tube,

while the subject tries to breathe through the closed tube. This causes the chest volume to expand and decompress the air in the lungs. The increase in chest volume slightly reduces the air volume of the box, thereby increasing the pressure. First, the change in volume of the chest is quantified using Boyle's law with the initial pressure and volume of the box, and the pressure in the box after expansion. The change in volume of the box is equal to the change in volume of the chest. A second measurement using the initial volume of the chest (unknown) and the initial pressure at the mouth, and the inspiratory volume (the unknown chest volume and the change in volume obtained in the first measurement) together with the pressure at the mouth during the inspiratory effort. By solving Boyle's law for the unknown volume, the original volume of gas present in the lungs when the shutter was closed is obtained, which is normally the volume present at the end of a normal exhalation or FRC.

Alternative methods for measurement of volume changes with plethysmography have been introduced to overcome the disadvantages of chamber plethysmography such as cost, complexity, and awkwardness of use. Important alternatives are elastic-resistance strain-gage plethysmography, impedance plethysmography, inductive plethysmography, and photoelectric plethysmography.

Electrical Plethysmography

Strain-Gage Plethysmography

In 1953, Whitney described the elastic-resistance strain-gage plethysmograph [4]. The strain-gage instrument quantifies the change in resistance of the gage as it is stretched due to the enlargement of the object (e.g., limb segment). The gage is typically a small elastic tube filled with mercury or an electrolyte or conductive paste. The ends of the tube are sealed with copper plugs or electrodes that make contact with the conductive column. These plugs are connected to a Wheatstone bridge circuit.

To illustrate the principle of the strain-gage method, a strain-gage of length l_0 is placed around the limb segment, a circular cross section with radius r_0 . The length of the strain-gage can thus also be expressed as $l_0 = 2\pi r_0$. Expansion of the limb gives a new length $l_1 = 2\pi r_1$, with r_1 the new radius of the limb. The increase in length of the strain-gage is thus $\delta l = 2\pi(r_1 - r_0)$, while the change in cross-sectional area of the limb δA is $\pi(r_1^2 - r_0^2)$. This can also be expressed as:

$$\delta A = \pi \left[2r_0(r_1 - r_0) + (r_1 - r_0)^2 \right] \quad (13.2)$$

Since $r_1 - r_0$ is usually small, $(r_1 - r_0)^2$ can be neglected. Consequently, δA can be written as $2\pi r_0(r_1 - r_0)$ which, on dividing by $A = \pi(r_0)^2$, gives:

$$\frac{\delta A}{A} = 2 \frac{r_1 - r_0}{r_0} \quad (13.3)$$

But since $\delta V/V = \delta A/A$ and $\delta l/l = \delta r/r$:

$$\frac{\delta V}{V} = 2 \frac{l_1 - l_0}{l_0} \quad (13.4)$$

Thus, the percentage increase in volume can be obtained by measuring the initial gage length and the change in length. In practice, this change in length of the strain-gage is recorded over a relatively short period to overcome the problem of back pressure that builds up in the limb or digit because of the venous occlusion, and the measurement is usually expressed as milliliters per minute per 100 g of tissue, or: volume flow rate = $2(\delta l/l_0) \times (100/t)$, where δl is the increase in gage length during time t . To measure $\delta l/t$, the gage must be calibrated by removing it from the limb and stretching it on a measuring jig until

the pen recorder returns to the zero level; this is the length l_0 . The gage can then be stretched accurately by typical amounts, to calibrate the output and calculate the volume flow rate.

Impedance Plethysmography

The physical principle of impedance plethysmography is the variation in electrical impedance of a tissue segment over the cardiac cycle due to a changing conductance. The change is caused by arterial in-flow to the segment while the venous drainage is occluded.

If a segment of limb is assumed to be cylindrical and of length l and volume V , the impedance Z of that part can be written as:

$$Z = \frac{\rho l^2}{V} \quad (13.5)$$

with ρ the specific resistivity of the tissue forming the cylinder.

Blood entering the tissue segment during the cardiac cycle introduces a parallel impedance Z_b , described as $Z_b = Z_0 Z_1 / (Z_0 - Z_1)$, with Z_0 the initial impedance and Z_1 the new value. A small change in volume δV is related to a small change in resistance δZ , such that:

$$\delta Z = Z_0 - Z_1 = \rho l^2 \left(\frac{1}{V_0} - \frac{1}{V_1} \right) = \rho l^2 \frac{(V_1 - V_0)}{V_1 V_0} \approx -\rho l^2 \frac{\delta V}{V^2} = -Z \frac{\delta V}{V} \quad (13.6)$$

when very small changes in volume are assumed [5]. Thus, δV can be written as:

$$\delta V = \rho \left(\frac{1}{Z_0^2} \right) \delta Z \quad (13.7)$$

and these parameters Z_0 and δZ can be obtained from the impedance plethysmogram. If it is assumed that $\rho = 150 \Omega \text{ cm}$, being the specific resistivity of soft tissue, the change in volume can be determined.

Two major techniques have been used to measure tissue impedance. One method uses two electrodes to measure both the voltage drop across the electrodes and the current flow. The main disadvantage of this technique is that the current distribution in the vicinity of the electrodes is not known, meaning the exact volume of the interrogated tissue is also unknown. In 1974, Kubicek et al. [6] described the use of four electrodes to measure tissue impedance: the outer electrodes supply a small-amplitude, high-frequency ac signal, while the inner two are used to measure the potential difference between two points on the same surface (see [Figures 13.2](#) and [13.3](#)).

Inductive Plethysmography

For measurement of volume changes during respiration, a system based on inductive plethysmography has been developed; the respiratory inductive plethysmograph was introduced in 1978. During inductive plethysmography, two coils are attached — one placed around the rib cage and the other around the abdomen. During respiration, the cross-sectional diameter of the coils changes, leading to a change in the inductances of the coils. By converting these inductances into proportional voltages, a measure for the changes in volume during respiration can be obtained. The conversion is achieved by using oscillators whose frequencies depend on a fixed internal capacitor and the inductance of each coil. These oscillator frequencies are converted to proportional voltages, voltages that are then recorded. After calibration on the patient, the system can be used for respiratory volume measurement [9].

Two general methods have been introduced for calibration of the respiratory inductive plethysmograph. These calibration methods are based on the following equation:

FIGURE 13.2 Electrode positioning for impedance plethysmography used for early detection of peripheral atherosclerosis: the outer two supply current while the inner two measure voltage. The combination of these two is used to obtain the changes in impedance, and these changes are then used to obtain the changes in volume of the leg. (From R. Shankar and J. G. Webster, *IEEE Trans. Biomed. Eng.*, 38, 62-67, 1993. With permission.)

$$V_T = V_{RC} + V_{AB} \quad (13.8)$$

with V_{RC} and V_{AB} the contributions of the rib cage (RC) and abdominal compartments (AB) to the tidal volume V_T . Calibration can be performed by determining the calibration constant in an isovolume measurement or by regression methods of differences in inductance changes due to a different body position or a different state of sleep [10]. Once it is calibrated, the respiratory inductive plethysmograph can be used for noninvasive monitoring of changes of thoracic volume and respiratory patterns.

13.2 Numerical Integration with Imaging

For diagnostic purposes in health care, a number of imaging modalities are currently in use (see also Chapter 79 on medical imaging). Webb nicely reviewed the scientific basis and physical principles of medical imaging [11].

With medical imaging modalities, diameters of objects can be determined in a noninvasive manner. By applying these diameters in an appropriate formula for volume calculation, the size of the object can be estimated. For example, in a clinical setting, the prostate volume V_p can be approximated with an ellipsoid volume calculation:

$$V_p = \frac{\pi}{6} H W L \quad (13.9)$$

with H the height, W the width, and L the length of the prostate as illustrated in Figure 13.4. Variations have been introduced to find the best formulae to estimate the prostate volume [12, 13]. Also, for the determination of ventricular volumes, formulae have been derived, based on the following variation of

FIGURE 13.3 A second example of electrode positioning for impedance plethysmography, here used to estimate stroke volume: the outer two supply current while the inner two measure voltage. (From N. Verschoor et al., *Physiol. Meas.*, 17, 29-35, 1996. With permission.)

the formula for prostate volume measurements: (1) the volume is obtained with the same formula as for prostate volume measurements, (2) the two short axes are equal, (3) the long axis is twice the short axis, and (4) the internal diameter is used for all axes.

By displaying cross-sectional images of a 3-D object (e.g., an organ), volume calculations can also be performed by integrating areas of the organ over a sequence of medical images as illustrated in [Figure 13.5](#). For ultrasound images, applications have been reported in the literature on prostate, heart, bladder, and kidney volume. The application of integration techniques involves the application of segmentation algorithms on sequences of images, either in transverse direction with fixed intersection distance or in the radial with images at a fixed intersection angle.

For a volume defined by the function $f(x,y,z)$, the volume can be calculated from:

$$V = \int_{x=x_1}^{x_2} \int_{y=y_1}^{y_2} \int_{z=z_1}^{z_2} f(x,y,z) dz dy dx \quad (13.10)$$

FIGURE 13.4 Volume estimate of a prostate, obtained from 3-D reconstruction of cross-sectional images, using the dimensions in three planes: the length, the height, and width in a volume formula describing an ellipsoid shape.

By applying numerical integration, the volume calculation using an integral is approximated by a linear combination of the values of the integrand. For reasons of simplicity, this approximation is first illustrated for a one-dimensional case:

$$\int_{x=a}^b f(x) dx \approx w_1 f(x_1) + w_2 f(x_2) + \dots + w_{nf} f(x_n) \quad (13.11)$$

In this equation, x_1, x_2, \dots, x_n are n points chosen in the interval of integration $[a, b]$, and the numbers w_1, w_2, \dots, w_n are n weights corresponding to these points. This approximation can also be expressed in the so-called Riemann sum:

$$\int_{x=a}^b f(x) dx \approx w_1 f(x_1) + w_2 f(x_2) + \dots + w_n f(x_n) = \sum_{i=1}^n f(\xi_i) (x_i - x_{i-1}) \quad (13.12)$$

For volume calculation, the Riemann sum needs to be extended to a three-dimensional case:

$$V = \int_{x=x_1}^{x_2} \int_{y=y_1}^{y_2} \int_{z=z_1}^{z_2} f(x, y, z) dz dy dx \approx \sum f(p_{ijk}) (x_{i+1} - x_i) (y_{j+1} - y_j) (z_{k+1} - z_k) \quad (13.13)$$

This three-dimensional case can be reduced by assuming that $(x_{i+1} - x_i)(y_{j+1} - y_j)f(p_{ijk})$ represents the surface S_k of a two-dimensional section at position z_k , while $(z_{k+1} - z_k)$ is constant for every k and equals h , the intersection distance:

FIGURE 13.5 Outlines of cross-sectional images of the prostate used for planimetric volumetry of the prostate: transverse cross-sections obtained with a step size of 4 mm have been outlined by an expert observer, and the contribution of each section to the total volume is obtained by determining the area enclosed by the prostate contour. The volume is then determined by summarizing all contributions after multiplying them with the step size.

$$V \approx h \sum_{k=0}^{n-1} S(z_k) = h \sum_{k=0}^{n-1} S(a+kh) \quad (13.14)$$

where a represents the position of the first section, n the number of sections, and h the step size, given by $h = (b - a)/n$, where b the position of the last section.

In general, three different forms of the approximation can be described, depending on the position of the section. The first form is known as the rectangular rule, and is presented in Equation 13.14. The midpoint rule is described by:

$$V \approx h \sum_{k=0}^{n-1} S(z_k) = h \sum_{k=0}^{n-1} S\left[a + \left(k + \frac{1}{2}h\right)\right] \quad (13.15)$$

The trapezoidal rule is similar to the rectangular rule, except that it uses the average of the right-hand and left-hand Riemann sum:

$$T_n(f) = h \left[\frac{f(a)}{2} + f(a+h) + f(a+2h) + \dots + f(a+(n-1)h) + \frac{f(b)}{2} \right] \quad (13.16)$$

The trapezoidal and midpoint rules are exact for a linear function and converge at least as fast as n^{-2} , if the integrand has a continuous second derivative [14].

FIGURE 13.6 An ellipsoid-shaped model of the prostate that was used for theoretical analysis of planimetric volumetry. Indicated are the intersection distance h and the scan angle α with the axis of the probe. (From R. G. Aarnink et al., *Physiol. Meas.*, 16, 141-150, 1995. With permission.)

A number of parameters are associated with the accuracy of the approximation of the volume integral with a Riemann sum; first of all, the number of cross sections n is important as the sum converges with n^{-2} : the more sections, the more accurate the results. Furthermore, the selection of the position of the first section is important. While the interval of integration is mostly well defined in theoretical analyses, for *in vivo* measurements, the first section is often less well defined. This means not only that the selection of this first section is random with the first possible section and this section increased with the step size, but also that sections can be missed. The last effect that may influence the numerical results is the effect of taking oblique sections, cross sections that are not taken perpendicular to the axis along which the intersection distance is measured. All the above assumes that every section S_k can be exactly determined.

The influence of the parameters associated with these kinds of measurements can be tested in a theoretical model. In a mathematical model with known exact volume or surface, the parameters — including step size, selection of the first section, and the scan angle — can be tested. Figure 13.6 shows a model used to model the prostate in two dimensions. It consists of a spheroid function with a length of the long axis of 50 mm and a length of the short axis of 40 mm. In mathematical form, this function can be described as:

$$y = f(x) = y_m \pm y_o \sqrt{1 - \left(\frac{x - x_m}{x_o} \right)^2} \quad (13.17)$$

with x_o half the diameter of the ellipse in x -direction (25 mm) and y_o half the diameter of the ellipse in y -direction (20 mm) and (x_m, y_m) the center point of the ellipse. The analytical solution of the integral to obtain the surface of this model is $\pi x_o y_o$.

Figure 13.6 also reveals the possible influence of the parameters h and α . Figure 13.7 shows the results for varying the step size h between 4 mm and 16 mm corresponding to between 13 and 3 sections used for numerical integration as a function of the position of the first section. The first section is selected (at random) between the first coordinate of the function, and this coordinate plus the step size h . The sections were taken perpendicular to the long axis. From this study, which is fully described by Aarnink et al. [15], it was concluded that if the ratio of step size to the longest diameter is 6 or more, then the

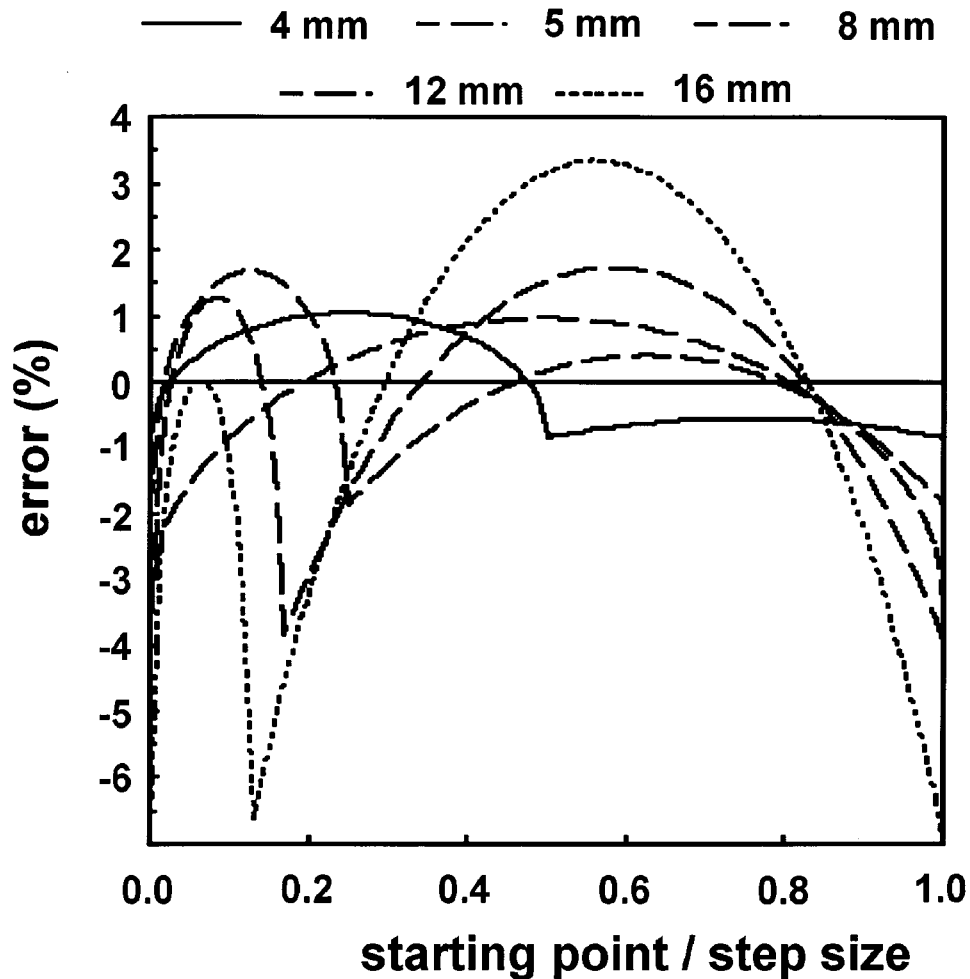

FIGURE 13.7 The errors in surface estimates by numerical integration for different step sizes h presented as percentage of the exact solution, as a function of the position of the first section, located between 0 and h . (From R. G. Aarnink et al., *Physiol. Meas.*, 16, 141-150, 1995. With permission.)

error in volume estimation is less than 5%. Although clinical application might introduce additional errors such as movement artifacts, this rule provides a good indication of the intersection distance that should be used for good approximations with numerical integration.

13.3 Indicator Dilution Methods

The principle of the indicator dilution theory to determine gas or fluid volume was originally developed by Stewart and Hamilton. It is based on the following concept: if the concentration of an indicator that is uniformly dispersed in an unknown volume is determined, and the volume of the indicator is known, the unknown volume can be determined. Assuming a single in-flow and single out-flow model, all input will eventually emerge through the output channel, and the volumetric flow rate can be used to identify the volume flow. It can be described with two equations, of which the second is used to determine the volume using the result of the first equation [16]:

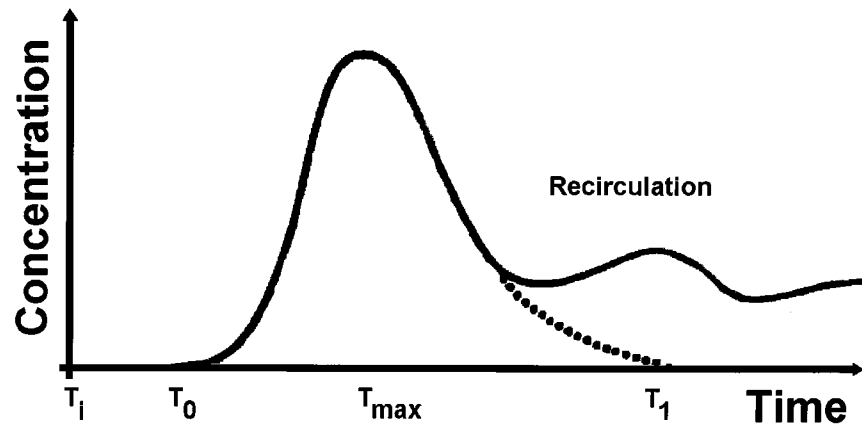

FIGURE 13.8 The time-concentration curve of the indicator is used to obtain the unknown volume of the fluid. The area under the time-concentration curve is needed to estimate the volumetric flow rate, and this flow rate can be used to estimate the volume flow. For accurate determination of the flow rate, it is necessary to extrapolate the first pass response before the area under the curve is estimated.

$$F = \frac{I_i}{\int_0^{\infty} C(t) dt} \quad (13.18)$$

$$\text{Volume} = F t_m \quad (13.19)$$

where F = flow rate
 I_i = total quantity of injected indicator
 $C(t)$ = concentration of the contrast as function of time
 Vol = volume flow
 t_m = mean transit time

The integrated value of the concentration over time can be obtained from the concentration-time curve (Figure 13.8) using planimetry and an approximation described by the Riemann sum expression (Equation 13.13). Care must be taken to remove the influence of the effect of recirculation of the indicator. An indicator is suitable for use in the dilution method if it can be detected and measured, and remains within the circulation during at least its first circuit, without doing harm to the object. Subsequent removal from the circulation is an advantage. Dyes such as Coomassie blue and indocyanine green were initially used, using the peak spectral absorption at certain wavelengths to detect the indicator. Also, radioisotopes such as I-labeled human serum albumin have been used. Currently, the use of cooled saline has become routine in measurement of cardiac output in the intensive care unit.

Thermodilution

To perform cardiac output measurements, a cold bolus (with a temperature gradient of at least 10E) is injected into the right atrium and the resulting change in temperature of the blood in the pulmonary artery is detected using a rapidly responding thermistor. After recording the temperature-time curve, the blood flow is calculated using a modified Stewart-Hamilton equation. This equation can be described as follows [17]:

$$V_i SW_i SH_i (T_b - T_i) = F \int T_b (dt) SW_b SH_b \quad (13.20)$$

The terms on the left represent the cooling of the blood (with temperature T_b), as caused by the injection of a cold bolus with volume V_i , with temperature T_i , specific weight SW_i and specific heat SH_i . The same amount of “indicator” must appear in the blood (with specific weight and heat SW_b and SH_b , respectively) downstream to the point of injection, where it is detected in terms of the time-course of the temperature T_b in the flow F by means of a thermistor. The flow can be described as:

$$F = \frac{T_b - T_i}{\int T_b (dt)} K \quad (13.21)$$

where K (the so-called calculation constant) is described as:

$$K = V_i \frac{SW_i - SH_i}{SW_b - SH_b} C \quad (13.22)$$

This constant is introduced to the computer by the user. T_i is usually measured at the proximal end of the injection line; therefore, a “correction factor” C must be introduced to correct for the estimated losses of cold saline in the catheter, due to the dead space volume. Furthermore, the warming effect of the injected fluid during passing through the blood must be corrected; this warming effect depends on the speed of injection, the length of immersion of the catheter, and the temperature gradient. This warming effect reduces the actual amount of injected fluid, so the correction factor C is less than 1 [17].

Radionuclide Techniques

Radionuclide imaging is a common noninvasive technique used in the evaluation of cardiac function and disease. It can be compared to X-ray radiology, but now the radiation emanating from inside the human body is used to construct the image. Radionuclide imaging has proven useful to obtain ejection fraction and left ventricular volume. As in thermodilution, a small volume of indicator is injected peripherally; in this case, radioisotopes (normally indicated as radiopharmaceuticals) are used. The radioactive decay of radioisotopes leads to the emission of alpha, beta, gamma, and X radiation, depending on the radionuclide used. For *in vivo* imaging, only gamma- or X-radiation can be detected with detectors external to the body, while the minimal amount of energy of the emitted photons should be greater than 50 keV. Using a photon counter such as a Gamma camera, equipped with a collimator, the radioactivity can be recorded. Two techniques are commonly used: the first pass method and the dynamic recording method [11].

First Pass Method

To inject a radionuclide bolus into the blood system, a catheter is inserted in a vein, for example, an external jugular or an antecubital vein. The camera used to detect the radioactive bolus is usually positioned in the left anterior oblique position to obtain optimal right and left ventricular separation, and is tilted slightly in an attempt to separate left atrial activity from that of the left ventricle. First, the background radiation is obtained by counting the background emissions. Then, a region of interest is determined over the left ventricle and a time-activity curve is generated by counting the photon emissions over time. The radioactivity count over time usually reveals peaks at different moments; the first peak occurs when the radioactivity in the right ventricle is counted, the second peak is attributed to left ventricular activity. More peaks can occur during recirculation of the radioactivity. After correction for

background emissions, the time-intensity curve is evaluated to determine the ejection fraction (EF) of the heart, which is given by:

$$EF = \frac{c_d - c_s}{c_d - c_b} \quad (13.23)$$

where c_d is the end diastolic count, c_s is the end systolic count, and c_b is the background count [18]. Using a dynamic cardiac phantom, the accuracy of the EF measurement and LV volume estimation by radio-nuclide imaging has been determined [18]. The count-based method was found to give accurate results for evaluating cardiac EF and volume measurements.

Dynamic Recording Method

During dynamic recording, the data acquisition is triggered by another signal, usually the ECG, to obtain the gated activity during ventricular systole and diastole. The contraction of the left ventricle of the heart is used to align the acquisition data from different cardiac cycles. During dynamic recording, information about the cardiac function is averaged over many heart beats during a period when the radiopharmaceuticals are uniformly distributed in the blood pool. Estimations of end systolic and end diastolic volumes are made and the ejection fraction is calculated (see above). Also, other parameters can be obtained; for example, the amplitude and phase of the ejection from the left ventricle. These parameters may show malfunction in the cardiac cycle. These dynamic recordings may also be applied to the brain, lungs, liver, kidney, and vascular systems and they can be important to judge the function of these organs (e.g., after kidney transplantation).

Gas Dilution

Gas dilution is a method to determine lung volumes because standard techniques for lung measurements measure only the inhaled or exhaled air as a function of time (spirometry) and cannot be used to assess the absolute lung volume. The subject is connected to a spirometer that contains a known concentration of gas (e.g., helium). The subject is then asked to breathe for several minutes, to equalize the concentration of helium in the lung and the spirometer. Using the law of conservation of matter, the volume of the lung can be calculated. Since the total amount of helium is the same before and after measurement, the fractional concentration times the volume before equals the fractional concentration times the volume after: $C_1 \times V_1 = C_2 \times (V_1 + V_2)$. The volume after the measurement can be extracted from this equation and, by subtracting the volume of the spirometer, the lung volume is calculated.

13.4 Water Displacement Volumetry

The measurement of the volume of an extremity such as arm or leg can be measured using a water tank, which is illustrated schematically in [Figure 13.9](#). The advantage of water displacement volumetry is the possibility for direct measurement of objects with an irregular form. In the clinical situation, volume determination of the leg can be valuable for monitoring the severity of edema or hematoma after surgery or trauma. A setup for water displacement can be developed by the user, and an example of such a system is described by Kaulesar Sukul et al. [19]. A special tank for water displacement volumetry of the leg was constructed consisting of two overflow tubes. The tank was filled to the lower overflow tube, and the overflow tube was subsequently closed. The patient was then asked to lower his leg into the tank, and the amount of overflow of the upper tube was measured. The total volume was then calculated by measuring the fluid volume delivered to the upper tube and the volume difference between the lower and upper overflow tube, the so-called “reserve volume.” The volume of ankle and foot was then measured by filling the tank to the upper overflow tube and measuring the amount of water in the cylinder when the foot and ankle were immersed in the water.

FIGURE 13.9 A schematic overview of a volume measuring method using water displacement: the desired volume of the object is represented by the overflow volume in the small tank after lowering the object into the large tank. This technique is especially useful for irregular-shaped objects.

FIGURE 13.10 Illustration of the disk model to measure leg volume. The leg is divided in different sections with a fixed intersection distance the circumference of each section is obtained. This circumference is then used to describe the leg as perfect circles with an assumed radius calculated from the circumference. This radius is then used to calculate the contribution of that section to the volume and the total volume is obtained by summation.

Disadvantages of water displacement volumetry are hygiene problems, it is time-consuming, and not suitable for measurements of the volume of extremities of patients in the immediate postoperative period. Therefore, alternatives have been sought, with the disk model method as a promising one. The calculation of the volume of the leg is performed by dividing the leg into disks of thickness h (e.g., 3 cm) as illustrated in Figure 13.10. The total volume is equal to the sum of the individual disk volumes:

$$V = \sum_{i=1}^n \frac{C_i^2}{4\pi} h = \sum_{i=1}^n \pi r_i^2 h = h \sum_{i=1}^n \pi r_i^2 \quad (13.24)$$

where C_i is the circumference of the disk at position i with assumed radius of r_i .

A study to compare water displacement volumetry with the results of the disk model method indicated that both methods give similar results. Consequently, because of the ease of application, the disk model method is the method of choice to measure volumes of extremities. Assuming the length of a leg to be 75 cm, a ratio between length and step size (3 cm was proposed in [19]) of 25 is obtained. According to

TABLE 13.1 Volume Measuring Techniques, Applications, and Equipment for Different Applications

Technique	Application	Companies	Products	Price (U.S.\$)
Spirometry	Lung volume	Nellcor Puritan Bennett Morgan Science Spirometrics CDX Corporation	Renaissance Spiro 110S	
Whole-body plethysmography	Lung volume	Morgan Science ACI Medical Inc.		25,000.00
Gas-dilution	Lung volume	Equilibrated Biosystems Inc. Melville		
Thermodilution	Heart	Abbott Critical Care System Baxter American Edwards Laboratories		
Strain-gage plethysmography Impedance plethysmography	Cardiac output Perfusion studies	Parks Medical Electronics Ambulatory monitoring systems Vitalog RJL systems Detroit Codman and Shurtleff Inc. Randolph Electrodiagnostic Instrument Inc. Burbank

Radionuclide imaging	Heart, peripheral organs	Schering		

a study by Aarnink et al. [15], this ratio can be reduced while still obtaining an accuracy of >95%. A disk height of 10 cm will be sufficient to measure the leg volume with an accuracy of at least 95%. However, it might be necessary to use a small interdisk section to obtain a higher accuracy, which might be needed to accurately monitor the edema changes in volume.

13.5 Equipment and Experiments

Table 13.1 summarizes the different methods for volume measurement and their applications. The table serves as a starting point to evaluate the available equipment for volume measurement.

13.6 Evaluation

Plethysmography is an easy and noninvasive method to obtain knowledge for assessing vascular diseases, cardiac output disorders, or pulmonary disfunctions. Systems for direct measurement of volume changes have been developed, but physical properties have also been introduced as an indirect measure of the change in volume. Each system has its own advantages and disadvantages.

For *chamber plethysmography*, the water-filled type is more stable with respect to temperature change but thermal problems may occur if the water temperature is significantly different from that of the limb segment. Furthermore, the hydrostatic effect of the water may alter the blood flow. Also, the rubber sleeve between the limb segment and the water may influence the release of sweat. It is a cumbersome measurement that is not very useful during or after exercise. The *air displacement* type introduces problems of drift because of its high coefficient of expansion, although self-compensating systems have been proposed. Also, the thermal behavior of the body plethysmograph may produce variations in pressure inside the airtight box. Two sources of temperature variation can be mentioned: the chest volume

variation induced by breathing produces heat and a temperature gradient may exist between the patient and the internal temperature of the box [20].

In *impedance plethysmography*, the changes in impedance in tissue are used, which are primarily due to changes in the conductivity of the current path with each pulsation of blood. Several theories attempt to explain the actual cause of these changes in tissue impedance. One explanation is that blood-filling of a segment of the body lowers the impedance of that segment. A second theory is that the increase in diameter due to additional blood in a segment of the body increases the cross-sectional area of the segment's conductivity path and thereby lowers the resistance of the path. A third explanation is based on the principle of pressure changes on the electrodes that occur with each blood pulsation and uses the changes in the impedance of the skin–electrode interface. The main difficulty with the procedure is the problem of relating the output resistance to any absolute volume measurement. Detection of the presence of arterial pulsations, measurement of pulse rate, and determination of time of arrival of a pulse at any given point in the peripheral circulation can all be satisfactorily handled by impedance plethysmography. Also, the impedance plethysmograph can measure time-variant changes in blood volume. A problem with impedance plethysmography may be the sensitivity to movement of the object. Research is being conducted to reduce the influences of these movement artifacts, either by different electrode configuration, electrode location, or using multiple sensors or different frequencies [21].

A low-cost *inductive plethysmograph* was designed by Cohen et al. to obtain a noninvasive measure of lung ventilation [22]. This plethysmograph indirectly monitors ventilation by measuring the cross-sectional area of the chest and abdomen. They attached commercially available elastic bands containing wire around the chest and abdomen and determined their inductances by measuring the frequency of an inductive-controlled oscillator.

New devices for plethysmographic measurements are under development, using different properties to obtain the quantitative knowledge required. For example, *acoustic plethysmography* measures body volume by determining changes in the resonant frequency of a Helmholtz resonator. A Helmholtz resonator consists of an enclosed volume of gas connected to its surroundings through a single opening. The gas can be forced to resonate acoustically by imposing periodic pressure fluctuations of the opening. The resonator frequency is inversely proportional to the square root of the volume of air in the resonator. An object placed in the resonator reduces the volume of air remaining in the resonator by its own volume, causing an increase in the resonator frequency. From a study to obtain density values of preterm infants, it was concluded that the acoustic plethysmograph can be used to measure total body volume of preterm infants [23].

In addition, volume measurements with diagnostic imaging modalities are well established in the clinical environment; for example, prostate ultrasonography or echocardiography. Besides important parameters such as step size and first step selection, accurate determination of the surface in different sections is important. While predominantly performed manually now, several attempts for automated detection of the surface have been reported [24–27]. Automatic detection of the surface in each section should be possible and would enable a system for automated measurement of the prostate, heart, liver, etc. Further research will indicate the usefulness of such a system in a clinical setting.

University of Wisconsin

An *angle* is defined as the figure formed by two lines or planes that intersect one another. Such lines or planes may be real, such as the edges and surfaces of a object, or they may be defined, such as lines from an observer to two distant stars.

The units of measurement of angle are degrees ($^{\circ}$) (1° is defined as $1/360$ of a circle), and radians (rad) (1 rad is defined as $1/(2\pi)$ of a circle). One radian is equal to 57.29578° , and small angles may be expressed in the unit of milliradians (1×10^{-3} rad). A degree of angle is further divided into $60'$ (minutes), and $1'$ of angle is divided into $60''$ (seconds). One second of angle, being $1/1,296,000$ of a circle, is a very small unit of measurement when related to manufactured parts, but is a significant unit when related to much larger dimensions such as the Earth ($1''$ of angle equals approximately 30 m of a great circle), or in space travel (an included angle of $1''$ represents about 9 km on the surface of the moon when it is observed from the Earth during its closest approach to Earth.)

Many terms are used to describe angles in many different fields of expertise. [Table 14.1](#) lists some of these terms, along with very basic definitions.

Many devices and instruments are used to measure or set angles. The following paragraphs describe the variety of equipment involved. See [Table 14.2](#) for a partial list of manufacturers and suppliers of this equipment. See [Table 14.3](#) for a partial list of specific models and approximate prices of angle measurement devices and systems.

14.1 Angle Gage Blocks

Angle gage blocks are right triangle-shaped, hardened and ground steel, flat, about 7 mm thick and 60 mm long. They are supplied in sets that include blocks with one of the acute angles equal to $1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 15, 20,$ or 30° . These blocks can be used in combination to set work pieces or measure objects in 1° increments. Other sets include blocks with as small as $1''$ steps. Special angle gage blocks can be made to any acute angle with the aid of a sine bar and thickness gage blocks.

Angle gage blocks provide a durable, simple, and inexpensive method for measuring and setting angles; for example, positioning work pieces in a vice or fixture prior to a machining operation such as milling, drilling, or grinding.

Because they are not adjustable and made of hardened steel, their accuracy can be assumed by simple observation of their physical condition. Look for indications of wear, nicks, or dents before using.

TABLE 14.1 Defining Terms Relating to Angles

Term	Definition
Angle	A figure formed by two lines or planes that intersect one another.
Acute angle	An angle less than 90°.
Azimuth	The horizontal angle measured along the Earth's horizon, between a fixed reference (usually due south) and an object.
Bank	A lateral inclination.
Circle	A closed plane curve where all of its points are the same distance from its center point.
Declination = declivity	A negative slope.
Degree	Equal to 1/360 of a circle.
Goniometer	An instrument for measuring angles (from the Greek word <i>gonio</i>).
Incline = Slope = Bias = Slant = Gradient = Grade	The deviation, plus or minus, from horizontal as defined by gravity.
Latitude	An angle measured north or south from the equator on a meridian to a point on the earth.
Lean = List = Tilt	The deviation from vertical as defined by gravity.
Longitude	The angle between the prime meridian (through Greenwich, England) and the meridian of a given place on Earth. This angle is defined as positive moving west.
Milliradian	An angle equal to 1/1000 rad.
Minute	An angle equal to 1/60°.
Oblique angle	An obtuse or acute angle.
Obtuse angle	An angle greater than 90°.
Quadrant	One quarter of a circle (90°).
Radian	The angle subtended by an arc of a circle equal to the radius of that circle. One radian is equal to 57.29578°.
Rake	Equals the deviation in degrees from being perpendicular (90°) to a line or a plane.
Right angle	An angle of 90°.
Rise	A positive incline.
Second	An angle equal to 1/60' (1/3600°).
Straight	An angle equal to 180°.
Taper	The change in diameter or thickness per unit length of axis.
Twist	The angle of turn per unit length of axis, as in a gun barrel or a screw thread.

14.2 Clinometers

A *clinometer* is an electronic device that measures vertical angle with respect to gravitational level. It is rectangular, with each side being a 90° to its adjacent sides. With a range of readings of at least ±45°, this shape allows measurements up to a full 360°. Floating zero can be set anywhere and resolutions of ±0.01° are obtainable. Some models will convert readings to inches per foot, % of grade, and millimeters per meter (mm m⁻¹).

A clinometer can be used anywhere the angle of a surface with respect to gravity or another surface needs to be measured. High accuracy and resolution are obtainable, but calibration should be checked periodically with respect to a known level surface and a known angle. Surfaces that are remote to one another or have an intervening obstruction pose no problem for a clinometer.

14.3 Optical Comparator

An *optical comparator* measures angles, along with other dimensions or profiles, by referencing a visual image (usually magnified) of an object to a reticule that is calibrated in the measurement units desired. A hand-held optical comparator is placed directly over the object to be measured and the operator's eye is moved to the proper distance above the comparator for good focus of the magnified image. Some models contain a battery- or line-powered light source. Reticules for these hand-held devices are generally graduated in 1° increments.

Projection-type optical comparators are available as bench or floor models and are made for either horizontal or vertical beam viewing. They use a high-intensity light source and magnifying optics to display an image of an object onto a rear-projection, frosted glass screen that is inscribed with angular as well as linear markings. The image displayed is the result of light being projected past the object, referred to as a shadow graph, or of light being reflected off the surface of the object. The method used is determined by the shape of the viewed object and its surface quality.

Magnification of the optical system in these devices can range from 10× by 100×, with screen diameters ranging from 0.3 m to 1 m.

These instruments are useful for measuring profiles of parts after final matching for the purpose of quality control or duplication.

As the name implies, the image that is projected can be superimposed on a mask or outline drawing placed directly on the view screen so that any deviations from the required shape can easily be determined. Optical comparators are heavy, nonportable devices that require a fairly high amount of maintenance and are best used in a fairly dark room.

14.4 Protractor

A *protractor* is an instrument used for measuring and constructing angles. A direct-reading protractor usually is graduated in 1° increments and can be semicircular or circular in shape. The simplest models are of one-piece construction and made from metal or plastic. Other models include a blade or pointer pivoted in the center of the graduated circle.

More precise protractors are equipped with a vernier scale that allows an angle to be indicated to 5' of arc. See [Figure 14.1](#) for an explanation of how to read such a vernier scale.

TABLE 14.3 Instruments and Devices Used to Measure or Indicate Angles

Type	Manufacturer	Model	Description	Approx. price	
Sine bar	Flexbar	16292	5 in. × 15/16 in. wide	\$130.00	
		16293	10 in. × 1 in. wide		
		16294	5 in. × 2 in. wide		
		12202	5 in. × 1 in. wide, economy		
	Fowler	52-455-010	5 in. center to center, 15/16 in. wide	\$30.00	
		52-455-015	10 in. C. to C., 1 in. wide		
		52-455-030	2.5 in. C. to C., 1 in. wide		
	SPI	30-712-4	10 in. C. to C., universal bench center	\$3048.00	
		98-379-1	5 in. C. to C., 1 in. wide, accuracy between rolls = 0.0003 in.	\$31.00	
		30-091-3	10 in. C. to C., 1 in. wide, accuracy between rolls = 0.0001 in.	\$203.00

Angle Gage	SPI	70-997-2	0 to 60°, 10' vernier (for setting workpiece in a vice)	\$122.00	
Angle Gage Blocks	Fowler	52-470-180	18 leaves, spring steel, 1 thru 10, 14, 14.5, 15, 20, 25, 30, 35, and 45°		
	SPI	31-375-9	18 gage set, 5° thru 90° in 5° steps, 5' accuracy	\$49.60	
	Starrett	Ag18.TR	18 block set, use in combination for steps of 1", 1" accuracy		
	Starrett	AG16.LM	16 block set, use in combination for steps of 1", 1/4" accuracy		
	SPI	30-140-8	10 block set, 1, 2, 3, 4, 5, 10, 15, 20, 25, 30°, Accuracy = ±0.0001" per inch.	\$170.00	
			1/4° and 1/2° blocks optional (each)	\$18.00	

14.5 Sine Bar

A *sine bar* is a device used to accurately measure angles or to position work pieces prior to grinding and other machining procedures. It is constructed from a precisely hardened and ground steel rectangular bar to which are attached two hardened and ground steel cylindrical rods of the same diameter. The axis of each rod is very accurately positioned parallel to the other and to the top surface of the bar.

A sine bar is used in conjunction with precision gage blocks that are placed under one of the two cylindrical rods to raise that rod above the other rod a distance H (see Figure 14.2) equal to the sine of the angle desired, times the distance D between the two rods. The standard distance between the rods is 250 mm (5 in.) or 500 mm (10 in.). The governing equation in using a sine bar is $\sin A = H/D$.

A work piece positioned using a sine bar is usually secured with the use of a precision vice. The vice may clamp directly to the work piece or, when using a sine bar that has tapped holes on its top surface, to the sine bar sides with the work piece bolted to the top of the sine bar.

14.6 Sine Plate

A variation of the sine bar is the *sine plate*. A sine plate consists of the three elements of a sine bar plus a bottom plate and side straps used to lock the plate in the desired position. In addition, one of the ground steel rods is arranged to form a hinge between the top and bottom plates. When using a sine plate, a work piece is secured to the top plate using bolts or clamps and the bottom plate is secured to a machine tool table using clamps or a magnetic chuck.

Compound sine plates are bidirectional, allowing angles to be measured and set in each of two orthogonal planes (true compound angles).

FIGURE 14.1 Vernier protractor. If the zero mark on the vernier scale is to the right of the zero mark on the main scale, as shown in this drawing, then the right side of the vernier scale must be used. Look for the mark on the vernier scale that best aligns with one of the marks of the protractor degree scale. Count the number of marks on the vernier scale from the zero mark to this mark. Each mark thus counted is, in this example, equal to 5' of arc and, therefore, the number of minutes to be added to the number of degrees indicated is 5 times the vernier marks counted. (In this example, the fourth mark aligns the best with the main scale indicating 20'). The number of degree indicated is the degree mark just to the left of the zero mark on the vernier scale. The left side of the vernier is similarly used when the indicated angle is to the left of the zero mark on the degree scale.

FIGURE 14.2 Sine bar. A sine bar is used in conjunction with precision gage blocks that are placed under one of the cylindrical rods, raising that end a distance, H , equal to the sine of the desired angle times the distance, D , between the two rods.

FIGURE 14.3 Measuring tapers. Two balls (for holes) or gage pins (for slots) should be selected to fit the hole size to be measured. The distance between the balls or pins should be as large as possible to allow for the best accuracy of measurement. The position of the balls can be determined and the equations shown in this figure applied to determine the angle of the taper.

14.7 Taper

An accurate method that can be used to measure a tapered hole is described in [Figure 14.3](#). In this method, one uses a pair of steel balls of proper diameters to match the hole size and angle of taper. This method can also be used to measure the angle between two adjacent planes, using either balls or gage pins.

Further Information

Further information on this subject can be found in company catalogs in both print and Internet formats. An additional reference is *Machinery's Handbook*, 25th ed., Industrial Press Inc., 200 Madison Avenue, New York, NY 10016-4078, 1996.

Tilt Measurement

Adam Chrzanowski
University of New Brunswick

James M. Secord
University of New Brunswick

- 15.1 Tiltmeters or Inclinometers
- 15.2 Geodetic Leveling
- 15.3 Hydrostatic Leveling
- 15.4 Suspended and Inverted Plumb Lines
- 15.5 Integration of Observations

If the relative position of two points is described by the three-dimensional orientation of a line joining them, then, in general, *tilt* is the angular amount that the orientation has changed, in a vertical plane, from a previous direction or from a reference direction. If the original or reference orientation is nearly horizontal, then the term “tilt” is usually used. If it is nearly vertical, then the change is often regarded as “inclination.” Here, “tilt” will refer to either. The two points can be separated by a discernable amount, the base, or the tilt can be measured at a point with the reference orientation being defined by the direction of the force of gravity at that point. Thus, the same instrument that measures tilt at a point can be called either a *tiltmeter* or an *inclinometer* (or clinometer), depending on the interpretation of the results. The instrument used to measure a series of tilts along any vertical orientation is often called an inclinometer (e.g., Dunnicliff [1]).

Angular tilt is directly related to the linear amount of change subtending the length of the base. Consequently, angular tilt does not have to be measured directly but can be derived from the mechanical or other measurement of this linear change if the length of the base is known.

Therefore, the following discussion has been subdivided into:

1. Tiltmeters or inclinometers (angular tilt at a point or over a limited, relatively small base length)
2. Geodetic leveling (tilt derived from a height difference over an extended base of virtually limitless length)
3. Hydrostatic leveling (tilt derived from a height difference over an extended base of limited length)
4. Suspended and inverted pendula, or plumb lines (inclination from a difference in horizontal relative position over a vertical base or height difference)

15.1 Tiltmeters or Inclinometers

Considering the basic principle of operation, tiltmeters may be divided into: liquid (including spirit bubble type), vertical pendulum, or horizontal pendulum. Dunnicliff [1] provides a comprehensive review of tiltmeters and inclinometers according to the method in which the tilt is sensed (i.e., mechanical, with accelerometer transducer, with vibrating wire transducer, or with electrolytic transducer).

The sensitivity of tilt falls into two distinct groups: geodetic or geophysical special tiltmeters with a resolution of 10^{-8} rad (0.002”) or even 10^{-9} rad; and engineering tiltmeters with resolutions from 0.1” to several seconds of arc, depending on the required range of tilt to be measured.

The first group includes instruments that are used mainly for geophysical studies of Earth tide phenomena and tectonic movements; for example, the Verbaander-Melchior [2] and the Zöllner [3, 4] horizontal pendulum tiltmeters, and the Rockwell Model TM-1 [5] liquid-bubble type. This category of instrument requires extremely stable mounting and a controlled environment. There are very few engineering projects where such sensitive instruments are required. However, deformation measurements of underground excavations for the storage of nuclear waste may be one of the few possible applications. An example is a mercury tiltmeter (Model 300) developed for that purpose by the Auckland Nuclear Accessory Co. Ltd. in New Zealand. In this instrument, the change in capacitance between electrodes and a mercury surface is proportional to the tilt. This tiltmeter, with a total range of 15", is claimed to give a resolution of 10^{-9} rad (0.0002"), which corresponds to a relative vertical displacement of only 6×10^{-7} mm over its base length of 587 mm.

In the second group, there are many models of liquid or pendulum tiltmeters of reasonable price (\$2000 to \$5000) that satisfy most needs in engineering studies. Apart from a spirit level or level vial by itself, the simplest form of tiltmeter is a base that is tens of centimeters long and leveled by centering the bubble in the vial by direct viewing or by an optical coincidence viewing of the two ends of the bubble. Direct viewing gives a resolution of 1/5 of a vial division (usually 2 mm), which typically has a sensitivity of 10" to 30" per division. Coincidence viewing increases the setting accuracy to 0.03 of the sensitivity of the vial. The discrepancy from horizontal between the two measurement points can be determined by a dial gage or micrometer that has a resolution of 0.0005 in. or 0.02 mm. Huggenberger AG claim a sensitivity of 0.3" (1×10^{-4} gon) over a range of $\pm 21'$ for their clinometer with a 100 mm base and coincidence centering of the bubble in the level vial. The clinometer can be attached to 1 m bases for either horizontal or vertical measurements.

If the vial is filled with an electrolytic liquid, the centering of the bubble can be done electrically. An example is the Electrolevel (by the British Aircraft Corp.), which uses the spirit bubble principle [6] and in which the movement of the bubble is sensed by three electrodes. A tilt produces a change in differential resistivity between the electrodes that is measured by means of a Wheatstone bridge. A resolution of 0.25" is obtained over a total range of a few minutes of arc. Many other liquid types of tiltmeters with various ranges (up to 30°) are available from various companies. Holzhausen [7] and Egan and Holzhausen [8] discuss the application of electrolytic tiltmeters (resolution of 2" over a range of $\pm 1^\circ$, manufactured by Applied Geomechanics) in the monitoring of various hydroelectric power dams in the U.S.

The Rank Organization in the United Kingdom [9] makes a liquid-dampened pendulum-type electronic level, the Talyvel, which gives an accuracy of $\pm 0.5''$ over a total range of $\pm 8'$. A similar transducer of the pendulum type is used in the Niveltronic tiltmeter (range of $\pm 150''$ with an accuracy of $\pm 0.2''$) produced by Tesa S.A. in Switzerland. Of particular popularity are servo-accelerometer tiltmeters with horizontal pendula. They offer ruggedness, durability, and can operate in low temperatures. The output voltage is proportional to the sine of the angle of tilt. Schaevitz Engineering produces such a servo-accelerometer that employs a small-mass horizontal paddle (pendulum) which tries to move in the direction of tilt, due to the force of gravity. Any resultant motion is converted by position sensors to a signal input to the electronic amplifier whose current output is applied to the torque motor. This develops a torque that is equal and opposite to the original. The torque motor current produces a voltage output that is proportional to the sine of the angle of tilt.

The typical output voltage range for tiltmeters is ± 5 V, which corresponds to the maximum range of tilt and readily allows for serial interfacing. The angular resolution of a tiltmeter depends on its range of tilt since a larger range would result in more angular tilt per unit voltage so a higher resolution tiltmeter would have a smaller range of measurable tilt. Typically, the resolution is 0.02% of the range (volts) [10].

There are many factors affecting the accuracy of tilt sensing, not just the resolution of the readout. A temperature change produces dimensional changes in the mechanical components and changes in the viscosity of the liquid in electrolytic tiltmeters and of the dampening oil in pendulum-type tiltmeters. Also, electric characteristics can alter with temperature changes. Drifts in tilt indications and fluctuations of the readout may also occur. Compensation for the effects of temperature changes can be incorporated

FIGURE 15.1 Ground subsidence derived from tilt measurements.

in the construction of an instrument, but at an increased cost. An alternative is to design a linear reaction by the instrument to the effects of temperature and to apply simple calibration corrections.

In less expensive models, compensation for the aforementioned sources of error is not very sophisticated, and such tiltmeters may show nonlinear output in reaction to changes in temperature and erratic drifts or other behavior that would be difficult to predict without testing. Consequently, very thorough testing and calibration are required even when the accuracy requirement is not very high [11]. Testing should investigate, at least, the linearity of output in reaction to induced tilts over the instrument's full range (\pm) and to changes in temperature. Some suggestions for testing and calibrating inclinometers, among other instruments, are given in Dunncliff [1]. It is further emphasized that regular and up-to-date calibration is important in order to ensure continuity in the fidelity of the data being gathered. In most cases, the behavior being investigated changes with time and incorrect data cannot be recaptured.

Compensators for vertical circle readings in precision theodolites work on the same principle as some engineering tiltmeters. The liquid compensator of the Kern E2 electronic theodolite [12] gave a repeatability of better than 0.3" over a range of $\pm 150''$ and was incorporated in their tiltmeter, NIVEL 20, in 1989. The same compensation system has been used in the currently available Leica TC2002 precision electronic total station [13]. Consequently, the theodolite may also be used as a tiltmeter, in some applications, giving the same accuracy as the Electrolevel, for example.

Tiltmeters have a wide range of applications. A series of tiltmeters, if arranged along a terrain profile in a mining area, may replace geodetic leveling in the determination of ground subsidence [11] as shown in Figure 15.1. For example, the subsidence (i.e., the variation from the previous or original profile) of point 4 (δh_4) with respect to point 1 may be estimated from the observed changes in tilt, from a base or original position, (α_1 in radians) and known distances between the points as:

$$\delta h_4 = s_1(\alpha_1 + \alpha_2)/2 + s_2(\alpha_2 + \alpha_3)/2 + s_3(\alpha_3 + \alpha_4)/2 \quad (15.1)$$

The fidelity of this method depends on the density of tilt measurements along the profile and the continuity of the profile (a constant slope of the terrain between measurement points is assumed). Similarly, deformation profiles of tall buildings may be determined by placing a series of tiltmeters at different levels of the structure [14]. Also, changes in borehole profiles can be created in a similar manner. The absolute profile of a borehole can be generated by considering the horizontal displacement in the direction of the orientation of the inclinometer (usually controlled by guide grooves in the borehole casing) for the i -th position, as it traverses a borehole with observation of α_i at a depth s_i . However, this would require calibration of the inclinometer to correct its output to show zero in its vertical position since the α_i are tilts from the vertical rather than angular changes from an original inclination.

In geomechanical engineering, the most popular application of tiltmeters and borehole inclinometers is in slope stability studies and in monitoring earth-fill dams. Torpedo-shaped biaxial inclinometers are used to scan boreholes drilled to the depth of an expected stable strata in the slope. By lowering the inclinometer on a cable with marked intervals and taking readings of the inclinometer at those intervals, a full profile of the borehole and its changes may be determined through repeated surveys, as mentioned above. SINCO and other producers of tiltmeters provide special borehole inclinometers (50 cm or 2 ft long) with guide wheels to control the orientation of the inclinometer. A special borehole casing (plastic or aluminum) with guiding grooves for the wheels is available. Usually, servo-accelerometer type inclinometers are used with various ranges of inclination measurements; for example, $\pm 6^\circ$, $\pm 53^\circ$, or even $\pm 90^\circ$. A 40 m deep borehole, if measured every 50 cm with an inclinometer having an accuracy of only $\pm 100''$, should allow for the determination of linear lateral displacement of the collar of the borehole with an accuracy of ± 2 mm.

In cases where there is difficult access to the monitored area or a need for continuous data acquisition or both, tiltmeters or borehole inclinometers can be left in place at the observing station with a telemetry monitoring system allowing for communication to the processing location. One example of a station setup of a telemetric monitoring of ground subsidence in a mining area near Sparwood, B.C. used a telemetry system developed for the Canadian Centre for Mining and Energy Technology (CANMET) by the University of New Brunswick [11, 15]. Terra Technology biaxial servo-accelerometer tiltmeters of $\pm 1^\circ$ range were used in the study. The telemetry system could work with up to 256 field stations. Each station accepted up to six sensors (not only tiltmeters but any type of instrument with electric output, e.g., temperature, power level or voltage). Another example is a fully automated borehole scanning system with a SINCO inclinometer and telemetric data acquisition that was also developed at the University of New Brunswick [16]. It has been used successfully in monitoring highwall stability at the Syncrude Canada Limited tarsands mining operation in northern Alberta.

15.2 Geodetic Leveling

Geodetic or differential leveling measures the height difference between two points using precision tilting levels, or precision automatic levels with compensators, with parallel plate micrometers and calibrated invar leveling staves or rods. Recent technology has provided digital automatic levels that use a CCD sensor in the instrument and bar codes, rather than linear graduations, on the staves [17]. Their ease of use and comparable precision have quickly made them rivals to the traditional optical instruments. In a single setup of the level, the height difference is the backsight rod reading minus the foresight rod reading. Any number of setup height differences can be combined to determine the height difference between two points of interest; however, the errors involved accumulate with the number of setups. With sight lengths limited to no more than 20 m, geodetic leveling can produce height differences with a precision of ± 0.1 mm per setup, which is equivalent to a precision of $\pm 0.5''$ in tilt. Although geodetic leveling is traditionally used to determine elevations, it is often used to monitor not only the settlement of sensitive structures but also to describe the tilt of components of a structure by determining the tilt between appropriate pairs of benchmarks (monumented in or on the structure) [18]. Since the level reference is created by an optical line of sight through a telescope (magnification up to $40\times$), a major source of systematic error is the effect of vertical atmospheric refraction. A vertical temperature gradient of even 1°C m^{-1} across the line of sight would bend the line of sight to be in error by 0.4 mm at 30 m. Gradients of this magnitude are commonly encountered in industrial settings and are usually even more evident outdoors. Less effect is realized if the sight lengths are kept short, but this must be weighted against the accumulation of random error with each additional setup (shorter sight lengths would require more setups to traverse the same height difference). The errors that seem to be insignificant in a single setup (or in a few setups) become magnified in height differences involving a large number of setups (e.g., rod scale error and settlement of the instrument or rods). Such errors have become quite noticeable in the monitoring of tectonic plate movement and undetected systematic effects can be misleading. Further discussion on precision leveling and sources of error is available in Vanicek et al. [19] and in Schomacker and Berry [20].

FIGURE 15.2 Hydrostatic equilibrium in connected vessels.

Having the elevations or heights, h_1 and h_2 , of two points or having measured, or determined, the height difference between them, $\Delta h_{1,2^t} = h_2 - h_1$, at a time t , means that, if $\delta\Delta h = \Delta h_{1,2^t} - \Delta h_{1,2^{t-1}}$, the tilt, $T_{1,2}$, can be calculated if the horizontal separation $s_{1,2}$ is known, since $T_{1,2} = \delta\Delta h/s_{1,2}$. The separation does not have to be known as precisely as the height difference since the total random error is $\sigma_{T^2} = \sigma_{\delta\Delta h}^2/s^2 + \sigma_{s^2}(\delta\Delta h^2/s^4)$. As an example, for two points that are 60 m apart with a height difference of 0.5 m (extreme in most structural cases) with the height difference known to $\pm 50 \mu\text{m}$ ($\sigma_{\delta\Delta h}$) and the distance known to ± 0.01 m (σ_s), the tilt would have a precision (σ_T) of $\pm 0.3''$. Further, neither the measurement of the height difference nor the determination of the separation have to be done directly between the two points. The leveling can be done along whatever route is convenient and the separation can be obtained in a variety of ways, for example, inverting from coordinated values for the points [21].

15.3 Hydrostatic Leveling

If two connected containers (Figure 15.2) are partially filled with a liquid, then the heights h_1 and h_2 are related through the hydrostatic equation (Bernoulli's equation, as given in [22]):

$$h_1 + P_1/(g_1\rho_1) = h_2 + P_2/(g_2\rho_2) = c \quad (15.2)$$

where P is the barometric pressure, g is the force of gravity, ρ is the density of the liquid which is a function of temperature, and c is a constant.

The above relationship has been employed in hydrostatic leveling, as shown schematically in Figure 15.3. The air tube connecting the two containers eliminates possible error due to different air pressures at two stations. The temperature of the liquid should also be maintained constant because, for example, a difference of 1.2°C between two containers may cause an error of 0.05 mm in a Δh determination

FIGURE 15.3 Hydrostatic leveling ($\Delta h_{12} = r_2 - r_1$).

for an average $h = 0.2$ m and $t = 20^\circ\text{C}$. Huggett et al. [23] devised a two-fluid tiltmeter to overcome the temperature effect by using two liquids with different temperature coefficients and claim a resolution of 10^{-8} to 10^{-9} rad over a separation of up to 1 km. In a discussion of liquid level gages, Dunicliff [1] emphasizes that care should be exercised to ensure that there is no discontinuity in the liquid since any gas (usually air, often entering when filling the tubing) in the liquid line will introduce an error in the level difference, especially in a vertical, more than in a horizontal, portion of tubing. He also mentions that the behavior of the liquid is influenced by the inside diameter and capillary effects of the tubing, while the outside diameter is likely what is quoted by manufacturers. Dunicliff [1] also provides a comprehensive summary of the variety of liquid level gages.

Two examples of typical hydrostatic instruments used in precision leveling will be mentioned here. The ELWAAG 001, developed in Germany [24], is a fully automatic instrument with a traveling (by means of an electric stepping motor) sensor pin that closes the electric circuit on touching the surface of the liquid. A standard deviation of ± 0.03 mm is claimed over distances of 40 m between the instruments [22]. Another automatic system, the Nivomatic Telenivelling System, is available from Telemac or Roctest Ltd. The Nivomatic uses inductance transducers that translate the up and down movements of its floats into electric signals (frequency changes in a resonant circuit). An accuracy of ± 0.1 mm is claimed over a 24 m length. P & S Enterprises, Ltd. produces a Pellissier model H5 portable hydrostatic level/tiltmeter, for which they claim an accuracy of ± 5 μm over a tube length of 14 m, for engineering and Earth tide measurements.

Hydrostatic levels may be used in a network formation of permanently installed instruments to monitor tilts in large structures. Robotti and Rossini [25] report on a DAG (Automatic Measuring Device of Levels and Inclinations) network monitoring system available from SIS Geotecnica (Italy) that offers an accuracy of about ± 0.01 mm using inductive transducers in the measurement of liquid levels. Various systems of double liquid (e.g., water and mercury) settlement gages based on the principle of hydrostatic leveling are used for monitoring power dams [26] with extended networks of connecting tubing.

Instruments with direct measurement of liquid levels are limited in their vertical range by the height of their containers. This problem may be overcome if liquid pressures are measured instead of the changes in elevation of the liquid levels. Pneumatic pressure cells or pressure transducer cells may be used. Both Dunicliff [1] and Hanna [26] give numerous examples of various settlement gages based on that principle. Meier [27] mentions the application of a differential pressure tiltmeter in the monitoring of a concrete dam.

FIGURE 15.4 Inclination measurements with plumb lines. (a) suspended pendulum; (b) inverted pendulum.

15.4 Suspended and Inverted Plumb Lines

Two types of mechanical plumbing are used in monitoring the stability of vertical structures:

1. Suspended pendula or plumb lines (Figure 15.4(a))
2. Floating pendula or inverted, or reversed, plumb lines (Figure 15.4(b))

Typical applications are in the monitoring of power dams and of the stability of reference survey pillars. Suspended pendula are also commonly used in mine orientation surveys and in monitoring the stability of mine shafts. Tilt, or inclination, is derived from differences in horizontal relative position combined with vertical separation in the same way as tilt is derived from geodetic leveling. So, similarly, the vertical separation between two reading tables or between a reading table and anchor point does not have to be known as precisely as the change in relative position. Two table readings, each ± 0.02 mm, with a relative position difference of 100 mm and a vertical separation of 10 m, known to ± 0.01 m, would result in a tilt precision of $\pm 2''$.

Inverted plumb lines have become standard instrumentation in large dams (e.g., Hydro Quebec uses them routinely). Their advantage over suspended plumb lines is in the possibility of monitoring the absolute displacements of structures with respect to deeply anchored points in the foundation rock which may be considered as stable. In power dams, the depth of anchors must be 30 m or even more below the foundation in order to obtain absolute displacements of the surface points. The main problem with inverted plumb lines is the drilling of vertical boreholes so that the vertical wire of the plumb line would have freedom to remain straight and vertical. A special technique for drilling vertical holes has been developed at Hydro Quebec [28].

Several types of recording devices that measure displacements of structural points with respect to vertical plumb lines are produced by different companies. The simplest are mechanical or electromechanical micrometers with which the plumb wire can be positioned with respect to reference lines of a recording (coordinating) table with an accuracy of ± 0.2 mm or better. Traveling microscopes may give the same accuracy. Automatic sensing and recording is possible with a Telecoordinator from Huggenberger

FIGURE 15.5 (a) Influence of air currents on a suspended plumbline. (b) Horizontal error due to the spiral shape of the wire.

AG in Switzerland. Telemac Co. (France) developed a system, Telependulum (marketed by Roctest), for continuous sensing of the position of the wire with remote reading and recording. A rigidly mounted reading table supports two pairs of induction type proximity sensors arranged on two mutually perpendicular axes. A hollow cylinder is fixed on the pendulum wire at the appropriate level, passing through the center of the table and between the sensors. Changes in the width of the gap between the target cylinder and the sensors are detected by the corresponding changes in the induction effect. The system has a resolution of ± 0.01 mm.

An interesting Automated Vision System has been developed by Spectron Engineering (Denver, Colorado). The system uses solid state electronic cameras to image the plumb line with a resolution of about $3 \mu\text{m}$ over a range of about 75 mm. Several plumb lines at Glen Canyon dam and at Monticello dam, near Sacramento, California, have been using the system since 1982 [29].

Two sources of error, which may be often underestimated by the user, may strongly affect plumb line measurements:

1. The influence of air currents
2. The spiral shape of the wire

If the wire of a plumb line (Figure 15.5(a)), with pendulum mass Q , is exposed along a length h to an air current of speed v at a distance H from the anchor point, then the plumb line is deflected by an amount [30]:

$$e = f_o h H / Q \quad (15.3)$$

where f_o is the acting force of air current per unit length of the wire. The value of f_o may be calculated approximately from [30]

$$f_o = 0.08 d v^2 / Q \quad (15.4)$$

where d is the diameter of the wire in millimeters, v is in meters per second, and Q is in kilograms. As an example, if $H = 50$ m, $h = 5$ m, $d = 1$ mm, $Q = 20$ kg, and $v = 1$ m s⁻¹ (only 3.6 km h⁻¹) then $e = 1$ mm.

The second source of error, which is usually underestimated in practice, is that the spiral shape (annealing) of the wire (Figure 15.5(b)) affects all wires unless they are specially straightened or suspended for a prolonged time (on the order of several months). If the wire changes its position (rotates) between two campaigns of measurements, then the recorded displacements could have a maximum error of $2r$. The value of r can be calculated from [30]:

$$r = \left(\pi d^4 E \right) / \left(64 R Q \right) \quad (15.5)$$

where E is Young's modulus of elasticity (about 2×10^{11} Pa for steel); R is the radius of the free spirals of the unloaded wire that, typically, is about 15 cm for wires up to 1.5 mm diameter; and d and Q are as above. For a plumb wire with $d = 1$ mm, $R = 15$ cm, and $Q = 196$ N (i.e., 20 kg), $r = 0.3$ mm.

If one plumb line cannot be established through all levels of a monitored structure, then a combination of suspended and inverted plumb lines may be used as long as they overlap at least at one level of the structure. At Hydro Quebec, the drill holes of the plumb lines are also used for monitoring height changes (vertical extension) by installing tensioned invar wires [31].

15.5 Integration of Observations

The above discussion has considered using individual instruments. Because many investigations, using other instrumentation as well as the measurement of tilt, involve the repetition of measurements, often over a long term, the fidelity of the measurements and their being referenced to the original or initial observation is vital to the investigation. It is risky to expect consistent behavior of instrumentation, particularly in environments with dramatic variations (especially in temperature), and over a long period of time. Any conclusion relating to the behavior of a structure is only as good as the data used in the analysis of the behavior. Two ways to ensure reliability are possible. One is to make regular testing and calibration a component of the observation regimen. The other is to analyze the observations as they are accumulated, either each observable as a temporal series of repeated measurements or observations of different locations or types together in an integrated analysis. The analytical tools for integrated analyses, as well as for calibration testing and temporal series analysis, have been developed [21, 32] and successfully implemented in several projects [15, 18, 33]. Proper calibration testing and correction, rigorous statistical analysis of trend in temporal series, and integrated analysis have proven to be valuable tools in the analysis of deformations and serve to enhance the monitoring of sensitive structures.

- 16.1 Introduction
- 16.2 Measurement of Linear Velocity
Reference-Based Measurement • Seismic Devices
- 16.3 Velocity: Angular
Relative: Tachometer • Absolute: Angular Rate Sensors
- 16.4 Conclusion

16.1 Introduction

The *linear velocity* of an object, or more correctly a particle, is defined as the time rate of change of position of the object. It is a vector quantity, meaning it has a direction as well as a magnitude, and the direction is associated with the direction of the change in position. The magnitude of velocity is called the speed (or pace), and it quantifies how fast an object is moving. This is what the speedometer in a car tells you; thus, the speedometer is well named. Linear velocity is always measured in terms of, or from, some reference object. Thus, the speedometer of a car tells how fast one is moving relative to the earth. Usually, linear velocity is identified using only the term “velocity.” Common units for velocity include meters per second and miles per hour, but any similar combination of units of length per unit of time is correct.

The *rotational velocity* (or angular velocity) of an object is defined as the time rate of change of angular position, and it is a measure of how fast an object is turning. It is completely analogous to linear velocity, but for angular motion. Common units are revolutions per minute, but any angular unit of measurement per unit of time can be used. Rotational velocity is a vector quantity also, with the direction of the vector being the same as the direction of the axis about which object is turning. For example, with a car stopped at a stop light with the motor running, the rotational velocity of the crankshaft of the motor is given by a magnitude (rotational speed), say 800 rpm (rev/min), and a direction associated with the direction in which the crankshaft is pointing. The axis of rotation of the object may be moving, rather than fixed as when the car is turning a corner. The roll, yaw, or pitch velocity of an airplane would be given in terms of rotational speeds about each of the turning axes in the same manner as for a crankshaft.

Usually, the reference from which linear or rotational velocity is given is understood from the context of the problem. It is often not stated explicitly. The measurement method used defines the reference.

Applications for velocity measurement include:

1. Controlling the speed at which metal stock is fed into a machine tool. If the metal is fed too quickly the result could be premature tool wear or it could even lead to machine failure. Feeding the material too slowly will reduce the yield of the machine tool.
2. Measuring the approach speed of a robotic tool onto its target.
3. Monitoring the speed of a generator in an electric power station.
4. An airport radar system measuring the speed of an approaching aircraft using the Doppler effect.
5. Measuring an automobile’s wheel speed in order to provide feedback to an antilock brake system.

FIGURE 16.1 Position-time function for an object moving on a straight path.

16.2 Measurement of Linear Velocity

The problem of velocity measurement is somewhat different from that of measurement of other quantities in that there is not a large number of transducer types and transducer manufacturers from which to choose for a given problem. Frequently, the problem is such that the person must use his/her knowledge of measurement of other quantities and ingenuity to develop a velocity measurement method suitable for the problem at hand. Velocity is often obtained by differentiation of displacement or integration of acceleration. As background information for this, the necessary equations are given below.

Figure 16.1 shows a graph that represents the position of an object as a function of time as it moves along a straight, vertical path (y direction). The quantity to be measured could be an average velocity, and its magnitude would then be defined as follows:

$$\text{Average speed} = V_{\text{avg}} = \frac{y_2 - y_1}{t_2 - t_1} = \frac{\Delta y}{\Delta t} \quad (16.1)$$

for the time interval t_1 to t_2 . As the time interval becomes small, the average speed becomes the instantaneous speed V_y , and the definition becomes:

$$V_y = \lim_{\Delta t \rightarrow 0} \frac{\Delta y}{\Delta t} = \frac{dy}{dt} \quad (16.2)$$

which is the slope of the position–time curve. The subscript indicates the y component. This speed, when associated with the known direction, becomes the velocity.

Since acceleration is defined as the time rate of change of velocity, the speed of an object may also be given by:

$$V_y(t) = V_i - \int_{t_i}^t a_y(t) dt \quad (16.3)$$

where $a_y(t)$ is the acceleration in the y direction (for Figure 16.1) and V_i is the speed at time t_i . Each of the above equations can be used as a basis for making a velocity measurement. Note that for motion in more than one dimension, there would be more than one component, and there would be corresponding equations for the other dimensions (x and y). However, velocity measurements are always done by individual component.

It is convenient in the discussion of techniques of measuring velocity to divide the methods into two categories: one will be called “referenced-based methods” and the other “seismic or inertial referenced transducers.” Referenced-based methods refer to measurements made for which the instrumentation has component(s) on both the moving object and the reference frame for the measurement. The seismic transducers do not require contact with the reference frame. However, they give a speed relative to the transducer speed at the start of the test. The initial motion must be determined from other considerations in the test setup and added to the relative speed.

Reference-Based Measurement

Using Equation 16.1, one value of the average speed in a given direction of an object can be determined from the distance traveled in that direction and the time required. Determining the muzzle speed of a projectile is an example. Having two pickups spaced a known distance apart, and recording the time for the projectile edge to pass between them is a common way of doing this. Typical pickups would include proximity transducers (see displacement measurement), laser or collimated light beams with diode sensors, and electric contacts closed (or opened) by the moving object. Measuring the time interval can be done with an electronic counter or displaying the output of the pickups on an oscilloscope. In designing such a system, care must be exercised to minimize or eliminate the effect to the object passing through the window on the positions of the sensors and their response. For example, pressure from a muzzle blast can move the sensors on their supports. This could distort the distance between them during the measurement; but afterwards, the appearance of the setup could be unchanged, so the experimenter would be unaware of the error.

Using a series of equally spaced pickups can determine the average speed for a sequence of positions. For some applications, illumination of the path of motion of the object with a stroboscope flashing at a known rate and use of time exposure photography can give a single picture of the object at a sequence of positions. With knowledge of the length scale and the flash rate, the average speed at a sequence of positions can be calculated. If the plane of motion is the same as the plane of the photograph, then two components of the velocity can be determined. A variation of this method is to use video recording of the motion and the time base of the video for measurement of time increments. Availability of high-speed video cameras, to 12,000 frames per second, extends the range of applicable velocities, and digital recording can enhance the ease and accuracy of making the distance measurements.

Another variation of this method is to use some type of position transducer to record the position–time function of the moving object and then differentiate this function to get speed–time. Displacement

FIGURE 16.2 Velocity transducers (LVT).

transducers were discussed in an earlier chapter, and the selection of an acceptable transducer is important. Range, resolution, and mass loading are important parameters. Because differentiation of experimental data is a noise-generating process, particular care must be exercised to reduce the electric noise in the displacement data to a minimum. Also, the calculated speed–time function might require some smoothing to reduce the numerically introduced noise.

One type of velocity transducer is based on a linear generator. When a coil cuts the magnetic field lines around a magnet, a voltage is induced in the coil, and this voltage is dependent on the following relation:

$$e_i \propto BLV \quad (16.4)$$

where e_i = induced voltage

B = magnetic field strength

L = length of wire in the coil

V = speed of the coil relative to the magnet.

This relation is used as the basis for linear velocity transducers, called LVTs, and a schematic is shown in Figure 16.2. Manufacturers of these transducers include Trans-Tek Inc. of Ellington, CN; Robinson-Halpern Products of Valley Forge, PA; and the Macro Sensors, Div. of Howard A. Schaevitz Technologies, Inc. of Pennsauken, NJ. The working displacement ranges are from 0.5 in. to 24 in., and typical sensitivities are from 40 mV/ips (inches per second) to 600 mV/ips.

Conversion of Linear to Rotational Velocity

A rotational dc generator (discussed in the next section) can also be used to measure linear velocities by placing a rack on the moving object and having the rack drive the generator through a pinion gear. This is the same principle by which a speedometer converts the linear velocity of an automobile to an angular velocity gage on the dashboard of a car.

Doppler Shift

The Doppler shift is an apparent change in the frequency of waves occurring when the source and observer are in motion relative to each other. This phenomenon is applicable to waves in general; for example, sound, light, microwaves, etc. It was first observed for sound waves, and it is named after the Austrian mathematician

and physicist Christian Doppler (1803–1853) who first published a paper on it for light waves in 1842. The frequency will increase when the source and observer approach each other (red shift) and decrease when they move apart (blue shift). This phenomenon was illustrated by having people listen to the pitch of an oncoming train. The high-pitched whistle would transition to a lower pitch as the train passed the observer.

Radar, which is named for radio detection and ranging, is another technique for detecting the position, motion, and nature of a remote object by means of radio waves reflected from its surface. Pulse radar systems use a single directional antenna to transmit and receive the waves. They transmit pulses of electromagnetic waves (usually microwaves), some of which are reflected by objects in the path of the beam. Reflections are received by the radar unit, processed electronically, and converted into images on a cathode-ray tube. The antenna must be connected only to the transmitter when sending and only to the receiver while receiving; this is accomplished by switching from one to the other and back again in the fraction of a microsecond between pulses. The distance of the object from the radar source is determined by measuring the time required for the radar signal to reach the target and return. The direction of the object with respect to the radar unit is determined from the direction in which the pulses were transmitted. In most units, the beam of pulses is continuously rotated at a constant speed, or it is scanned (swung back and forth) over a sector at a constant rate. Pulse radar is used primarily for aircraft and naval navigation and for military applications. In Doppler radar, or continuous-wave radar, two antennas are used — one to transmit and the other to receive. Because the time a continuous-wave signal takes to reach the target and return cannot be measured, Doppler radar cannot determine distance. The velocity of the object is determined using the Doppler effect. If the object is approaching the radar unit, the frequency of the returned signal is greater than the frequency of the transmitted signal. If the object is receding, the returned frequency is less; and if the object is not moving relative to the radar unit, the frequency of the returned signal is the same as the frequency of the transmitted signal.

One value of this Doppler technology is shown on the evening weather broadcast. Radar can measure wind rotation inside a thunderstorm and identify possible tornadoes. The VORAD system by Eaton is an on-board system for vehicle safety. It detects when a dangerous approach to another vehicle is taking place. It will automatically apply the brakes in an emergency situation.

Light Interference Methods

Velocity measurements can be made using light interference principles. [Figure 16.3](#) shows the setup used by Michelson in the 1890s to demonstrate light interference. A beam of monochromatic light is split into two beams. One beam is directed onto a stationary mirror. The other beam is directed onto a moving target. The observer sees the superposition of the two beams. As the mirror moves in one direction, summation of the waves of the two beams will alternately reinforce and cancel each other. The amount of motion for one cycle of light intensity variation is the wavelength of the light being used. The frequency of these light-to-dark transitions is proportional to the velocity of the moving target. Highly accurate measurements are available with interferometer techniques. For example 1 m is 1,650,763.73 fringe counts for the orange light emitted by krypton-86.

Refinements of this principle are needed for convenience of use. Lasers are used as the light source, for example. One commercial supplier of this type of device, commonly called a Laser Doppler Vibrometer, is Polytec PI, Inc. of Costa Mesa, CA. The basic principle gives velocity parallel to the laser beam, but Polytec PI also has a unit that utilizes scattered laser light which permits measurement of the in-plane velocity. It is called a laser surface velocimeter.

VISAR System

Another application of interferometry to the measurement of velocity–time profiles is a device called VISAR, for “velocity interference system for any reflector.” Earlier interferometer systems had required that the target have a highly polished reflecting surface and that there be very little surface tilt during a test. The VISAR system functions with either specularly or diffusely reflecting surfaces, and is quite insensitive to tilting of the target. It was developed for shock wave research work, and is useful for measurement of very high speeds. Reference [3] gives a detailed description of the principles of operation.

FIGURE 16.3 The basic components of a Michelson interferometer. The clear glass slab C is called a compensating plate. It has the same dimensions and orientation as the 45° mirror in order to make the light paths in glass equal along the two arms, a condition necessary when a white-light source is used.

The signal from the VISAR is generated with a photodiode or other light-sensitive device, and is basically a measure of the rate of fringe variation. Additional data reduction is required to obtain speeds. The sensitivities of the devices are specified in “fringes per meter/second.” Typical sensitivities are in the range of 100 m/s to 4000 m/s per fringe.

The first VISARs were laboratory devices, individually assembled from the needed optical components. Commercial units are now available. Valyn International of Albuquerque, NM, makes VISARs and components. Figure 16.4 shows a schematic of a test setup. This unit can measure speeds from 100 m s⁻¹ to 10 km s⁻¹ or more. The standard measurement range, given as depth of field, of the VISAR is 12 mm, but systems measuring over 10 m have been used. Applications for the VISAR include:

- In-bore projectile velocity
- Flyer plate velocity
- Flying foil velocity
- Hugoniot equation of state
- Structural response to shock loading

Seismic Devices

The devices discussed in the previous section required a link of some type between the reference and the moving object. Seismic devices do not have this requirement. A seismic device refers to a transducer, which is based on a mass attached to the transducer base, usually with a linear spring. The base is attached to the surface whose motion is desired, and the motion of the seismic mass relative to the base is recorded with a motion transducer. Figure 16.5 shows the principal components of this transducer type. Use of the governing equation of motion for the seismic mass permits the determination of the motion of the base from the relative motion function.

If the motion transducer in the seismic instrument measures the displacement of the mass relative to the base, the output of the transducer is proportional to the acceleration of the transducer base for a specific frequency range and the device is called an *accelerometer*. Acceleration measurement using this

VISAR TEST CONFIGURATION

FIGURE 16.4 Schematic diagram showing how fiber optic components, available from Valyn, can transport laser light to and from a shock experiment, minimizing any laser light beam hazards. (Courtesy: Valyn International, Albuquerque, NM.)

type of device (or with other types of accelerometers) permits the determination of the velocity–time function by integration through the application of Equation 16.3. In this equation, $a_y(t)$ would be determined from the output of the accelerometer.

The simplicity of this concept is evident and, because integration is a smoothing process, the numerically introduced noise encountered with a “differentiation of displacement” method of speed measurement does not occur. However, other errors can be introduced. First, any error in the acceleration

FIGURE 16.5 Seismic type of motion-measuring instrument.

measurement will be carried over. However, additional precautions are necessary to obtain good results for speed measurement. The problem areas include the following:

- The initial speed, V_i , must be known at the beginning of the time of interest. Because this quantity is added to the change in speed, an error in it will be a constant on each value.
- A bias, or zero shift, in the accelerometer signal will be included as a constant acceleration, and thus introduce a linearly increasing error in the calculated values throughout the time interval of interest. This bias may be introduced from electrical or thermal characteristics of the circuit, or, in the case of measurement of accelerations during impact after a free fall, by the 1 g acceleration of gravity.
- If the frequency content of the acceleration falls outside the usable bandwidth of the accelerometer and recording circuit, errors in acceleration occur. The low-frequency cutoff depends on the recording equipment and circuit, and the high frequency cutoff depends on the natural frequency and damping of the accelerometer, as well as the bandwidth of each piece of equipment in the recording circuit.
- Accelerometer theory is based on harmonic excitation of the system. For many velocity measurement applications, the input is a transient. Combination of these two factors can result in inaccurate accelerometer data; for example, ringing may occur, and cause errors in the calculated speeds. This problem is accentuated for lightly damped accelerometers.

When this method of speed measurement must be used, a series of check tests should be conducted to evaluate the accuracy of the method for that particular system.

A variation of the above method is to put an integrating circuit in the accelerometer and perform the integration with an analog circuit. Then, the output of the “velocity” transducer is proportional to the change in speed. This type of device is subject to all of the potential error sources discussed above. A manufacturer of this type of transducer is Wilcoxon Research of Gaithersburg, MD.

FIGURE 16.6 Permanent-magnet dc tach-generator.

It can be shown that if the electromechanical transducer in a seismic instrument gives an output which is proportional to the speed on one end relative to the other end, then the output of the seismic transducer is proportional to the speed of the transducer in an inertial reference frame, i.e., relative to the earth, for input motion frequencies well above the natural period of the seismic mass. Thus, use of a linear velocity transducer as the motion measurement transducer in a seismic instrument makes it a “seismic velocity transducer.” This type of device is called several different names, including seismometer, geophone, and vibrometer, as well as velocity transducer.

The natural frequency and damping in these instruments are selected to match the application. As with an accelerometer, the usable bandwidth depends on these two characteristics. The low-frequency limit for this type of transducer is dependent on the accuracy required in the measurement. The governing equation is given in Doebelin [3]. As an example, it can be used to show that if an accuracy of 5% is required, the lowest data frequency must be 4.6 times the natural frequency of the transducer, and that the upper data frequency is not limited. In fact, the higher the upper frequency, the more accurate the results.

Seismometers are used for recording and studying motion from earthquakes, and these devices can be quite large. Natural periods can be in the range of 10 s to 50 s, and damping is normally selected as 0.7 of critical to extend the frequency range as much as possible. Geophones are commonly used for oil well logging and related work. Their natural periods are in the vicinity of 10 s. Manufacturers of these devices include Teledyne Brown Engineering and GeoSpace Corporation of Houston, TX.

16.3 Velocity: Angular

Measurement of angular velocity is often applied to rotating machinery such as pumps, engines, and generators. The most familiar unit of measurement in rotating machinery applications is revolutions per minute (rpm). In most cases, the measurement of rpm involves the generation of a pulse train or sine wave whose frequency is proportional to angular velocity. The measuring technologies using pulse trains and waves include ac and dc generator tachometers, optical sensors, variable reluctance sensors, rotating magnet sensors, Wiegand effect sensors, stroboscopy, etc.

These types of measurements are taken with respect to the base of the item being measured. They are relative measurements because one is measuring the motion between two bodies.

Another class of measurement problem is that of moving or inertial bodies. In this case, a measurement of absolute motion is performed. Some fixed reference must be stated or implied. This reference is often the Earth. A universal reference is sometimes required for celestial measurements. These inertial measurements are typically taken with gyroscope-type devices.

Relative: Tachometer

Electrical (dc and ac) Tachometer Generator

A rotating generator produces a voltage signal proportional to the rotational velocity of the input shaft. A dc generator produces a voltage level proportional to speed, as in Figure 16.6. The ac generator produces

FIGURE 16.7 Ac tach-generator.

FIGURE 16.8 Generated electromotive force. Moving conductor.

an ac voltage output with a frequency proportional to rotational speed, as shown in Figure 16.7. In a simple two-phase motor, the ac voltage is applied to one phase of the motor and the measurement is taken off the other. Typical operating frequencies are 60 Hz and 400 Hz. This carrier frequency should be 5 to 10 times the required frequency response of the ac generator tachometer. The direction of travel is determined by the phase of the signal with opposite directions being 180° out of phase. The basic dc generator is shown in Figure 16.8.

Sources of tachometer generators include the GE Company of Fairfield, CT; Kollmorgen Motion Technologies Group of Radford, VA; Sierracin/Magnedyne of Vista, CA; and Micro Mo Electronics of Clearwater, FL.

Counter Types

An entire class of angular velocity measuring techniques exists that uses pulses generated by electromechanical interaction. The common thread is a pulse-to-voltage converter giving a voltage output proportional to velocity.

Rotating Magnet Sensors: Passive speed sensors convert mechanical motion to ac voltage without an external power source. These self-contained magnetic sensors produce a magnetic field that, when in the proximity of ferrous objects in motion, generates a voltage.

When a magnetic sensor is mounted in the proximity of a ferrous target, such as gear teeth on a rotating shaft, the voltage output frequency is directly proportional to the rotational speed of the target. A frequency-to-voltage converter can then convert the signal to a voltage. An engineering unit conversion from voltage to velocity then provides an actual velocity measurement.

Typical applications for these types of sensors include:

FIGURE 16.9 Magnetic speed sensor output voltage vs. speed. (Courtesy: Smith Systems, Inc., Brevard, NC.)

FIGURE 16.10 A slotted disk provides one pulse output for each rotation.

- Transmission speed
- Engine rpm
- Over/under speed
- Wheel speed
- Pump shaft speed
- Multiple engine synchronization
- Feedback for speed control
- Crankshaft position/engine timing
- Computer peripheral speeds

The typical specifications for magnetic speed sensors are given by a graph of output voltage versus surface speed in inches per second, as in [Figure 16.9](#).

Sources for magnetic sensors include Smith Systems of Brevard, NC; Optek Technology of Carrolton, TX; Allied-Signal of Morristown, NJ; and Baluff of Florence, KY.

Optical Sensors

Optical methods of angular velocity detection employ a light emitter and a light detector. A light-emitting diode (LED) paired with a light-sensitive diode is the most common arrangement.

A slotted disk is placed in the axis of a rotating shaft. Each slot or slit will allow the light to pass through the disk. [Figure 16.10](#) shows a typical arrangement. The detector will generate a pulse train with a rate proportional to the angular velocity.

FIGURE 16.11 Hall-effect gear tooth sensor. (Courtesy: Allegro Microsystems, Inc., Worcester, MA.)

The effects of external light sources must be considered in the application of optical sensors.

Sources of optical sensor systems include Scientific Technologies of Fremont, CA; Banner Engineering Corp. of Minneapolis, MN; and Aromat Corp. of New Providence, NJ.

Hall Effect

The Hall effect describes the potential difference that develops across the width of a current-carrying conductor. E.H. Hall first used this effect in 1879 to determine the sign of current carriers in conductors. Hall effect devices are finding their way into many sensing applications. A typical Hall effect sensor application is the wheel speed sensor for antilock braking systems in automobiles. The Allegro ATS632LSC gear-tooth sensor, shown in [Figure 16.11](#), is an optimized Hall-effect IC/magnet combination. The sensor consists of a high-temperature plastic shell that holds together a compound samarium–cobalt magnet, a single-element self-calibrating Hall effect IC, and a voltage regulator. The operation of this circuit is shown in [Figure 16.12](#).

Wiegand Effect

The Wiegand effect is useful for proximity sensing, tachometry, rotary shaft encoding, and speed sensing in applications such as:

- Electronic indexing for water, gas, and electric meters and remote metering systems
- Measuring shaft speed in engines and other machinery
- Tachometers, speedometers, and other rotational counting devices

Wiegand effect technology employs unique magnetic properties of specially processed, small-diameter ferromagnetic wire. By causing the magnetic field of this wire to suddenly reverse, a sharp, uniform voltage pulse is generated. This pulse is referred to as a Wiegand pulse. Sensors utilizing this effect require only a few simple components to produce sharply defined voltage pulses in response to changes in the applied magnetic field. These sensors consist of a short length of Wiegand wire, a sensing coil, and alternating magnetic fields that generally are derived from small permanent magnets.

The major advantages of the Wiegand effect based sensors are:

- No external power requirement
- Two-wire operation
- Noncontact with no wear
- 20 kHz pulse rate
- High-level voltage output pulse
- Wide operating temperature range (e.g., -40°C to $+125^{\circ}\text{C}$)

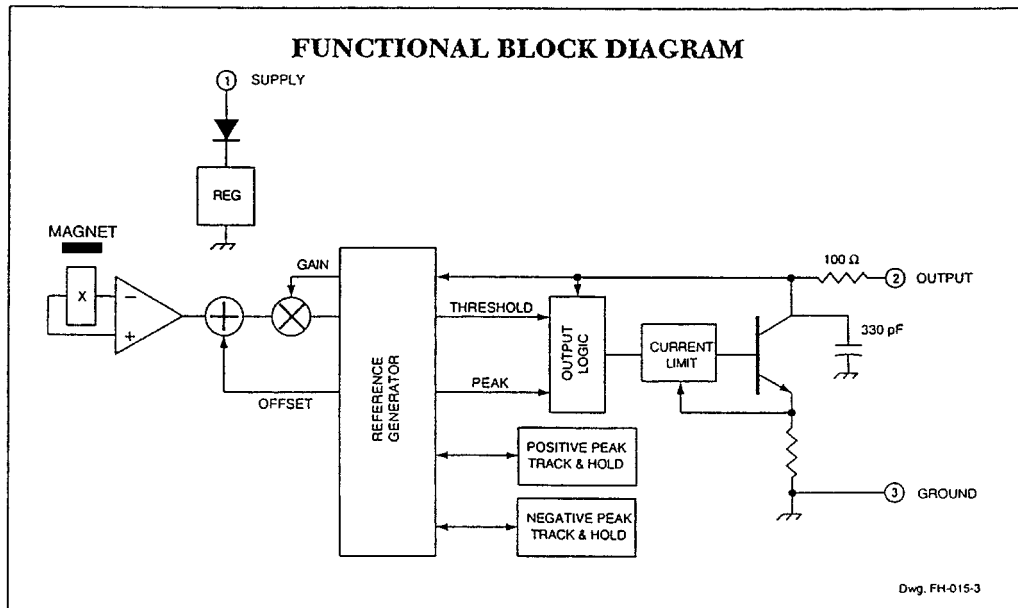

FIGURE 16.12 Hall-effect gear tooth sensor circuit. (Courtesy: Allegro Microsystems, Inc., Worcester, MA.)

FIGURE 16.13 Small magnets cause sudden reversal in the ferromagnetic wire in a Wiegand sensor. (Courtesy: HID Corporation, North Haven, CT.)

When an alternating magnetic field of proper strength is applied to the Wiegand wire, the magnetic field of the core switches polarity and then reverses, causing the Wiegand pulse to be generated, as shown in Figure 16.13. The magnetic switching action of the Wiegand wire induces a voltage across the pickup coil of approximately $10 \mu\text{s}$ duration. These alternating magnetic fields are typically produced by magnets that are affixed to the rotating or moving equipment, by a stationary read head and moving Wiegand wires, or by an alternating current generated field.

Absolute: Angular Rate Sensors

Gyroscopes

Many absolute angular rate-measuring devices fall under the designation of gyroscope. A mechanical gyroscope is a device consisting of a spinning mass, typically a disk or wheel, mounted on a base so that its axis can turn freely in one or more directions and thereby maintain its orientation regardless of any movement of the base. It is important to make an initial distinction between angular velocity gyros and rate-integrating gyros. Angular velocity gyros are used to measure motion and as signal inputs to stabilization systems. Rate-integrating gyros are used as the basis for highly accurate inertial navigation systems. They allow a stable platform to maintain a fixed attitude with reference. These devices can be very complex. Three gyros are often teamed with three double-integrated accelerometers to provide an accurate measurement of absolute vehicle motion.

Ricardo Dao of Humphrey Inc. provided an excellent comparison of angular rate sensors in an article in *Measurements & Control* [14]. The five different technologies are summarized below.

FIGURE 16.14 A vibrating quartz tuning fork uses the Coriolis effect to sense angular velocity. (Courtesy: BEI Sensors and Systems Co., Concord, CA.)

Spinning mass: The traditional gyro consists of a spinning wheel in a gimbaled frame. The principle of conservation of angular momentum provides the measurement tool.

Fluidic: A stream of helium gas flows past two thin tungsten wires [14]. The tungsten wires act as two arms of a Wheatstone bridge. At rest, the gas flow cools the sensing wires equally and the transducer bridge is balanced with zero output. When angular motion is applied to the sensor, one sensor wire will be subjected to increased flow while the other will see less flow. The resistance of the two wires will change and the bridge will be unbalanced. The sensor will produce a voltage output proportional to the angular velocity.

A pump is used to circulate the helium gas. This pump is a piezoelectric crystal circular disk that is excited with an external circuit. The pump produces a laminar flow of relatively high-velocity gas across the two parallel sensing wires.

Piezoelectric vibration: A number of angular velocity sensors have been developed that use micromachined quartz elements. A number of shapes are used, but the operating principle is similar for each. The quartz element vibrates at its natural frequency. Angular motion causes a secondary vibration that, when demodulated, is proportional to angular vibration. A description of one design follows.

The QRS and GyroChip™ family of products uses a vibrating quartz tuning fork to sense angular velocity [15, 16]. Using the Coriolis effect, a rotational motion about the sensor's longitudinal axis produces a dc voltage proportional to the rate of rotation. Figure 16.14 shows that the sensor consists of a microminiature double-ended quartz tuning fork and supporting structure, all fabricated chemically from a single wafer of monocrystalline piezoelectric quartz (similar to quartz watch crystals).

Use of piezoelectric quartz material simplifies the active element, resulting in exceptional stability over temperature and time. The drive tines, being the active portion of the sensor, are driven by an oscillator circuit at a precise amplitude, causing the tines to move toward and away from each other at a high frequency.

Each tine will have a Coriolis force acting on it of: $\{F = 2m W_i \times V_r\}$ where the tine mass is m , the instantaneous radial velocity is V_r , and the input rate is W_i . This force is perpendicular to both the input rate and the instantaneous radial velocity.

The two drive tines move in opposite directions, and the resultant forces are perpendicular to the plane of the fork assembly and in opposite directions. This produces a torque that is proportional to the

FIGURE 16.15 Magnetohydrodynamic angular rate sensor. (Courtesy: ATA Sensors, Albuquerque, NM.)

input rotational rate. Since the radial velocity is sinusoidal, the torque produced is also sinusoidal at the same frequency of the drive tines, and in-phase with the radial velocity of the tine.

The pickup tines, being the sensing portion of the sensor, respond to the oscillating torque by moving in and out of plane, producing a signal at the pickup amplifier. After amplification, those signals are demodulated into a dc signal that is proportional to the rotation of the sensor.

The output signal of the GyroChip™ reverses sign with the reversal of the input rate since the oscillating torque produced by the Coriolis effect reverses phase when the direction of rotation reverses. The GyroChip™ will generate a signal only with rotation about the axis of symmetry of the fork; that is, the only motion that will, by Coriolis sensing, produce an oscillating torque at the frequency of the drive tines. This also means that the GyroChip™ can truly sense a zero rate input.

MHD effect: The magnetohydrodynamic angular rate sensor is used to measure angular vibrations in the frequency range of 1 Hz to 1000 Hz. It is used where there is a high shock environment and a high rate of angular motion such as 10 to 250 rad s^{-1} . It does not measure a constant or dc velocity. It is used to measure impacts shorter than 1 s duration and vibrations between 1 Hz and 1000 Hz.

The principle of operation is illustrated in Figure 16.15 [17, 18]. A permanent magnet is attached to the outer case of the sensor. When the case turns, a moving magnetic field is produced (B). There is also a conductive fluid inside the sensor. When the sensor case turns, the fluid tends to stay in one place, according to Newton's first law. This produces a relative motion (U) between a magnetic field and conductor. This motion will produce a voltage (E) across the conductor proportional to relative velocity according to Faraday's law.

Since the fluid is constrained to move in an angular path, the voltage signal will be proportional to angular velocity about the center axis of the sensor. Due to this constraint, the sensor is insensitive to linear motion. The voltage signal is amplified through a transformer or an amplifier for output to a measuring device.

Fiber optic/laser: A beam of light is directed around the axis of rotation. A phase shift of the optical or laser beam is detected to measure angular velocity. The principle of operation is similar to the Doppler shift.

Differenced and integrated accelerometers: An array of accelerometers can be used to measure angular motion. The output of the accelerometers is differenced when they are aligned, or summed when they are mounted in opposite directions. This differencing will eliminate the linear component of motion. As shown in Figure 16.16, the magnitude of the differenced signals, a_1 and a_2 , is divided by the distance between the two sensors, l . This gives a measure of angular acceleration. The angular acceleration is integrated over time to give angular velocity. It is important to address the same concerns in this process as when integration was discussed in the linear section. It is assumed that there is a rigid mounting structure between the two accelerometers.

This technique is commonly applied to crash testing of anthropomorphic test devices (ATDs). The ATDs are used in automotive crash testing and aerospace egress system testing.

$$\omega = \int \frac{a_1 - a_2}{\ell} dt$$

FIGURE 16.16 Angular acceleration by differencing accelerometers and integration.

16.4 Conclusion

But alas, as Poincaré [20] stated, there is no way to determine absolute velocity.

Curtin University of Technology

Acceleration is measured by accelerometers as an important parameter for general-purpose absolute motion measurements, and vibration and shock sensing. Accelerometers are commercially available in a wide variety of ranges and types to meet diverse application requirements. They are manufactured small in size, light in weight, rugged, and robust to operate in harsh environment. They can be configured as active or passive sensors. An active accelerometer (e.g., piezoelectric) gives an output without the need for an external power supply, while a passive accelerometer only changes its electric properties (e.g., capacitance) and requires an external electrical power. In applications, the choice of active or passive type accelerometer is important, since active sensors cannot measure static or dc mode operations. For

FIGURE 17.1 A typical deflection-type seismic accelerometer. In this basic accelerometer, the seismic mass is suspended by a spring or cantilever inside a rigid frame. The frame is connected to the vibrating structure; as vibrations take place, the mass tends to remain fixed so that relative displacements can be picked up. They are manufactured in many different types and sizes and they exhibit diverse characteristics.

true static measurements, passive sensors must be used. In general, accelerometers are preferred over displacement and velocity sensors for the following reasons:

1. They have a wide frequency range from zero to very high values. Steady accelerations can easily be measured.
2. Acceleration is more frequently needed since destructive forces are often related to acceleration rather than to velocity or displacement.
3. Measurement of transients and shocks can readily be made, more easily than displacement or velocity sensing.
4. Displacement and velocity can be obtained by simple integration of acceleration by electronic circuitry. Integration is preferred over differentiation.

Accelerometers can be classified in a number of ways, such as *deflection* or *null-balance* types, mechanical or electrical types, dynamic or kinematic types. The majority of industrial accelerometers can be classified as either deflection type or null-balance type. Those used in vibration and shock measurements are usually the deflection types, whereas those used for measurements of motions of vehicles, aircraft, etc. for navigation purposes may be either type. In general, null-balance types are used when extreme accuracy is needed.

A large number of practical accelerometers are of the deflection type; the general configuration is shown in [Figure 17.1](#). There are many different deflection-type accelerometers. Although their principles of operation are similar, they only differ in minor details, such as the spring elements used, types of damping provided, and types of relative motion transducers employed. These types of accelerometers behave as second-order systems; the detailed mathematical analysis will be given in later sections.

Accelerometers can be classified as *dynamic*, meaning that the operation is based on measuring the force required to constrain a seismic mass to track the motion of the accelerated base, such as spring-constrained-slug types. Another type is the *kinematic* accelerometer, which is based on timing the passage of an unconstrained proof mass from spaced points marked on the accelerated base; this type is found in highly specific applications such as interspace spacecraft and in gravimetry type measurements.

For practical purposes, accelerometers can also be classified as *mechanical* or *electrical*, depending on whether the restoring force or other measuring mechanism is based on mechanical properties, (e.g., the law of motion, distortion of a spring or fluid dynamics, etc.) or on electrical or magnetic forces.

Calibrations of accelerometers are necessary in acceleration, vibration, and shock sensing. The calibration methods can broadly be classified to be *static* or *dynamic*. Static calibration is conducted at one

or several levels of constant acceleration. For example, if a tilting table calibration method is selected, the vertical component of the free fall is used without a choice of magnitude. On the other hand, if a centrifuge is selected, it produces a constant acceleration as a function of the speed of rotation, and the magnitudes can be chosen in a wide range from 0 to well over 50,000 g. The dynamic calibration is usually done using an electrodynamic shaker. The electrodynamic shaker is designed to oscillate in a sinusoidal motion with variable frequencies and amplitudes. They are stabilized at selected levels of calibration. This is an absolute method that consists of measuring the displacement with a laser interferometer and a precise frequency meter for accurate frequency measurements. The shaker must be driven by a power amplifier, thus giving a sinusoidal output with minimal distortion. The National Bureau of Standards uses this method as a reference standard. Precision accelerometers, mostly of the piezoelectric type, are calibrated by the absolute method and then used as the working standard. A preferred method is back-to-back calibration, where the test specimen is directly mounted on the working standard that, in turn, is mounted on an electrodynamic shaker.

Before providing details of different type of accelerometers, the common features such as accelerometer dynamics, velocity, distance, shock frequency responses, etc. will be introduced in the next section.

17.1 Accelerometer Dynamics: Frequency Response, Damping, Damping Ratio, and Linearity

This section concerns the physical properties of acceleration, vibration, and shock measurements in which accelerometers are commonly used. A full understanding of accelerometer dynamics is necessary in relation to characteristics of acceleration, vibration, and shock. The vibrations can be periodic, stationary random, nonstationary random, or transient.

Periodic Vibrations

In periodic vibrations, the motion of an object repeats itself in an oscillatory manner. This can be represented by a sinusoidal waveform:

$$x(t) = X_{\text{peak}} \sin(\omega t) \quad (17.1)$$

where $x(t)$ = time-dependent displacement
 $\omega = 2\pi f$ = angular frequency
 X_{peak} = maximum displacement from a reference point

The velocity of the object is the time rate of change of displacement:

$$u(t) = dx/dt = \omega X_{\text{peak}} \cos(\omega t) = U_{\text{peak}} \sin(\omega t + \pi/2) \quad (17.2)$$

where $u(t)$ = time-dependent velocity
 $U_{\text{peak}} = \omega X_{\text{peak}}$ = maximum velocity

The acceleration of the object is the time rate change of velocity:

$$a(t) = du/dt = d^2 x/dt^2 = -\omega^2 X_{\text{peak}} \sin(\omega t) = A_{\text{peak}} \sin(\omega t + \pi) \quad (17.3)$$

where $a(t)$ = time-dependent acceleration
 $A_{\text{peak}} = \omega^2 X_{\text{peak}} = \omega U_{\text{peak}}$ = maximum acceleration

FIGURE 17.2 Logarithmic relationship between acceleration, velocity, and displacement. Velocity at a particular frequency can be obtained by dividing acceleration by a factor proportional to frequency. For displacement, acceleration must be divided by a factor proportional to the square of the frequency. Phase angles need to be determined separately, but they can be neglected in time-averaged measurements.

From the above equations, it can be seen that the basic form and the period of vibration remains the same in acceleration, velocity, and displacement. But velocity leads displacement by a phase angle of 90° and acceleration leads velocity by another 90° . The amplitudes of the three quantities are related as a function of frequency, as shown in [Figure 17.2](#).

In nature, vibrations can be periodic but not necessarily sinusoidal. If they are periodic but nonsinusoidal, they can be expressed as a combination of a number of pure sinusoidal curves, described by Fourier analysis as:

$$x(t) = X_0 + X_1 \sin(\omega_1 t + \phi_1) + X_2 \sin(\omega_2 t + \phi_2) + \dots + X_n \sin(\omega_n t + \phi_n) \quad (17.4)$$

where $\omega_1, \omega_2, \dots, \omega_n$ = frequencies (rad s^{-1})

X_0, X_1, \dots, X_n = maximum amplitudes of respective frequencies

$\phi_1, \phi_2, \dots, \phi_n$ = phase angles

The number of terms may be infinite: the higher the number of elements, the better the approximation. These elements constitute the *frequency spectrum*. The vibrations can be represented in time domain or frequency domain, both of which are extremely useful in the analysis. As an example, in [Figure 17.3](#), the time response of the seismic mass of an accelerometer is given against a rectangular pattern of excitation of the base.

Stationary Random Vibrations

Random vibrations are often met in nature where they constitute irregular cycles of motion that never repeat themselves exactly. Theoretically, an infinitely long time record is necessary to obtain a complete description of these vibrations. However, statistical methods and probability theory can be used for the

FIGURE 17.3 Time response of a shock excitation of a single degree-of-freedom system. As the duration of the shock pulse increases, sustained oscillations get shorter in time but larger in amplitude. The maximum system response may be as high as twice the magnitude of the shock pulse.

analysis by taking representative samples. Mathematical tools such as probability distributions, probability densities, frequency spectra, cross- and auto-correlations, Digital Fourier Transforms (DFT), Fast Fourier Transforms (FFT), auto spectral analysis, RMS values, and digital filter analysis are some of the techniques that can be employed. Interested readers should refer to references for further information.

Transients and Shocks

Often, short-duration and sudden-occurrence vibrations need to be measured. Shock and transient vibrations may be described in terms of force, acceleration, velocity, or displacement. As in the case of random transients and shocks, statistical methods and Fourier Transforms are used in the analysis.

Nonstationary Random Vibrations

In this case, the statistical properties of vibrations vary in time. Methods such as time averaging and other statistical techniques can be employed. A majority of accelerometers described here can be viewed and analyzed as seismic instruments consisting of a mass, a spring, and a damper arrangement, as shown in Figure 17.1. Taking only the mass-spring system, if the system behaves linearly in a time invariant manner, the basic second-order differential equation for the motion of the mass alone under the influence of a force can be written as:

$$f(t) = m d^2 x / dt^2 + c dx / dt + kx \quad (17.5)$$

where $f(t)$ = force
 m = mass
 c = velocity constant
 k = spring constant

Nevertheless, in seismic accelerometers, the base of the arrangement is also in motion. Therefore, Equation 17.5 can be generalized by taking the effect motion of the base into account. Then, Equation 17.5 can be modified as:

$$m d^2 z / dt^2 + c dz / dt + kz = mg \cos(\theta) - m d^2 x_1 / dt^2 \quad (17.6)$$

where $z = x_2 - x_1 =$ the relative motion between the mass and the base

$x_1 =$ displacement of the base

$x_2 =$ displacement of the mass

$\theta =$ the angle between sense axis and gravity

In order to lay a background for further analysis, taking the simple case, the complete solution to Equation 17.5 can be obtained by applying the superposition principle. The superposition principle states that if there are simultaneously superimposed actions on a body, the total effect can be obtained by summing the effects of each individual action.

Equation 17.5 describes essentially a second-order system that can be expressed in Laplace transform as:

$$X(s)/F(s) = 1/ms^2 + cs + k \quad (17.7)$$

or

$$X(s)/F(s) = K/[s^2/\omega_n^2 + 2\zeta s/\omega_n + 1] \quad (17.8)$$

where $s =$ the Laplace operator

$K = 1/k =$ static sensitivity

$\omega_n = \sqrt{k/m} =$ undamped critical frequency, rad/s

$\zeta = c/2\sqrt{km} =$ damping ratio

As can be seen, in the performance of accelerometers, important parameters are the static sensitivity, the natural frequency, and the damping ratio, which are functions of mass, velocity, and spring constants. Accelerometers are designed to have different characteristics by suitable selection of these parameters.

Once the response is expressed in the form of Equations 17.7 and 17.8, analysis can be taken further, either in the time domain or in the frequency domain. The time response of a typical second-order system for a unit-step input is given in Figure 17.4. The Bode plot gain phase responses are depicted in Figure 17.5. Detailed discussions about frequency response, damping, damping ratio, and linearity are made in relevant sections, and further information can be obtained in the references.

Systems in which a single structure moves in more than one direction are termed *multi-degree-of-freedom systems*. In this case, the accelerations become functions of dimensions as d^2x/dt^2 , d^2y/dt^2 , and d^2z/dt^2 . Hence, in multichannel vibration tests, multiple transducers must be used to create uniaxial, biaxial, or triaxial sensing points for measurements. Mathematically, a linear multidegree-of-freedom system can be described by a set of coupled second-order linear differential equations; and when the frequency response is plotted, it normally shows one resonance peak per degree of freedom.

Frequently, acceleration and vibration measurements of thin plates or small masses are required. Attaching an accelerometer with a comparable mass onto a thin plate or a small test piece can cause "mass loading." Since acceleration is dependent on the mass, the vibration characteristics of the loaded test piece could be altered, thus yielding wrong measurements. In such cases, a correct interpretation of the results of the measuring instruments must be made. Some experimental techniques are also available for the correction of the test results in the form of performing repetitive tests conducted by sequentially adding small known masses and by observing the differences.

The following sections discuss different types of accelerometers.

17.2 Electromechanical Force-Balance (Servo) Accelerometers

Electromechanical accelerometers, essentially servo or null-balance types, rely on the principle of feedback. In these instruments, acceleration-sensitive mass is kept very close to a neutral position or zero displacement point by sensing the displacement and feeding back this displacement. A proportional

FIGURE 17.4 Unit step time responses of a second-order system with various damping ratios. The maximum overshoot, delay, rise, settling times, and frequency of oscillations depend on the damping ratio. Smaller damping ratios give faster response but larger overshoot. In many applications, a damping ratio of 0.707 is preferred.

magnetic force is generated to oppose the motion of the mass displaced from the neutral, thus restoring neutral position — just as a mechanical spring in a conventional accelerometer would do. The advantages of this approach are the better linearity and elimination of hysteresis effects as compared to mechanical springs. Also, in some cases, electric damping can be provided, which is much less sensitive to temperature variations.

One very important feature of null-balance type instruments is the capability of testing the static and dynamic performances of the devices by introducing electrically excited test forces into the system. This remote self-checking feature can be quite convenient in complex and expensive tests where it is extremely critical that the system operates correctly before the test commences. They are also useful in acceleration control systems, since the reference value of acceleration can be introduced by means of a proportional current from an external source. They are usually used for general-purpose motion measurements and monitoring low-frequency vibrations. They are specifically applied in measurements requiring better accuracy than achieved by those accelerometers based on mechanical springs as the force-to-displacement transducer.

There are a number of different types of electromechanical accelerometers: coil-and-magnetic types, induction types, etc.

Coil-and-Magnetic Type Accelerometers

These accelerometers are based on Ampere’s law; that is: “a current carrying conductor disposed within a magnetic field experiences a force proportional to the current, the length of the conductor within the field, the magnetic field density, and the sine of the angle between the conductor and the field.”

Figure 17.6 illustrates one form of accelerometer making use of the above principle. The coil is located within the cylindrical gap defined by a permanent magnet and a cylindrical soft iron flux return path. It is mounted by means of an arm situated on a minimum friction bearing so as to constitute an acceleration-sensitive seismic mass. A pick-off mechanism senses the displacement of the coil under

FIGURE 17.5 Bode plots of gains and phase angles against frequency of a second-order system. Curves are functions of frequencies as well as damping ratios. These plots can be obtained theoretically or by practical tests conducted in the frequency range.

acceleration and causes the coil to be supplied with a direct current via a suitable servo-controller to restore or maintain a null condition.

Assuming a downward acceleration with the field being radial (90°) and using Ampere's law, the force experienced by the coil may be written as:

$$F = ma = ilB \quad (17.9)$$

or the current

$$i = ma/lB \quad (17.10)$$

where B = the effective flux density

l = the total effective length of the conductor in the magnetic field

Current in the restoring circuit is linearly proportional to acceleration, provided: (1) armature reaction effects are negligible and fully neutralized by the compensating coil in opposition to the moving coil, and (2) the gain of the servo system is large enough to prevent displacement of the coil from the region in which the magnetic field is constant.

FIGURE 17.6 A basic coil and permanent magnet accelerometer. The coil is supported by an arm with minimum friction bearings to form a proof mass in a magnetic field. Displacement of the coil due to acceleration induces an electric potential in the coil to be sensed and processed. A servo system maintains the coil in a null position.

In these accelerometers, the magnetic structure must be shielded adequately to make the system insensitive to external disturbances or Earth's magnetic field. Also, in the presence of acceleration, there will be a temperature rise due to i^2R losses. The effect of these i^2R losses on the performance is determined by the thermal design and heat transfer properties of the accelerometer. In many applications, special care must be exercised in choosing the appropriate accelerometer such that the temperature rises caused by unexpected accelerations cannot affect excessively the scale factors or the bias conditions.

A simplified version of another type of servo-accelerometer is given in [Figure 17.7](#). The acceleration a of the instrument case causes an inertial force F on the sensitive mass m , tending to make it pivot in its bearings or flexure mount. The rotation θ from neutral is sensed by an inductive pickup and amplified, demodulated, and filtered to produce a current i_a directly proportional to the motion from the null. This current is passed through a precision stable resistor R to produce the output voltage signal and is applied to a coil suspended in a magnetic field. The current through the coil produces magnetic torque on the coil, which takes action to return the mass to neutral. The current required to produce magnetic torque that just balances the inertial torque due to acceleration is directly proportional to acceleration a . Therefore, the output voltage e_0 becomes a measure of acceleration a . Since a nonzero displacement θ is necessary to produce the current i_a , the mass is not exactly returned to null, but becomes very close to zero because of the high gain amplifier. Analysis of the block diagram reveals that:

$$e_0/R = (mra - e_0 K_c/R) \times (K_p K_a / K_s) / (s^2/\omega_{nl}^2 + 2\zeta_1 s/\omega_{nl} + 1) \quad (17.11)$$

Rearranging this expression gives:

$$mrRK_p K_a a / K_s = (s^2/\omega_{nl}^2 + 2\zeta_1 s/\omega_{nl} + 1 + K_c K_p K_a / K_s) e_0 \quad (17.12)$$

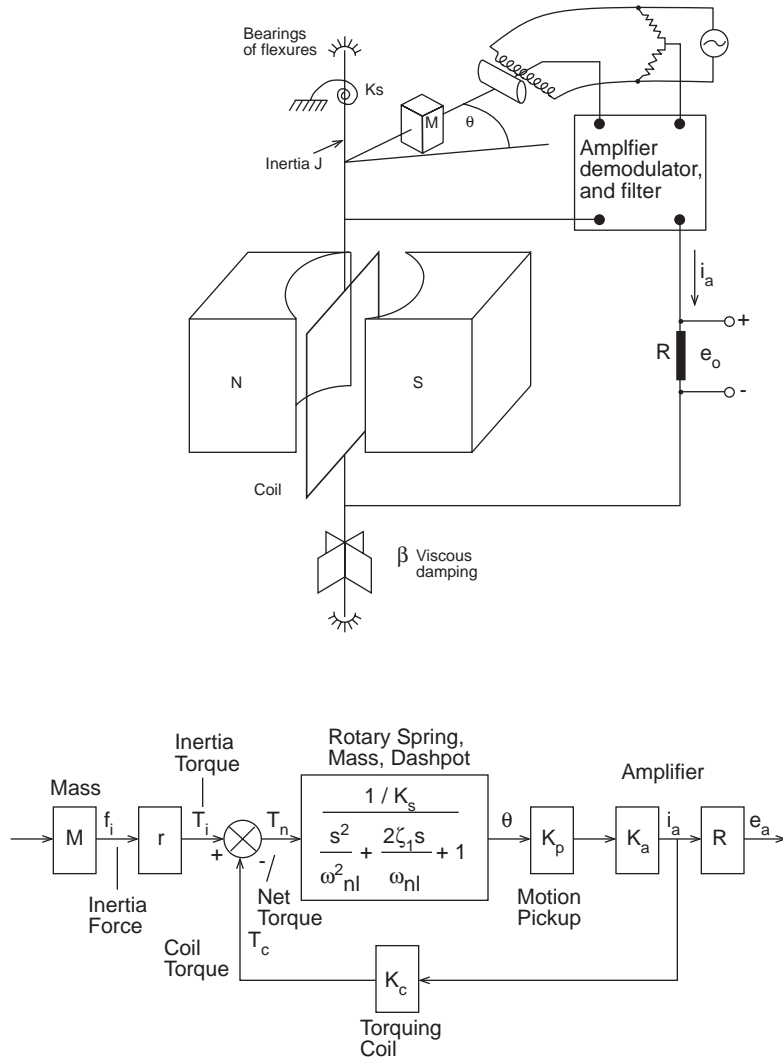

FIGURE 17.7 A simplified version of a rotational type servo-accelerometer. Acceleration of the instrument case causes an inertial force on the sensitive mass, tending to make it pivot in its bearings or flexure mount. The rotation from neutral is sensed by inductive sensing and amplified, demodulated, and filtered to produce a current directly proportional to the motion from the null. The block diagram representation is useful in analysis.

By designing the amplifier gain, K_a is made large enough so that $K_c K_p K_a a / K_s \gg 1.0$; then:

$$e_o / a (s) = K / \left(s^2 / \omega_{nl}^2 + 2\zeta_{nl} s / \omega_{nl} + 1 + K_c K_p K_a a / K_s \right) e_o \quad (17.13)$$

where

$$K \equiv MrR / K_c, \quad \left(V \, m^{-1} \, s^{-2} \right) \quad (17.14)$$

$$\omega_n \equiv \omega_{nl} \sqrt{K_c K_p K_a / K_s} \quad \text{rad/s} \quad (17.15)$$

$$\zeta \cong \zeta_1 / \sqrt{K_c K_p K_a / K_s} \quad (17.16)$$

Equation 17.14 shows that the sensitivity depends on the values of m , r , R , and K_c , all of which can be made constant. In this case, a high-gain feedback is useful in shifting the requirements for accuracy and stability from mechanical components to a selected few parameters where the requirements can easily be met. As in all feedback systems, the gain cannot be made arbitrarily high because of dynamic instability; however, a sufficiently high gain can be achieved to obtain good performance. An excellent comprehensive treatment of this topic is given by Doebelin, 1990; interested readers should refer to [3].

Induction Type Accelerometers

The cross-product relationship of current, magnetic field, and force gives the basis for induction type electromagnetic accelerometers, which are essentially generators rather than motors. One type of instrument, cup-and-magnet, includes a pendulous element with a pick-off and a servo-controller driving a tachometer coupling and a permanent magnet and a flux return ring, closely spaced with respect to an electrically conductive cylinder attached to the pendulous element. A rate proportional drag-force is obtained by electromagnetic induction effects between magnet and conductor. The pick-off senses pendulum deflection under acceleration and causes the servo-controller to turn the rotor in a sense to drag the pendulous element toward null. Under steady-state conditions, motor speed is a measure of the acceleration acting on the instrument. Stable servo operation is achieved employing a time-lead network to compensate the inertial time lag of the motor and magnet combination. The accuracy of servo type accelerometers is ultimately limited by consistency and stability of the scale factors of coupling devices and magnet-and-cup as a function of time and temperature.

Another accelerometer based on induction types is the *eddy current induction torque generation*. It was noted that the force-generating mechanism of an induction accelerometer consists of a stable magnetic field, usually supplied by a permanent magnet, which penetrates orthogonally through a uniform conduction sheet. The movement of the conducting sheet relative to the magnetic field in response to an acceleration results in a generated electromotive potential in each circuit in the conductor. This action is in accordance with the law of Faraday's principle. In induction-type accelerometers, the induced eddy currents are confined to the conductor sheet, making the system essentially a drag coupling.

A typical commercial instrument based on the servo-accelerometer principle might have a micromachined quartz flexure suspension, differential capacitance angle pick-off, air squeeze film, plus servo lead compensation for system damping. Of the various available models, a 30 g range unit has threshold and resolution of 1 μg , frequency response flat within 0.05% at 10 Hz and 2% at 100 Hz, natural frequency 500 Hz, damping ratio 0.3 to 0.8, and transverse or cross-axis sensitivity 0.1%. If, for example, the output current is about 1.3 mA g^{-1} and a 250 Ω readout resistor would give about ± 10 V full scale at 30 g. These accelerometers are good with respect to precision, and are used in many applications, such as aircraft and missile control systems, the measurement of tilt angles, axle angular bending in weight and balance systems, etc.

17.3 Piezoelectric Accelerometers

Piezoelectric accelerometers are used widely for general-purpose acceleration, shock, and vibration measurements. They basically are motion transducers with large output signals and comparatively small sizes. They are available with very high natural frequencies and are therefore suitable for high-frequency applications and shock measurements.

These devices utilize a mass in direct contact with the piezoelectric component, or crystal, as shown in Figure 17.8. When a varying motion is applied to the accelerometer, the crystal experiences a varying force excitation ($F = ma$), causing a proportional electric charge q to be developed across it.

FIGURE 17.8 A compression-type piezoelectric accelerometer. The crystals are under compression at all times, either by a mass or mass and spring arrangement. Acceleration causes a deformation of the crystal, thus producing a proportional electric signal. They are small in size and widely used. They demonstrate poor performance at low frequencies.

$$q = d_{ij} F = d_{ij} ma \quad (17.17)$$

where q = the charge developed
 d_{ij} = the material's piezoelectric coefficient

As Equation 17.17 shows, the output from the piezoelectric material is dependent on its mechanical properties, d_{ij} . Two commonly used piezoelectric crystals are lead-zirconate titanate ceramic (PZT) and quartz. They are both self-generating materials and produce a large electric charge for their size. The piezoelectric strain constant of PZT is about 150 times that of quartz. As a result, PZTs are much more sensitive and smaller in size than their quartz counterparts. In the accelerometers, the mechanical spring constants for the piezoelectric components are high, and the inertial masses attached to them are small. Therefore, these accelerometers are useful for high frequency applications. Figure 17.9 illustrates a typical frequency response for a PZT device. Since piezoelectric accelerometers have comparatively low mechanical impedances, their effects on the motion of most structures is negligible. They are also manufactured to be rugged and they have outputs that are stable with time and environment.

Mathematically, their transfer function approximates to a third-order system as:

$$e_0(s)/a(s) = (K_q/C\omega_n^2)\tau s / \left[(\tau s + 1) \left(s^2/\omega_n^2 + 2\zeta s/\omega_n + 1 \right) \right] \quad (17.18)$$

where K_q = the piezoelectric constant related to charge (C cm)
 τ = the time constant of the crystal

It is worth noting that the crystal itself does not have a time constant τ , but the time constant is observed when the accelerometer is connected into an electric circuit (e.g., an RC circuit).

The low-frequency response is limited by the piezoelectric characteristic $\tau s/(\tau s + 1)$, while the high-frequency response is related to mechanical response. The damping factor ζ is very small, usually less than 0.01 or near zero. Accurate low-frequency response requires large τ , which is usually achieved by

FIGURE 17.9 Frequency response of a typical piezoelectric accelerometer. Measurements are normally confined to the linear portion of the response curve. The upper frequency of the accelerometer is limited by the resonance of the PZT crystal. The phase angle is constant up to the resonance frequency.

the use of high-impedance voltage amplifiers. At very low frequencies, thermal effects can have severe influences on the operation characteristics.

In piezoelectric accelerometers, two basic design configurations are used: compression types and shear stress types. In compression-type accelerometers, the crystal is held in compression by a preload element; therefore, the vibration varies the stress in compressed mode. In the shear accelerometer, vibration simply deforms the crystal in shear mode. The compression type has a relatively good mass/sensitivity ratio and hence exhibits better performance. But, since the housing acts as an integral part of the spring mass system, it may produce spurious interfaces in the accelerometer output, if excited in its proper natural frequency.

Microelectronic circuits have allowed the design of piezoelectric accelerometers with charge amplifiers and other signal conditioning circuits built into the instrument housing. This arrangement allows greater sensitivity, high-frequency response, and smaller size accelerometers, thus lowering the initial and implementation costs.

Piezoelectric accelerometers are available in a wide range of specifications and are offered by a large number of manufacturers. For example, the specifications of a shock accelerometer may have 0.004 pC g^{-1} in sensitivity and a natural frequency of up to 250,000 Hz, while a unit designed for low-level seismic measurements might have 1000 pC g^{-1} in sensitivity and only 7000 Hz natural frequency. They are manufactured as small as $3 \times 3 \text{ mm}$ in dimensions with about 0.5 g in mass, including cables. They have excellent temperature ranges, and some of them are designed to survive intensive radiation environment of nuclear reactors. However, piezoelectric accelerometers tend to have larger cross-axis sensitivity than other types; about 2% to 4%. In some cases, large cross-axis sensitivity can be used during installation for the correct orientation of the device. These accelerometers can be mounted with threaded studs, with cement or wax adhesives, or with magnetic holders.

FIGURE 17.10 Bonding of piezoelectric and piezoresistive elements onto an inertial system. As the inertial member vibrates, deformation of the tension and compression gages causes the resistance to change. The change in resistance is picked up and processed further. Accelerometers based on PZTs are particularly useful in medium- to high-frequency applications.

17.4 Piezoresistive Accelerometers

Piezoresistive accelerometers are essentially semiconductor strain gages with large gage factors. High gage factors are obtained because the material resistivity is dependent primarily on the stress, not only on dimensions. The increased sensitivity is critical in vibration measurement because it allows the miniaturization of the accelerometer. Most piezoresistive accelerometers use two or four active gages arranged in a Wheatstone bridge. Extra-precision resistors are used, as part of the circuit, in series with the input to control the sensitivity, balancing, and offsetting temperature effects. The mechanical construction of a piezoresistive accelerometer is shown in [Figure 17.10](#).

In some applications, overload stops are necessary to protect the gages from high-amplitude inputs. These instruments are useful for acquiring vibration information at low frequencies (e.g., below 1 Hz). In fact, the piezoresistive sensors are inherently true static acceleration measurement devices. Typical characteristics of piezoresistive accelerometers may be 100 mV g⁻¹ in sensitivity, 0 to 750 Hz in frequency range, 2500 Hz in resonance frequency, 25 g in amplitude range, 2000 g in shock rating, 0 to 95°C in temperature range, with a total mass of about 25 g.

17.5 Differential-Capacitance Accelerometers

Differential-capacitance accelerometers are based on the principle of change of capacitance in proportion to applied acceleration. They come in different shapes and sizes. In one type, the seismic mass of the accelerometer is made as the movable element of an electrical oscillator as shown in [Figure 17.11](#). The seismic mass is supported by a resilient parallel-motion beam arrangement from the base. The system is characterized to have a certain defined nominal frequency when undisturbed. If the instrument is accelerated, the frequency varies above and below the nominal value, depending on the direction of acceleration.

FIGURE 17.11 A typical differential capacitive accelerometer. The proof mass is constrained in its null position by a spring. Under acceleration, variable frequencies are obtained in the electric circuit. In a slightly different version, the proof mass may be constrained by an electrostatic-feedback-force, thus resulting in convenient mechanical simplicity.

The seismic mass carries an electrode located in opposition to a number of base-fixed electrodes that define variable capacitors. The base-fixed electrodes are resistance coupled in the feedback path of a wide-band, phase-inverting amplifier. The gain of the amplifier is made of such a value to ensure maintenance of oscillations over the range of variation of capacitance determined by the applied acceleration. The value of the capacitance C for each of the variable capacitor is given by:

$$C = \epsilon k S / h \quad (17.19)$$

where k = dielectric constant
 ϵ = capacitivity of free space
 S = area of electrode
 h = variable gap

Denoting the magnitude of the gap for zero acceleration as h_0 , the value of h in the presence of acceleration a may be written as:

$$h = h_0 + ma / K \quad (17.20)$$

where m = the value of the proof mass and K is the spring constant. Thus,

$$C = \epsilon k S / (h_0 + ma / K) \quad (17.21)$$

If, for example, the frequency of oscillation of the resistance-capacitance type circuit is given by the expression:

$$f = \sqrt{6} / 2\pi RC \quad (17.22)$$

Substituting this value of C in Equation 17.21 gives:

$$f = \left(h_0 + ma/K \right) \sqrt{6/2\pi R\epsilon kS} \quad (17.23)$$

Denoting the constant quantity $(\sqrt{6/2\pi R\epsilon kS})$ as B and rewriting Equation 17.23 gives:

$$f = Bh_0 + Bma/K \quad (17.24)$$

The first term on the right-hand side expresses the fixed bias frequency f_0 , and the second term denotes the change in frequency resulting from acceleration, so that the expression may be written as:

$$f = f_0 + f_a \quad (17.25)$$

If the output frequency is compared with an independent source of constant frequency f_0 , f_a can be determined.

A commonly used example of a capacitive-type accelerometer is based on a thin diaphragm with spiral flexures that provide the spring, proof mass, and moving plate necessary for the differential capacitor, as shown in [Figure 17.12](#). Plate motion between the electrodes pumps air parallel to the plate surface

FIGURE 17.12 Diaphragm-type capacitive accelerometer. The seismic element is cushioned between the electrodes. Motion of the mass between the electrodes causes air movement passing through the holes, which provides a squeeze film damping. In some cases, oil can be used as the damping element.

and through holes in the plate to provide squeeze film damping. Since air viscosity is less temperature sensitive than oil, the desired damping ratio of 0.7 hardly changes more than 15%. A family of such instruments are readily available, having full-scale ranges from ± 0.2 g (4 Hz flat response) to ± 1000 g (3000 Hz), cross-axis sensitivity less than 1%, and full-scale output of ± 1.5 V. The size of a typical device is about 25 mm^3 with a mass of 50 g.

17.6 Strain-Gage Accelerometers

Strain gage accelerometers are based on resistance properties of electrical conductors. If a conductor is stretched or compressed, its resistance alters due to two reasons: dimensional changes and the changes in the fundamental property of material called *piezoresistance*. This indicates that the resistivity ρ of the conductor depends on the mechanical strain applied onto it. The dependence is expressed as the gage factor

$$\left(\frac{dR}{R}\right)/\left(\frac{dL}{L}\right) = 1 + 2\nu + \left(\frac{d\rho}{\rho}\right)/\left(\frac{dL}{L}\right) \quad (17.26)$$

where 1 = resistance change due to length
 2ν = resistance change due to area
 $(d\rho/\rho)/(dL/L)$ = resistance change due to piezoresistivity

In acceleration measurements, the resistance strain gages can be selected from different types, including unbonded metal-wire gages, bonded metal-wire gages, bonded metal-foil gages, vacuum-deposited thin-metal-film gages, bonded semiconductor gages, diffused semiconductor gages, etc. But, usually, bonded and unbonded metal-wire gages find wider applications in accelerometers. Occasionally, bonded semiconductor gages, known as piezoresistive transducers, are used but suffer from high-temperature sensitivities, nonlinearity, and some mounting difficulties. Nevertheless, in recent years, they have found new application areas with the development of micromachine transducer technology, which is discussed in detail in the micro-accelerometer section.

Unbonded-strain-gage accelerometers use the strain wires as the spring element and as the motion transducer, using similar arrangements as in Figure 17.10. They are useful for general-purpose motion and vibration measurements from low to medium frequencies. They are available in wide ranges and characteristics, typically ± 5 g to ± 200 g full scale, natural frequency 17 Hz to 800 Hz, 10 V excitation voltage ac or dc, full-scale output ± 20 mV to ± 50 mV, resolution less than 0.1%, inaccuracy less than 1% full scale, and cross-axis sensitivity less than 2%. Their damping ratio (using silicone oil damping) is 0.6 to 0.8 at room temperature. These instruments are small and lightweight, usually with a mass of less than 25 g.

Bonded-strain-gage accelerometers generally use a mass supported by a thin flexure beam. The strain gages are cemented onto the beam to achieve maximum sensitivity, temperature compensation, and sensitivity to both cross-axis and angular accelerations. Their characteristics are similar to unbonded-strain gage accelerometers, but have larger sizes and weights. Often, silicone oil is used for damping. Semiconductor strain gages are widely used as strain sensors in cantilever-beam/mass types of accelerometers. They allow high outputs (0.2 V to 0.5 V full scale). Typically, a ± 25 g acceleration unit has a flat response from 0 Hz to 750 Hz, a damping ratio of 0.7, a mass of 28 g, and an operational temperature of -18°C to $+93^\circ\text{C}$. A triaxial $\pm 20,000$ g model has flat response from 0 kHz to 15 kHz, a damping ratio 0.01, a compensation temperature range of 0°C to 45°C , $13 \times 10 \times 13$ mm in size, and 10 g in mass.

17.7 Seismic Accelerometers

These accelerometers make use of a seismic mass that is suspended by a spring or a lever inside a rigid frame. The schematic diagram of a typical instrument is shown in Figure 17.1. The frame carrying the

seismic mass is connected firmly to the vibrating source whose characteristics are to be measured. As the system vibrates, the mass tends to remain fixed in its position so that the motion can be registered as a relative displacement between the mass and the frame. This displacement is sensed by an appropriate transducer and the output signal is processed further. Nevertheless, the seismic mass does not remain absolutely steady; but for selected frequencies, it can satisfactorily act as a reference position.

By proper selection of mass, spring, and damper combinations, the seismic instruments may be used for either acceleration or displacement measurements. In general, a large mass and soft spring are suitable for vibration and displacement measurements, while a relatively small mass and stiff spring are used in accelerometers.

The following equation may be written by using Newton's second law of motion to describe the response of seismic arrangements similar to shown in Figure 17.1.

$$m d^2 x_2 / dt^2 + c dx_2 / dt + k x_2 = c dx_1 / dt + k x_1 + mg \cos(\theta) \quad (17.27)$$

where x_1 = the displacement of the vibration frame

x_2 = the displacement of the seismic mass

c = velocity constant

k = spring constant

Taking $m d^2 x_1 / dt^2$ from both sides of the equation and rearranging gives:

$$m d^2 z / dt^2 + c dz / dt + kz = mg \cos(\theta) - m d^2 x_1 / dt^2 \quad (17.28)$$

where $z = x_2 - x_1$ is the relative motion between the mass and the base

θ = the angle between sense axis and gravity

In Equation 17.27, it is assumed that the damping force on the seismic mass is proportional to velocity only. If a harmonic vibratory motion is impressed on the instrument such that:

$$x_1 = x_0 \sin \omega_1 t \quad (17.29)$$

where ω_1 is the frequency of vibration, in rad s⁻¹.

Writing

$$m d^2 x_1 / dt^2 = m x_0 \omega_1^2 \sin \omega_1 t$$

modifies Equation 17.28 as:

$$m d^2 z / dt^2 + c dz / dt + kz = mg \cos(\theta) + m a_1 \sin \omega_1 t \quad (17.30)$$

where $a_1 = m x_0 \omega_1^2$

Equation 17.30 will have transient and steady-state solutions. The steady-state solution of the differential Equation 17.30 can be determined as:

$$z = \left[mg \cos(\theta) / k \right] + \left[m a_1 \sin \omega_1 t / (k - m \omega_1^2 + j c \omega_1) \right] \quad (17.31)$$

Rearranging Equation 17.31 results in:

FIGURE 17.13 A typical displacement of a seismic instrument. Amplitude becomes large at low damping ratios. The instrument constants should be selected such that, in measurements, the frequency of vibration is much higher than the natural frequency (e.g., greater than 2). Optimum results are obtained when the value of instrument constant c/c_c is about 0.7.

$$z = \left[mg \cos(\theta) / \omega_m \right] + \left\{ a_1 \sin(\omega_1 - \phi) / \left[\omega_m^2 (1 - r^2)^2 + (2\zeta r)^2 \right]^{1/2} \right\} \quad (17.32)$$

where $\omega_n = \sqrt{k/m}$ = the natural frequency of the seismic mass

$\zeta = c/2\sqrt{km}$ = the damping ratio, also can be written in terms of critical damping ratio as $\zeta = c/c_c$, where ($c_c = 2\sqrt{km}$)

$\phi = \tan^{-1}(c\omega_1/(k - m\omega_1^2))$ = the phase angle

$r = \omega_1/\omega_n$ = the frequency ratio

A plot of Equation 17.32, $(x_1 - x_2)_0/x_0$ against frequency ratio ω_1/ω_n , is illustrated in [Figure 17.13](#). This figure shows that the output amplitude is equal to the input amplitude when $c/c_c = 0.7$ and $\omega_1/\omega_n > 2$. The output becomes essentially a linear function of the input at high frequency ratios. For satisfactory system performance, the instrument constant c/c_c and ω_n should carefully be calculated or obtained from calibrations. In this way, the anticipated accuracy of measurement can be predicted for frequencies of interest. A comprehensive treatment of the analysis is given by McConnell [1].

If the seismic instrument has a low natural frequency and a displacement sensor is used to measure the relative motion z , then the output is proportional to the displacement of the transducer case. If the velocity sensor is used to measure the relative motion, the signal is proportional to the velocity of the transducer. This is valid for frequencies significantly above the natural frequency of the transducer. However, if the instrument has a high natural frequency and the displacement sensor is used, the measured output is proportional to the acceleration:

$$kz = m d^2 x_1 / dt^2 \quad (17.33)$$

This equation is true since displacement x_2 becomes negligible in comparison to x_1 .

FIGURE 17.14 A potentiometer accelerometer. The relative displacement of the seismic mass is sensed by a potentiometer arrangement. The potentiometer adds extra weight, making these accelerometers relatively heavier. Suitable liquids filling the frame can be used as damping elements. These accelerometers are used in low-frequency applications.

In these instruments, the input acceleration a_0 can be calculated by simply measuring $(x_1 - x_2)_0$. Generally, in acceleration measurements, unsatisfactory performance is observed at frequency ratios above 0.4. Thus, in such applications, the frequency of acceleration must be kept well below the natural frequency of the instrument. This can be accomplished by constructing the instrument to have a low natural frequency by selecting soft springs and large masses.

Seismic instruments are constructed in a variety of ways. Figure 17.14 illustrates the use of a voltage divider potentiometer for sensing the relative displacement between the frame and the seismic mass. In the majority of potentiometric instruments, the device is filled with a viscous liquid that interacts continuously with the frame and the seismic mass to provide damping. These accelerometers have low frequency of operation (less than 100 Hz) and are mainly intended for slow varying acceleration and low-frequency vibrations. A typical family of such instrument offers many different models, covering the range of ± 1 g to ± 50 g full scale. The natural frequency ranges from 12 Hz to 89 Hz, and the damping ratio ζ can be kept between 0.5 to 0.8 using a temperature-compensated liquid damping arrangement. Potentiometer resistance can be selected in the range of 1000 Ω to 10,000 Ω , with corresponding resolution of 0.45% to 0.25% of full scale. The cross-axis sensitivity is less than $\pm 1\%$. The overall accuracy is $\pm 1\%$ of full scale or less at room temperatures. The size is about 50 mm³; with a mass of about 1/2 kg.

Linear variable differential transformers (LVDT) offer another convenient means to measure the relative displacement between the seismic mass and the accelerometer housing. These devices have higher natural frequencies than potentiometer devices, up to 300 Hz. Since the LVDT has lower resistance to the motion, it offers much better resolution. A typical family of liquid-damped differential-transformer accelerometers exhibits the following characteristics: full scale range from ± 2 g to ± 700 g, natural frequency from 35 Hz to 620 Hz, nonlinearity 1% of full scale, the full scale output is about 1 V with an LVDT excitation of 10 V at 2000 Hz, damping ratio 0.6 to 0.7, residual voltage at null is less than 1%, and hysteresis less than 1% full scale; the size is 50 mm³, with a mass of about 120 g.

Electric resistance strain gages are also used for displacement sensing of the seismic mass as shown in Figure 17.15. In this case, the seismic mass is mounted on a cantilever beam rather than on springs. Resistance strain gages are bonded on each side of the beam to sense the strain in the beam resulting from the vibrational displacement of the mass. Damping for the system is provided by a viscous liquid that entirely fills the housing. The output of the strain gages is connected to an appropriate bridge circuit. The natural frequency of such a system is about 300 Hz. The low natural frequency is due to the need for a sufficiently large cantilever beam to accommodate the mounting of the strain gages. Other types of seismic instruments using piezoelectric transducers and seismic masses are discussed in detail in the section dedicated to piezoelectric-type accelerometers.

FIGURE 17.15 A strain gage seismic instrument. The displacement of the proof mass is sensed by piezoresistive strain gages. The natural frequency of the system is low, due to the need of a long lever beam to accommodate strain gages. The signal is processed by bridge circuits.

Seismic vibration instruments are affected seriously by the temperature changes. Devices employing variable resistance displacement sensors will require correction factors to account for resistance change due to temperature. The damping of the instrument may also be affected by changes in the viscosity of the fluid due to temperature. For example, the viscosity of silicone oil, often used in these instruments, is strongly dependent on temperature. One way of eliminating the temperature effect is by using an electrical resistance heater in the fluid to maintain the temperature at a constant value regardless of surrounding temperatures.

17.8 Inertial Types, Cantilever, and Suspended-Mass Configuration

There are a number of different inertial accelerometers, including gyropendulum, reaction-rotor, vibrating string, and centrifugal-force-balance types. In many of them, the force required to constrain the mass in the presence of the acceleration is supplied by an inertial system.

A vibrating string type instrument, [Figure 17.16](#), makes use of proof mass supported longitudinally by a pair of tensioned, transversely vibrating strings with uniform cross-section, and equal lengths and masses. The frequency of vibration of the strings is set to several thousand cycles per second. The proof mass is supported radially in such a way that the acceleration normal to strings does not affect the string tension. In the presence of acceleration along the sensing axis, a differential tension exists on the two strings, thus altering the frequency of vibration. From the second law of motion, the frequencies can be written as:

$$f_1^2 = T_1 / (4m_s l) \quad \text{and} \quad f_2^2 = T_2 / (4m_s l) \quad (17.34)$$

where T is the tension, and m_s and l are the masses and lengths of strings, respectively.

Quantity $(T_1 - T_2)$ is proportional to ma , where a is the acceleration along the axis of the strings. An expression for the difference of the frequency-squared terms may be written as:

$$f_1^2 - f_2^2 = (T_1 - T_2) / (4m_s l) = ma / (4m_s l) \quad (17.35)$$

Hence,

$$f_1 - f_2 = ma / [(f_1 + f_2) 4m_s l] \quad (17.36)$$

FIGURE 17.16 A vibrating string accelerometer. A proof mass is attached to two strings of equal mass and length and supported radially by suitable bearings. The vibration frequencies of strings are dependent on the tension imposed by the acceleration of the system in the direction of the sensing axis.

The sum of frequencies ($f_1 + f_2$) can be held constant by servoing the tension in the strings with reference to the frequency of a standard oscillator. Then, the difference between the frequencies becomes linearly proportional to acceleration. In some versions, the beam-like property of the vibratory elements is used by gripping them at nodal points corresponding to the fundamental mode of vibration of the beam. Improved versions of these devices lead to cantilever-type accelerometers, as discussed next.

In cantilever-type accelerometers, a small cantilever beam mounted on the block is placed against the vibrating surface, and an appropriate mechanism is provided for varying the beam length. The beam length is adjusted such that its natural frequency is equal to the frequency of the vibrating surface — hence the resonance condition obtained. Slight variations of cantilever beam-type arrangements are finding new applications in microaccelerometers.

In a different type suspended mass configuration, a pendulum is used that is pivoted to a shaft rotating about a vertical axis. Pick-offs are provided for the pendulum and the shaft speed. The system is servo-controlled to maintain it at null position. Gravitational acceleration is balanced by the centrifugal acceleration. Shaft speed is proportional to the square root of the local value of the acceleration.

All inertial force accelerometers described above have the property of absolute instruments. That is, their scale factors can be predetermined solely by establishing mass, length, and time quantities, as distinguished from voltage, spring stiffness, etc.

17.9 Electrostatic Force Feedback Accelerometers

Electrostatic accelerometers are based on Coulomb's law between two charged electrodes. They measure the voltage in terms of force required to sustain a movable electrode of known area, mass, and separation from an affixed electrode. The field between the electrodes is given by:

$$E = Q/\epsilon kS \quad (17.37)$$

where E is the intensity or potential gradient (dV/dx), Q is charge, S area of the conductor, and k is the dielectric constant of the space outside the conductor.

Using this expression, it can be shown that the force per unit area of the charged conductor (in N m^{-2}) is given by:

$$F/S = Q^2/(2\epsilon kS^2) = \epsilon kE^2/2 \quad (17.38)$$

In an electrostatic-force-feedback-type accelerometer (similar in structure to that in Figure 17.10), an electrode of mass m and area S is mounted on a light pivoted arm for moving relative to the fixed electrodes. The nominal gap, h , between the pivoted and fixed electrodes is maintained by means of a force balancing servo system capable of varying the electrode potential in response to signals from a pick-off that senses relative changes in the gaps.

Considering one movable electrode and one stationary electrode, and assuming that the movable electrode is maintained at a bias potential V_1 and the stationary one at a potential V_2 , the electrical intensity E in the gap can be expressed as:

$$E_1 = (V_1 - V_2)/h \quad (17.39)$$

so that the force of attraction may be found as:

$$F_1 = \epsilon kE^2S/(2h^2) = \epsilon k(V_1 - V_2)^2 S/(2h^2) \quad (17.40)$$

In the presence of acceleration, if V_2 is adjusted to restrain the movable electrode to null position; the expression relating acceleration and electrical potential may be given by:

$$a = F_1/m = \epsilon k(V_1 - V_2)^2 S/(2h^2 m) \quad (17.41)$$

The device thus far described can measure acceleration in one direction only, and the output is of quadratic character; that is:

$$(V_1 - V_2) = D \sqrt{a} \quad (17.42)$$

where D = the constant of proportionality.

The output can be linearized in a number of ways; for example, by quarter-square method. If the servo controller applies a potential $-V_2$ to other fixed electrode, the force of attraction between this electrode and the movable electrode becomes:

$$a = F_1/m = \epsilon k(V_1 + V_2)^2 S/(2h^2 m) \quad (17.43)$$

and the force balance equation of the movable electrode when the instrument experiences a downward acceleration a is:

$$ma = F_1 - F_2 = \left[(V_1 + V_2)^2 - (V_1 - V_2)^2 \right] \epsilon k S / (2h^2 m)$$

or

$$= \epsilon k S (4V_1 V_2) / (2h^2 m) \quad (17.44)$$

Hence, if the bias potential V_1 is held constant and the gain of the control loop is high so that variations in the gap are negligible, the acceleration becomes a linear function of the controller output voltage V_2 as:

$$a = V_2 \left[\epsilon k S (2V_1) / (h^2 m) \right] \quad (17.45)$$

The principal difficulty in mechanizing the electrostatic force accelerometer is the relatively high electric field intensity required to obtain adequate force. Also, extremely good bearings are necessary. Damping can be provided electrically, or by viscosity of gaseous atmosphere in the interelectrode space if the gap h is sufficiently small.

The main advantages of the electrostatic accelerometers include extreme mechanical simplicity, low power requirements, absence of inherent sources of hysteresis errors, zero temperature coefficients, and ease of shielding from stray fields.

17.10 Microaccelerometers

By the end of the 1970s, it became apparent that the essentially planar processing IC (integrated circuit) technology could be modified to fabricate three-dimensional electromechanical structures, called micromachining. Accelerometers and pressure sensors were among the first IC sensors. The first accelerometer was developed in 1979. Since then, technology has been progressing steadily to the point where an extremely diverse range of accelerometers is readily available. Most sensors use bulk micromachining rather than surface micromachining techniques. In bulk micromachining, the flexures, resonant beams, and all other critical components of the accelerometer are made from bulk silicon in order to exploit the full mechanical properties of single-crystal silicon. With proper design and film process, bulk micromachining yields an extremely stable and robust accelerometer.

The selective etching of multiple layers of deposited thin films, or surface micromachining, allows movable microstructures to be fabricated on silicon wafers. With surface micromachining, layers of structure material are disposed and patterned, as shown in [Figure 17.17](#). These structures are formed by polysilicon and a sacrificial material such as silicon dioxide. The sacrificial material acts as an intermediate spacer layer and is etched away to produce a free-standing structure. Surface machining technology also allows smaller and more complex structures to be built in multiple layers on a single substrate.

The operational principles of microaccelerometers are very similar to capacitive force-balance-type accelerometers or vibrating beam types, as discussed earlier. Nevertheless, manufacturing techniques may change from one manufacturer to another. In general, vibrating beam accelerometers are preferred because of better air gap properties and improved bias performance characteristics.

The vibrating beam accelerometers, also called resonant beam force transducers, are made in such a way that an acceleration along a positive input axis places the vibrating beam in tension. Thus, the resonant frequency of the vibrating beam increases or decreases with the applied acceleration. A mechanically coupled beam structure, also known as a double-ended tuning fork (DETF), is shown in [Figure 17.18](#).

FIGURE 17.17 Steps of surface micromachining. The acceleration-sensitive, three-dimensional structure is formed on a substrate and a sacrificial element. The sacrificial element is etched to leave a free-standing structure. The spacing between the structure and substrate is about $2\ \mu\text{m}$.

FIGURE 17.18 A double-ended tuning fork (DETF) acceleration transducer. Two beams are vibrated 180° out of phase to eliminate reaction forces at the beam ends. The resonant frequency of the beam is altered by acceleration. The signal processing circuits are also integrated in the same chip.

In DETF, an electronic oscillator capacitively couples energy into two vibrating beams to keep them oscillating at their resonant frequency. The beams vibrate 180° out of phase to cancel reaction forces at the ends. The dynamic cancellation effect of the DETF design prevents energy from being lost through the ends of the beam. Hence, the dynamically balanced DETF resonator has a high Q factor, which leads to a stable oscillator circuit. The acceleration signal is an output from the oscillator as a frequency-modulated square wave that can be used for digital interface.

The frequency of resonance of the system must be much higher than any input acceleration and this limits the measurable range. In a typical military micromachine accelerometer, the following characteristics

are given: range ± 1200 g, sensitivity 1.11 Hz g^{-1} , bandwidth 2500 Hz, unloaded DETF frequency 9952 Hz, frequency at $+1200$ g is 11221 Hz, frequency at -1200 g is 8544 Hz, the temperature sensitivity $5 \text{ mg } ^\circ\text{C}$. Accelerometer size is 6 mm diameter \times 4.3 mm length, with a mass of about 9 g, and it has a turn on time less than 60 s. The accelerometer is powered with +9 to +16 V dc and the nominal output is a 9000 Hz square wave.

Surface micromachining has also been used to manufacture specific application accelerometers, such as air-bag applications in automotive industry. In one type, a three-layer differential capacitor is created by alternate layers of polysilicon and phosphosilicate glass (PSG) on a 0.38 mm thick and 100 mm long wafer. A silicon wafer serves as the substrate for the mechanical structure. The trampoline-shaped middle layer is suspended by four supporting arms. This movable structure is the seismic mass for the accelerometer. The upper and lower polysilicon layers are fixed plates for the differential capacitors. The glass is sacrificially etched by hydrofluoric acid.

17.11 Cross-Axis Sensitivity

A vibrational structure may have been subjected to different forms of vibrations, such as compressional, torsional, transverse, etc.; or a combination of all these vibrations may take place simultaneously, which makes the analysis and measurements difficult and complex. It was discussed earlier that the differential equations governing the vibrational motion of a structure were dependent on the number of degrees of freedom, which can be described as a function of the space coordinates $f(x, y, z, t)$. For example, the transverse vibrations of structures may be a fourth-order differential equation.

Fortunately, most common acceleration and vibration measurements are simple in nature, being either compressional or torsional types. They can easily be expressed as second-order differential equations, as explained in the frequency response section. However, during measurements, most accelerometers are affected by transverse vibrations and their sensitivity can play a major role in the accuracy of the measurements.

The transverse, also known as cross-axis sensitivity, of an accelerometer is its response to acceleration in a plane perpendicular to the main accelerometer axis, as shown in [Figure 17.19](#). The cross-axis sensitivity is normally expressed in percent of the main axis sensitivity and should be as low as possible. There is not a single value of cross-axis sensitivity, but it varies depending on the direction. The direction of minimum sensitivity is usually supplied by the manufacturer.

The measurement of the maximum cross-axis sensitivity is part of the individual calibration procedure and should always be less than 3% to 4%. If high levels of transverse vibration are present, this may result in erroneous overall results. In this case, separate arrangements should be made to establish the level and frequency contents of the cross-axis vibrations. Cross-axis sensitivities of typical accelerometers are mentioned in the relevant sections: 2% to 3% for piezoelectric types and less than 1% in most others.

17.12 Selection, Full-Scale Range, and Overload Capability

Ultimate care must be exercised for the selection of the correct accelerometer to meet the requirements of a particular application. At first glance, there may seem to be a confusingly large repertoire of accelerometers available; however, they can be classified into two main groups. The first group are the general-purpose accelerometers offered in various sensitivities, frequencies, full scale, and overload ranges, with different mechanical and electrical connection options. The second group of accelerometers are the special types that have characteristics targeted toward a particular application.

In deciding the application type (e.g., general purpose or special) and the accelerometer to be employed, the following characteristics need to be considered: transient response or cross-axis sensitivity; frequency range; sensitivity, mass and dynamic range; cross-axis response; and environmental conditions such as temperature, cable noise, etc. Some useful hints about these characteristics are given below.

FIGURE 17.19 Vectorial illustration of cross-axis sensitivity. Accelerometers may sense vibrations not only in the direction of main axis, but also perpendicular to the main axis. These cross-axis responses are minimized in many accelerometers to a value less than 1%. Sometimes, this sensitivity is used to determine the correct orientation of the device.

The Frequency Range

Acceleration measurements are normally confined to using the linear portion of the response curve. The response is limited at the low frequencies as well as at the high frequencies by the natural resonances. As a rule of thumb, the upper frequency limit for the measurement can be set to one third of the accelerometer's resonance frequency such that the vibrations measured will be less than 1 dB in linearity. It should be noted that an accelerometer's useful frequency range is significantly higher, that is, to 1/2 or 2/3 of its resonant frequency. The measurement frequencies may be set to higher values in applications where lower linearity (e.g., 3 dB) may be acceptable, as in the case of monitoring internal conditions of machines since the reputability is more important than the linearity. The lower measuring frequency limit is determined by two factors. The first is the low-frequency cut-off of the associated preamplifiers. The second is the effect of ambient temperature fluctuations to which the accelerometer could be sensitive.

The Sensitivity, Mass, and Dynamic Range

Ideally, the higher the transducer sensitivity, the better; but compromises might have to be made for sensitivity versus frequency, range, overload capacity, and size.

Accelerometer mass becomes important when using it on small and light test objects. The accelerometer should not load the structural member, since additional mass can significantly change the levels and frequency presence at measuring points and invalidate the results. As a general rule, the accelerometer mass should not be greater than one tenth the effective mass of the part or the structure that is mounted onto for measurements.

The dynamic range of the accelerometer should match the high or low acceleration levels of the measured objects. General-purpose accelerometers can be linear up to 5000 g to 10,000 g, which is well into the range of most mechanical shocks. Special accelerometers can measure up to 100,000 g.

An important point in the practical application of accelerometers is that if mechanical damping is a problem, air damping is preferable to oil damping, since oil damping is extremely sensitive to viscosity changes. If the elements are temperature stable, electronic damping may be sufficient.

The Transient Response

Shocks are characterized as sudden releases of energy in the form short-duration pulses exhibiting various shapes and rise times. They have high magnitudes and wide frequency contents. In applications where transients and shock measurements are involved, the overall linearity of the measuring system may be limited to high and low frequencies by phenomena known as *zero shift* and *ringing*, respectively. The zero shift is caused by both the phase nonlinearity in the preamplifiers and the accelerometer not returning to steady-state operation conditions after being subjected to high shocks. Ringing is caused by high-frequency components of the excitation near resonance frequency preventing the accelerometer to return back to its steady-state operation condition. To avoid measuring errors due to these effects, the operational frequency of the measuring system should be limited to the linear range.

Full-Scale Range and Overload Capability

Most accelerometers are able to measure acceleration in both positive and negative directions. They are also designed to be able to accommodate overload capacity. Appropriate discussions are made on full-scale range and overload capacity of accelerometers in the relevant sections. Manufacturers usually supply information on these two characteristics.

Environmental Conditions

In the selection and implementation of accelerometers, environmental conditions such as temperature ranges, temperature transients, cable noise, magnetic field effects, humidity, acoustic noise, etc. need to be considered. Manufacturers also supply information on environmental conditions.

17.13 Signal Conditioning

Common signal conditioners are appropriate for interfacing accelerometers to computers or other instruments for further signal processing. Caution needs to be exercised to provide appropriate electric load to self-generating accelerometers. Generally, the generated raw signals are amplified and filtered suitably by the circuits within the accelerometer casing supplied by manufacturers. Nevertheless, piezoelectric and piezoresistive transducers require special signal conditioners with certain characteristics, as discussed next. Examples of signal conditioning circuits are also given for microaccelerometers.

Signal Conditioning Piezoelectric Accelerometers

The piezoelectric accelerometer supplies a very small energy to the signal conditioner. It has a high capacitive source impedance. The equivalent circuit of a piezoelectric accelerometer can be regarded as an active capacitor that charges itself when loaded mechanically. The configuration of external signal conditioning elements is dependent on the equivalent circuit selected. The charge amplifier design of the conditioning circuit is the most common approach since the system gain and low-frequency responses are well defined. The performance of the circuit is independent of cable length and capacitance of the accelerometer.

The charge amplifier consists of a charge converter output voltage that occurs as a result of the charge input signal returning through the feedback capacitor to maintain the input voltage at the input level close to zero, as shown in [Figure 17.20](#). An important point about charge amplifiers is that their sensitivities can be standardized. They basically convert the input charge to voltage first and then amplify this voltage. With the help of basic operational-type feedback, the amplifier input is maintained at essentially

Charge amplifier

FIGURE 17.20 A typical charge amplifier. The transducer charge, which is proportional to acceleration, is first converted to voltage form to be amplified. The output voltage is a function of the input charge. The response of the amplifier can be approximated by a first-order system. In PZT transducers, the preamplifier is integrated within the same casing.

zero volts; therefore, it looks like a short circuit to the input. The charge converter output voltage that occurs as a result of a charge input signal is returned through the feedback capacitor to maintain the voltage at the input level near zero. Thus, the charge input is stored in the feedback capacitor, producing a voltage across it, that is equal to the value of the charge input divided by the capacitance of the feedback capacitor. The complete transfer function of the circuit describing the relationship between the output voltage and the input acceleration magnitude can be determined by:

$$E_o/a_0 = S_a jR_f C_f \omega \left\{ 1 + jR_f C_f \left[1 + (C_a + C_c) / (1 + G) \times C_f \right] \omega \right\} \quad (17.46)$$

where E_o = charge converter output (V)
 a_0 = magnitude of acceleration ($m\ s^{-2}$)
 S_a = accelerometer sensitivity ($mV\ g^{-1}$)
 C_a = accelerometer capacitance (F)
 C_c = cable capacitance (F)
 C_f = feedback capacitance (F)
 R_f = feedback loop resistance
 G = amplifier open loop gain

In most applications, since C_f is selected to be large compared to $(C_a + C_c)/(1 + G)$, the system gain becomes independent of the cable length. In this case, the denominator of the equation can be simplified to give a first-order system with roll-off at:

$$f_{-3\text{dB}} = 1 / (2\pi R_f C_f) \quad (17.47)$$

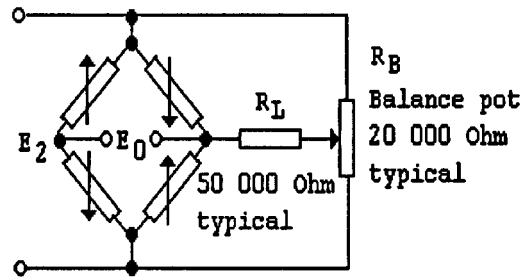

FIGURE 17.21 Bridge circuit for piezoresistive and strain gage accelerometers. The strain gages form the four arms of the bridge. The two extra resistors are used for balancing and fine adjustment purposes. This type of arrangement reduces temperature effects.

with a slope of 10 dB per decade. For practical purposes, the low-frequency response of this system is a function of well-defined electronic components and does not vary with cable length. This is an important feature when measuring low-frequency vibrations.

Many accelerometers are manufactured with preamplifiers and other signal-conditioning circuits integrated with the transducer enclosed in the same casing. Some accelerometer preamplifiers include integrators to convert the acceleration proportional outputs to either velocity or displacement proportional signals. To attenuate noise and vibration signals that lie outside the frequency range of interest, most preamplifiers are equipped with a range of high-pass and low-pass filters. This avoids interference from electric noise or signals inside the linear portion of the accelerometer frequency range. Nevertheless, it is worth mentioning that these devices usually have two time constants, external and internal. The mixture of these two time constants can lead to problems, particularly at low frequencies. The internal time constant is usually fixed by the manufacturer in design and construction. Special care must be observed to take care of the effect of external time constants in many applications by mainly observing impedance matching.

Signal Conditioning of Piezoresistive Transducers

Piezoresistive transducers generally have high amplitude outputs, low output impedances, and low intrinsic noise. Most of these transducers are designed for constant voltage excitations. They are usually calibrated for constant current excitations to make them independent of external influences. Many piezoresistive transducers are configured as full-bridge devices. Some have four active piezoresistive arms and, together with two fixed precision resistors permit shunt calibration in the signal conditioner, as shown in [Figure 17.21](#).

Microaccelerometers

In microaccelerometers, signal conditioning circuitry is integrated within the same chip with the sensor as shown in [Figure 17.22](#). A typical example of the signal conditioning circuitry is given in [Figure 17.23](#) in block diagram form. In this type of accelerometer, the electronic system is essentially a crystal-controlled oscillator circuit and the output signal of the oscillator is a frequency modulated acceleration signal. Some circuits provide a buffered square-wave output that can directly be interfaced digitally. In this case, the need for analog to digital conversion is eliminated, thus removing one of the major sources of error. In other types of accelerometers, signal conditioning circuits such as analog to digital converters (ADC) are retained within the chip.

FIGURE 17.22 A block diagram of an accelerometer combined with MCU. The signal conditioning, switching, and power supply circuits are integrated to form a microaccelerometer. The device can directly be interfaced with a digital signal processor or a computer. In some cases, ADCs and memory are also integrated.

FIGURE 17.23 Block diagram of a signal-conditioning circuit of a microaccelerometer. The output signal of the oscillator is a frequency-modulated acceleration signal. The circuit provides a buffered square-wave frequency output that can be read directly into a digital device.

Time measurements can be divided into two general categories. The first category is *time-of-day* measurements. Time-of-day is labeled with a unique expression containing the year, month, day, hour, minute, second, etc., down to the smallest unit of measurement that we choose. When we ask the everyday question, “What time is it?”, we are asking for a time-of-day measurement.

The second type of time measurement (and the one more commonly referred to by metrologists) is a *time interval* measurement. A time interval measurement requires measuring the interval that elapses between two events. Time interval is one of the four basic standards of measurement (the others are length, mass, and temperature). Of these four basic standards, time interval can be measured with the most resolution and the least amount of uncertainty.

Timekeeping involves both types of measurements. First, we must find a *periodic event* that repeats at a constant rate. For example, the pendulum in a clock may swing back and forth at a rate of once per second. Once we know that the pendulum swings back and forth every second, we can establish the second as our basic unit of time interval. We can then develop a system of timekeeping, or a *time scale*. A time scale is an unambiguous way to order events. It is created by measuring a small time unit (like the second) and then counting the number of elapsed seconds to establish longer time intervals, like minutes, hours, and days. The device that does the counting is called a *clock*.

There are many types of periodic events that can form the basis for many types of clocks. Let’s continue our discussion by looking at the evolution of clocks and timekeeping.

TABLE 18.1 Relationship of Frequency Uncertainty to Timing Uncertainty

Frequency Uncertainty	Measurement Period	Timing Uncertainty
$\pm 1.00 \times 10^{-3}$	1 s	± 1 ms
$\pm 1.00 \times 10^{-6}$	1 s	± 1 μ s
$\pm 1.00 \times 10^{-9}$	1 s	± 1 ns
$\pm 2.78 \times 10^{-7}$	1 h	± 1 ms
$\pm 2.78 \times 10^{-10}$	1 h	± 1 μ s
$\pm 2.78 \times 10^{-13}$	1 h	± 1 ns
$\pm 1.16 \times 10^{-8}$	1 day	± 1 ms
$\pm 1.16 \times 10^{-11}$	1 day	± 1 μ s
$\pm 1.16 \times 10^{-14}$	1 day	± 1 ns

18.1 The Evolution of Clocks and Timekeeping

All clocks share several common features. Each clock has a device that produces the periodic event mentioned previously. This device is called the *resonator*. In the case of the pendulum clock, the pendulum is the resonator. Of course, the resonator needs an energy source, a mainspring or motor, for example, before it can move back and forth. Taken together, the energy source and the resonator form an *oscillator*. Another part of the clock counts the “swings” of the oscillator and converts them to time units like hours, minutes, and seconds, or smaller units like milliseconds (ms), microseconds (μ s), and nanoseconds (ns). And finally, part of the clock must display or record the results.

The frequency uncertainty of a clock’s resonator relates directly to the timing uncertainty of the clock. This relationship is shown in [Table 18.1](#).

Throughout history, clock designers have searched for more stable frequency sources to use as a resonator. As early as 3500 B.C., time was kept by observing the movement of an object’s shadow between sunrise and sunset. This simple clock is called a *sundial*, and the resonance frequency is the apparent motion of the sun. Later, waterclocks, hourglasses, and calibrated candles allowed dividing the day into smaller units of time. In the early 14th century, mechanical clocks began to appear. Early models used a *verge and foliet mechanism* for a resonator and had an uncertainty of about 15 min/day ($\cong 1 \times 10^{-2}$). A major breakthrough occurred in 1656, when the Dutch scientist Christiaan Huygens built the first *pendulum clock*. The pendulum, a mechanism with a “natural” period of oscillation, had been studied by Galileo Galilei as early as 1582, but Huygens was the first to invent an escapement that kept the pendulum swinging. The uncertainty of Huygens’s clock was less than 1 min/day ($\cong 7 \times 10^{-4}$), and later reduced to about 10 s/day ($\cong 1 \times 10^{-4}$). Huygens later developed the spring and balance wheel assembly still found in some of today’s wristwatches.

Pendulum technology continued to improve until the 20th century. By 1761, John Harrison had built a marine chronometer using a spring and balance wheel escapement. One of Harrison’s clocks gained only 54 s during a 5-month voyage to Jamaica, or about 1/3 s/day ($\cong 4 \times 10^{-6}$). The practical performance limit of mechanical clocks was reached in 1921, when W.H. Shortt demonstrated a clock with two pendulums — one a slave and the other a master. The slave pendulum moved the clock’s hands, and freed the master pendulum of mechanical tasks that would disturb its regularity. The Shortt clock had an uncertainty of just a few seconds per year ($\cong 1 \times 10^{-7}$) and became the reference used by laboratories [1,2].

In 1927, Joseph W. Horton and Warren A. Marrison of Bell Laboratories built the first clock based on a quartz crystal oscillator. By the 1940s, quartz clocks had replaced the Shortt pendulum as primary laboratory standards. Quartz clocks work because of the piezoelectric property of quartz crystals. When an electric current is applied to a quartz crystal, it resonates at a constant frequency. With no gears or escapements to disturb their resonance frequency, quartz clocks can easily outperform pendulum clocks. Uncertainties of ± 100 μ s/day ($\cong 1 \times 10^{-9}$) are possible, and quartz oscillators are used extensively in wristwatches, wall and desk clocks, and electronic circuits [2–4].

The resonance frequency of quartz relies upon a mechanical vibration that is a function of the size and shape of the quartz crystal. No two crystals can be precisely alike or produce exactly the same

frequency. Quartz oscillators are also sensitive to environmental parameters like temperature, humidity, pressure, and vibration [5]. These shortcomings make quartz clocks inadequate for many applications, and led to the development of atomic oscillators.

18.2 Atomic Oscillators

Atomic oscillators use the quantized energy levels in atoms and molecules as the source of their resonance frequency. The laws of quantum mechanics dictate that the energies of a bound system, such as an atom, have certain discrete values. An electromagnetic field can boost an atom from one energy level to a higher one. Or an atom at a high energy level can drop to a lower level by emitting electromagnetic energy. The resonance frequency (f) of an atomic oscillator is the difference between the two energy levels divided by Planck's constant (h):

$$f = \frac{E_2 - E_1}{h} \quad (18.1)$$

Time is kept by observing and counting the frequencies at which electromagnetic energy is emitted or absorbed by the atoms. In essence, the atom serves as a pendulum whose oscillations are counted to mark the passage of time [3].

There are three major types of atomic oscillators. The least expensive and most common type is the *rubidium oscillator*, based on the 6.835 GHz resonance of ^{87}Rb . Rubidium oscillators range in price from about \$2000 to \$8000. They are well-suited for applications that require a small, high-performance oscillator with an extremely fast warm-up time. The frequency uncertainty of a rubidium oscillator ranges from about $\pm 5 \times 10^{-10}$ to $\pm 5 \times 10^{-12}$.

The second type of atomic oscillator, the *cesium beam*, serves as the primary reference for most precision timing services. As will be seen in Section 18.3, the resonance frequency of cesium (9.1926 GHz) is used to define the SI second. The primary frequency standard in the United States is a cesium oscillator called NIST-7 with a frequency uncertainty of about $\pm 5 \times 10^{-15}$. Commercially available cesium oscillators differ in quality, but their frequency uncertainty should be at least $\pm 5 \times 10^{-12}$. The price of a cesium oscillator is high, ranging from about \$30,000 to \$80,000.

A third type of atomic oscillator, the *hydrogen maser*, is based on the 1.42 GHz resonance frequency of the hydrogen atom. Although the performance of hydrogen masers is superior to cesium in some ways, they are not widely used due to their high cost. Few are built, and most are owned by national standards laboratories. The price of a hydrogen maser often exceeds \$200,000 [2,3,6].

Table 18.2 summarizes the evolution of clock design and performance.

18.3 Time Scales and the SI Definition of the Second

As observed, the uncertainty of all clocks depends upon the irregularity of some type of periodic motion. By quantifying this periodic motion, one can define the second, which is the basic unit of time interval in the International System of Units (SI). Since atomic time standards are so clearly superior to their predecessors, they are used to define the SI second. Since 1971, the cesium atom has been used to define the second:

The duration of 9,192,631,770 periods of the radiation corresponding to the transition between two hyperfine levels of the ground state of the cesium-133 atom.

International Atomic Time (TAI) is an atomic time scale that conforms as closely as possible to the SI definition of the second. TAI is maintained by the Bureau International des Poids et Mesures (BIPM) in Sevres, France. As of 1996, it is created by averaging data obtained from about 250 laboratory and commercial atomic standards located at more than 40 different laboratories. Most of these standards are

TABLE 18.2 The Evolution of Clock Design and Performance

Type of Clock	Resonator	Date [Ref.]	Typical Timing Uncertainty (24 h)	Typical Frequency Uncertainty (24 h)
Sundial	Apparent motion of sun	3500 B.C.	NA	NA
Verge escapement	Verge and foliet mechanism	14th century	± 15 min	$\pm 1 \times 10^{-2}$
Pendulum	Pendulum	1656	± 10 s	$\pm 7 \times 10^{-4}$
Harrison chronometer	Pendulum	1761	± 400 ms	$\pm 4 \times 10^{-6}$
Shortt pendulum	Two pendulums, slave and master	1921	± 10 ms	$\pm 1 \times 10^{-7}$
Quartz crystal	Quartz crystal	1927 [4]	± 100 μ s	$\pm 1 \times 10^{-9}$
Rubidium gas cell	Rubidium atomic resonance (6834.682608 MHz)	1958 [7]	± 1 μ s	$\pm 1 \times 10^{-11}$
Cesium beam	Cesium atomic resonance (9192.63177 MHz)	1952 [8]	± 10 ns	$\pm 1 \times 10^{-13}$
Hydrogen maser	Hydrogen atomic resonance (1420.405752 MHz)	1960 [9]	± 10 ns	$\pm 1 \times 10^{-13}$

based on cesium, although the number of contributing hydrogen masers is increasing. The National Institute of Standards and Technology (NIST) and the United States Naval Observatory (USNO) are among the many laboratories that contribute to TAI.

Before the acceptance of atomic time scales, astronomical time scales were used. These time scales are based on the *mean solar day*, or one revolution of the Earth on its axis. Until 1956, the *mean solar second* served as the SI second. The mean solar second is defined as 1/86,400 of the mean solar day, where 86,400 is the number of seconds in the day. This mean solar second provides the basis for Universal Time (UT). Several variations of UT have been defined:

UT0: The original mean solar time scale, based on the rotation of the Earth on its axis. UT0 was first kept by pendulum clocks. As better clocks based on quartz oscillators became available, astronomers noticed errors in UT0 due to polar motion, which led to the UT1 time scale.

UT1: The most widely used astronomical time scale, UT1 is an improved version of UT0 that corrects for the shift in longitude of the observing station due to polar motion. Since the Earth's rate of rotation is not uniform, UT1 is not completely predictable, and has an uncertainty of ± 3 ms per day.

UT2: Mostly of historical interest, UT2 is a smoothed version of UT1 that corrects for known deviations in the Earth's rotation caused by angular momenta of the Earth's core, mantle, oceans, and atmosphere.

The *ephemeris second* served as the SI second from 1956 to 1971. The ephemeris second was a fraction of the tropical year, or the interval between the annual vernal equinoxes on or about March 21. The tropical year was defined as 31,556,925.9747 ephemeris seconds. Determining the precise instant of the equinox is difficult, and this limited the uncertainty of Ephemeris Time (ET) to ± 50 ms over a 9-year interval. ET was primarily used by astronomers as the time-independent variable for planetary ephemerides. In 1984, ET was replaced by *Terrestrial Time* (TT), which is equal to TAI + 32.184 s. The uncertainty of TT is ± 10 μ s [10, 11].

18.4 Coordinated Universal Time (UTC)

Since January 1, 1972, all national laboratories and broadcast time services distribute Coordinated Universal Time (UTC), which differs from TAI by an integer number of seconds. The difference between UTC and TAI increases when *leap seconds* are inserted in UTC. When necessary, leap seconds are added to the UTC time scale on either June 30 or December 31. Their purpose is to keep atomic time (UTC) within ± 0.9 s of astronomical time (UT1). Many time services broadcast a *DUT1 correction*, or the current value of UT1 minus UTC. By applying this correction to UTC, one can obtain UT1.

Leap seconds occur slightly less than once per year because UT1 is currently changing by about 800 ms per year with respect to UTC. The first leap second was introduced on June 30, 1972. So far, all leap seconds have been positive, which indicates that the mean solar second (defined by the Earth's rotation) is longer than the atomic second (defined by cesium). UTC is running faster than UT1 for two reasons. The first, and most important reason, is that the definition of the atomic second caused it to be slightly shorter than the mean solar second. The second reason is that the speed of the Earth's rotation is generally decreasing. When a positive leap second is added to UTC, the sequence of events is:

23 h 59 m 59 s

23 h 59 m 60 s

0 h 0 m 0 s

The insertion of the leap second creates a minute that is 61 s long. This effectively “stops” the UTC time scale for 1 s, so that UT1 has a chance to catch up. Unless a dramatic, unforeseen change in the Earth's rotation rate takes place, future leap seconds will continue to be positive [10, 11].

18.5 Introduction to Time Transfer

Many applications require different clocks at different locations to be set to the same time (*synchronization*), or to run at the same rate (*syntonization*). A common application is to transfer time from one location and synchronize a clock at another location. This requires a 1 pulse per second (pps) output referenced to UTC. Once we have an on-time pulse, we know the arrival time of each second and can syntonize a local clock by making it run at the same rate. However, we still must know the *time-of-day* before we can synchronize the clock. For example, is it 12:31:38 or 12:31:48? To get the time-of-day, we need a *time code* referenced to UTC. A time code provides the UTC hour, minute, and second, and often provides date information like month, day, and year.

To summarize, synchronization requires two things: an on-time pulse and a time code. Many *time transfer signals* meet both requirements. These signals originate from a UTC clock referenced to one or more cesium oscillators. The time signal from this clock is then distributed (or transferred) to users.

Time can be transferred through many different mediums, including coaxial cables, optical fibers, radio signals (at numerous places in the spectrum), telephone lines, and computer networks. Before discussing the available time transfer signals, the methods used to transfer time are examined.

Time Transfer Methods

The single largest contributor to time transfer uncertainty is *path delay*, or the delay introduced as the signal travels from the transmitter (source) to the receiver (destination). To illustrate the path delay problem, consider a time signal broadcast from a radio station. Assume that the time signal is nearly perfect at its source, with an uncertainty of ± 100 ns of UTC. If a receiving site is set up 1000 km away, we need to calculate how long it takes for the signal to get to the site. Radio signals travel at the speed of light ($\cong 3.3 \mu\text{s km}^{-1}$). Therefore, by the time the signal gets to the site, it is already 3.3 ms late. We can compensate for this path delay by making a 3.3 ms adjustment to the clock. This is called *calibrating the path*.

There is always a limit to how well we can calibrate a path. For example, to find the path length, we need coordinates for both the receiver and transmitter, and software to calculate the delay. Even then, we are assuming that the signal took the shortest path between the transmitter and receiver. Of course, this is not true. Radio signals can bounce between the Earth and ionosphere, and travel much further than the distance between antennae. A good path delay estimate requires knowledge of the variables that influence radio propagation: the time of year, the time of day, the position of the sun, the solar index, etc. Even then, path delay estimates are so inexact that it might be difficult to recover time with ± 1 ms uncertainty (10,000 times worse than the transmitted time) [12, 13].

FIGURE 18.1 One-way time transfer.

Designers of time transfer systems have developed many innovative ways to deal with the problem of path delay. The more sophisticated methods have a *self-calibrating path* that automatically compensates for path delay. The various time transfer systems can be divided into five general categories:

1. *One-way method (user calibrates path)*: This is the simplest and most common kind of time transfer system, a one-way system where the user is responsible for calibrating the path (if required). As illustrated in Figure 18.1, the signal from the transmitter to the receiver is delayed τ_{ab} by the medium. To obtain the best results, the user must estimate τ_{ab} and calibrate the path by compensating for the delay.

Often, the user of a one-way system only requires timing uncertainty of ± 1 s, so no effort is made to calibrate the path. For example, the user of a high-frequency (HF) broadcast can synchronize a clock at the 1 s level without worrying about the effect of path delay.

2. *One-way method (self-calibrating path)*: This method is a variation of the simple one-way method shown in Figure 18.1. However, the time transfer system (and not the user) is responsible for estimating and removing the τ_{ab} delay.

One of two techniques is commonly used to reduce the size of τ_{ab} . The first technique is to make a rough estimate of τ_{ab} and to send the time out early by this amount. For example, if it is known that τ_{ab} will be at least 20 ms for all users, we can send out the time 20 ms early. This advancement of the timing signal will reduce the uncertainty for all users. For users where τ_{ab} is $\cong 20$ ms, it will remove nearly all of the uncertainty caused by path delay.

A more sophisticated technique is to compute τ_{ab} in software. A correction for τ_{ab} can be computed and applied if the coordinates of both the transmitter and receiver are known. If the transmitter is stationary, a constant can be used for the transmitter position. If the transmitter is moving (a satellite, for example) it must broadcast its coordinates in addition to broadcasting a time signal. The receiver's coordinates must be computed by the receiver (in the case of radionavigation systems), or input by the user. Then, a software-controlled receiver can compute the distance between the transmitter and receiver and compensate for the path delay by correcting for τ_{ab} . Even if this method is used, uncertainty is still introduced by position errors for either the transmitter or receiver and by variations in the transmission speed along the path.

Both techniques can be illustrated using the GOES satellite time service (discussed later) as an example. Because the GOES satellites are in geostationary orbit, it takes about 245 ms to 275 ms for a signal to travel from Earth to the satellite, and back to a random user on Earth. To compensate for this delay, the time kept by the station clock on Earth is advanced by 260 ms. This removes most of τ_{ab} . The timing uncertainty for a given user on Earth should now be ± 15 ms. The satellite also sends its coordinates along with the timing information. If a microprocessor-controlled receiver is used, and if the coordinates of the receiver are known, the receiver can make an even better estimate of τ_{ab} , typically within ± 100 μ s.

3. *Common-view method*: The common-view method involves a single reference transmitter (R) and two receivers (A and B). The transmitter is in “common view” to both receivers. Both receivers compare the simultaneously received signal to their local clock and record the data (Figure 18.2). Receiver A receives the signal over the path τ_{ra} and compares the reference to its local clock (R – Clock A). Receiver B receives the signal over the path τ_{rb} and records (R – Clock B). The two receivers then exchange and difference the data. Errors from the two paths (τ_{ra} and τ_{rb}) that are

FIGURE 18.2 Common-view time transfer.

FIGURE 18.3 Two-way time transfer.

common to the reference cancel out, and the uncertainty caused by path delay is nearly eliminated. The result of the measurement is $(\text{Clock A} - \text{Clock B}) - (\tau_{ra} - \tau_{rb})$.

Keep in mind that the common-view technique does not synchronize clocks in *real time*. The data must be exchanged with another user, and the results might not be known until long after the measurements are completed.

4. *Two-way method*: The two-way method requires two users to both transmit and receive through the same medium at the same time (Figure 18.3). Sites A and B simultaneously exchange time signals through the same medium and compare the received signals with their own clocks. Site A records $A - (B + \tau_{ba})$ and site B records $B - (A + \tau_{ab})$, where τ_{ba} is the path delay from A to B, and τ_{ab} is the path delay from A to B. The difference between these two sets of readings produces $2(A - B) - (\tau_{ba} - \tau_{ab})$. If the path is reciprocal ($\tau_{ab} = \tau_{ba}$), then the difference, $A - B$, is known perfectly because the path between A and B has been measured. When properly implemented using a satellite or fiber optic links, the two-way method outperforms all other time transfer methods and is capable of ± 1 ns uncertainty.

Two-way time transfer has many potential applications in telecommunications networks. However, when a wireless medium is used, there are some restrictions that limit its usefulness. It might require expensive equipment and government licensing so that users can transmit. And like the common-view method, the two-way method requires users to exchange data. However, because users can transmit, it is possible to include the data with the timing information and to compute the results in real time.

5. *Loop-back method*: Like the two-way method, the loop-back method requires the receiver to send information back to the transmitter. For example, a time signal is sent from the transmitter (A)

to the receiver (B) over the path τ_{ab} . The receiver (B) then echoes or reflects the signal back to the transmitter (A) over the path τ_{ba} . The transmitter then adds the two path delays ($\tau_{ab} + \tau_{ba}$) to obtain the round-trip delay, and divides this number by 2 to estimate the one-way path delay. The transmitter then advances the time signal by the estimated one-way delay.

Several factors contribute uncertainty to the loop-back method. One is that it is not always known if the signal from A to B traveled the same path as the signal from B to A. In other words, we cannot assume a *reciprocal* path. Even if we have a reciprocal path, we are not using the same path at the same time. First, the transmitter sent data to the receiver, then the receiver sent data back to the transmitter. In the interval between data transmissions, the path may have changed, and these changes contribute to the uncertainty.

The loop-back method might not be practical through a wireless medium because returning information to the transmitter requires a radio transmitter, a broadcast license, etc. When the medium is a telephone or network connection, however, it is possible to implement the loop-back method entirely in software.

Time Codes

A *time code* is a message containing time-of-day information, that allows the user to set a clock to the correct time-of-day. International Telecommunications Union (ITU) guidelines state that all time codes should distribute the UTC hour, minute, and second, as well as a DUT1 correction [14].

Time codes are broadcast in a number of different formats (including binary, binary coded decimal [BCD], and ASCII) and there is very little standardization. However, standards do exist for redistributing time codes within a facility. These standard time codes were first created by the Inter-Range Instrumentation Group (IRIG) in 1956 and are still widely used by equipment manufacturers today. IRIG defined a number of time codes, but the most common is probably IRIG-B. The IRIG codes make it possible for manufacturers to build compatible equipment. For example, a satellite receiver with an IRIG-B output can drive a large time-of-day display that accepts an IRIG-B input. Or, it can provide a timing reference to a network server that can read IRIG-B.

The IRIG time code formats are serial, width-modulated codes that can be used in either dc level shift or amplitude-modulated (AM) form. For example, IRIG-B has a 1 s frame period and can be transmitted as either a dc level shift modulation envelope or as a modulated 1000 Hz carrier. BCD and straight binary time data (days, hours, minutes, seconds) is included within the 1 s frame. Simple IRIG-B decoders retrieve just the encoded data and provide 1 s resolution. Other decoders count carrier cycles and provide timing resolution equal to the period of the 1000 Hz cycle (1 ms). More advanced decoders phase lock an oscillator to the time code and provide resolution limited only by the time code signal-to-noise ratio (typically $\pm 2 \mu\text{s}$).

18.6 Radio Time Transfer Signals

Many types of receivers receive time codes transmitted by radio. The costs vary widely, from less than \$500 to \$15,000 or more. Radio clocks come in several different forms. Some are standalone (or rack mount) devices with a digital time display. These often have a computer interface like RS-232 or IEEE-488. Others are available as cards that plug directly into a computer's bus. When selecting a radio clock, make sure that the signal is usable in the area and that the appropriate type of antenna can be mounted.

When reviewing radio time signals, please remember that the stated uncertainty values refer to the raw signal. Additional delays are introduced before the signal is processed by the receiver and used to synchronize a clock. For example, there is cable delay between the antenna and receiver. There are equipment delays introduced by hardware, and processing delays introduced by software. If unknown, these delays can cause *synchronization errors*. Depending on the application, synchronization errors may or may not be important. However, they must be measured and accounted for when performing an uncertainty analysis of a timing system.

HF Radio Signals (including WWV and WWVH)

High-frequency (HF) or *shortwave* radio broadcasts are commonly used for time transfer at moderate performance levels. These stations are popular for several reasons: they provide worldwide coverage, they work with low-cost receivers, and they provide an audio announcement that lets you “listen” to the time.

To use an HF time signal, you need a shortwave radio. Many types of shortwave radios are available, ranging from simple portables that cost less than \$100 to communication-type receivers costing many thousands of dollars. A few companies manufacture dedicated HF timing receivers that automatically find the best signal to use by scanning several different frequencies. Some of them have a built-in computer interface (usually RS-232) so you can use them to set a computer clock.

There are many HF time and frequency stations located around the world, including the NIST-operated stations, WWV and WWVH. WWV is near Fort Collins, CO, and WWVH is on the island of Kauai, HI. Both stations broadcast continuous time and frequency signals on 2.5, 5, 10, and 15 MHz. WWV also broadcasts on 20 MHz. All frequencies carry the same program, and at least one frequency should be usable at all times. The stations can also be heard by telephone: dial (303) 499-7111 for WWV and (808) 335-4363 for WWVH.

The audio portion of the WWV/WWVH broadcast includes seconds pulses or ticks produced by a double-sideband, 100% modulated signal on each RF carrier. The first pulse of every hour is an 800 ms pulse of 1500 Hz. The first pulse of every minute is an 800 ms pulse of 1000 Hz at WWV and 1200 Hz at WWVH. The remaining seconds pulses are brief audio bursts (5 ms pulses of 1000 Hz at WWV and 1200 Hz at WWVH) that sound like the ticking of a clock. All pulses occur at the beginning of each second. The 29th and 59th seconds pulses are omitted. Each tick is preceded by 10 ms of silence and followed by 25 ms of silence to avoid interference from other time stations and to make it easier to hear the tick. At the start of each minute, a voice announces the current UTC hour and minute. WWV uses a male voice to announce the time, and WWVH uses a female voice.

In addition to audio, a time code is also sent on a 100 Hz subcarrier. The time code is a modified version of IRIG-H and is sent once per minute in BCD format, at a 1 bit per second (bps) rate. Within 1 min, enough bits are sent to express the minute, hour, and day of year, the DUT1 correction, and a Daylight Saving Time (DST) indicator. The coded time information refers to the time at the start of the 1-min frame.

WWV and WWVH are best suited for synchronization at the 1 s (or fraction of a second) level. The actual uncertainty depends on the user’s distance from the transmitter, but should be less than 30 ms. Although ± 1 ms uncertainty is possible with a well-calibrated path, there are other signals available that are easier to use and more reliable at the 1 ms level [15].

LF Radio Signals (including WWVB and LORAN-C)

Before the development of satellite signals, low-frequency (LF) signals were the method of choice for time transfer. While the use of LF signals has diminished, they still have one major advantage — they can often be received indoors without an external antenna. This makes them ideal for many consumer electronic applications.

Many countries have time services in the LF band from 30 kHz to 300 kHz, as well as in the VLF (very low frequency) band from 3 kHz to 30 kHz. These signals lack the bandwidth needed to provide voice announcements, but often provide an on-time pulse and/or a time code. As with HF signals, the user must calibrate the path to get the best results. However, because part of the LF signal is *groundwave* and follows the curvature of the Earth, a good path delay estimate is much easier to make. Two examples of LF signals used for time transfer are WWVB and LORAN-C. WWVB transmits a binary time code on a 60 kHz carrier. LORAN-C transmits on-time pulses at 100 kHz but has no time code.

WWVB

WWVB is an LF radio station (60 kHz) operated by NIST from the same site as WWV near Ft. Collins, CO. The signal currently covers most of North America, and a power increase (6 dB and scheduled for 1998) would increase the coverage area and improve the signal-to-noise ratio within the United States.

Although far more stable than an HF path, the WWVB path is influenced by the path length, and by daily and seasonal changes. Path length is important because part of the signal travels along the ground (*groundwave*), and another part is reflected from the ionosphere (*skywave*). The groundwave path is more stable and considerably easier to estimate than the skywave path. If the path is relatively short (less than 1000 km), then it is often possible for a receiver to continuously track the groundwave signal, because it always arrives first. If the path length increases, a mixture of groundwave and skywave will be received. And over a very long path, the groundwave could become so weak that it will only be possible to receive the skywave. In this instance, the path becomes much less stable.

Time of day is also important. During the day, the receiver might be able to distinguish between groundwave and skywave and path stability might vary by only a few microseconds. However, if some skywave is being received, *diurnal* phase shifts will occur at sunrise and sunset. For example, as the path changes from all darkness to all daylight, the ionosphere lowers. This shortens the path between the transmitter and receiver, and the path delay decreases until the entire path is in sunlight. The path delay then stabilizes until either the transmitter or receiver enters darkness. Then the ionosphere rises, increasing the path delay.

The WWVB time code is synchronized with the 60 kHz carrier and is broadcast once per minute. The time code is sent in BCD format. Bits are sent by shifting the power of the carrier. The carrier power is reduced 10 dB at the start of each second. If full power is restored 200 ms later, it represents a 0 bit. If full power is restored 500 ms later, it represents a 1 bit. Reference markers and position identifiers are sent by restoring full power 800 ms later. The time code provides year, day, hour, minute, and second information, a DUT1 correction, and information about Daylight Saving Time, leap years, and leap seconds [15].

LORAN-C

LORAN-C is a ground-based radionavigation system. Most of the system is operated by the U.S. Department of Transportation (DOT), but some stations are operated by foreign governments. The system consists of groups of stations (called chains). Each chain has one master station, and from two to five secondary stations. The stations are high power, typically 275 to 1800 kW, and broadcast on a carrier frequency of 100 kHz using a bandwidth from 90 kHz to 110 kHz.

Because there are many LORAN-C chains using the same carrier frequency, the chains transmit pulses so that individual stations can be identified. Each chain transmits a pulse group consisting of pulses from all of the individual stations. The pulse group is sent at a unique Group Repetition Interval (GRI). For example, the 7980 chain transmits pulses every 79.8 ms. By looking for pulse groups spaced at this interval, the receiver can identify the 7980 chain.

Once a specific station within the chain is identified, the pulse shape allows the receiver to locate and track a specific groundwave cycle of the carrier. Generally, a receiver within 1500 km of the transmitter can track the same groundwave cycle indefinitely, and avoid reception of the skywave. Since the receiver can distinguish between groundwave and skywave, the diurnal phase shifts are typically quite small (<500 ns). However, if the path length exceeds 1500 km, the receiver could lose lock, and “jump” to another cycle of the carrier. Each cycle jump introduces a 10 μ s timing error, equal to the period of 100 kHz.

LORAN-C does not deliver a time code, but can deliver an on-time pulse referenced to UTC. This is possible because the arrival time of a pulse group coincides with the UTC second at a regular interval. This *time of coincidence* (TOC) occurs once every 4 to 16 min, depending on the chain being tracked. To get a synchronized 1 pps output, one needs a timing receiver with TOC capability and a good path delay estimate. One also needs a TOC table for the chain being tracked (available from the United States Naval Observatory). Once a LORAN-C clock is set on time, it can produce a 1 pps output with an uncertainty of ± 500 ns [12, 16].

Geostationary Operational Environmental Satellite (GOES)

NIST provides a continuous time code through the GOES (Geostationary Operational Environmental Satellite) satellites. These satellites are operated by the National Oceanic and Atmospheric Administration (NOAA). The service provides coverage to the entire Western Hemisphere.

Two satellites are used to broadcast time. GOES/East at 75° West longitude broadcasts on a carrier frequency of 468.8375 MHz. GOES/West at 135° West longitude broadcasts on a carrier frequency of 468.825 MHz. The satellites are in geostationary orbit 36,000 km above the equator. The GOES master clock is synchronized to UTC(NIST) and located at NOAA's facility in Wallops Island, VA. The satellites serve as transponders that relay signals from the master clock.

The GOES time code includes the year, day-of-year, hour, minute, and second, the DUT1 correction, satellite position information, and Daylight Saving Time and leap second indicators. The time code is interlaced with messages used by NOAA to communicate with systems gathering weather data. A 50 bit message is sent every 0.5 s, but only the first 4 bits (one BCD word) contains timing information. A complete time code frame consists of 60 BCD words and takes 30 s to receive.

By using the satellite position information, GOES receiving equipment can measure and compensate for path delay if the receiver's coordinates are known. The timing uncertainty of the GOES service is $\pm 100 \mu\text{s}$ [15].

Global Positioning System (GPS)

The Global Positioning System (GPS) is a radionavigation system developed and operated by the U.S. Department of Defense (DOD). It consists of a constellation of 24 Earth-orbiting satellites (21 primary satellites and 3 in-orbit spares). The 24 satellites orbit the Earth in six fixed planes inclined 55° from the equator. Each satellite is 20,200 km above the Earth and has an 11-h, 58-min orbital period, which means a satellite will pass over the same place on Earth 4 min earlier each day. Since the satellites continually orbit the Earth, GPS should be usable anywhere on the Earth's surface.

Each GPS satellite broadcasts on two carrier frequencies: L1 at 1575.42 MHz and L2 at 1227.6 MHz. Each satellite broadcasts a spread spectrum waveform, called a *pseudo random noise* (PRN) code on L1 and L2, and each satellite is identified by the PRN code it transmits. There are two types of PRN codes. The first type is a *coarse acquisition* code (called the C/A code) with a chip rate of 1023 chips per millisecond. The second is a *precision* code (called the P code) with a chip rate of 10230 chips per millisecond. The C/A code repeats every millisecond. The P code only repeats every 267 days, but for practical reasons is reset every week. The C/A code is broadcast on L1, and the P code is broadcast on both L1 and L2.

For national security reasons, the DOD started the *Selective Availability* (SA) program in 1990. SA intentionally increases the positioning and timing uncertainty of GPS by adding about 300 ns of noise to both the C/A code and the P code. The resulting signal is distributed through the *Standard Positioning Service* (SPS). The SPS is intended for worldwide use, and can be used free of charge by anyone with a GPS receiver. The *Precise Positioning Service* (PPS) is only available to users authorized by the United States military. PPS users require a special receiver that employs cryptographic logic to remove the effects of SA. Since PPS use is restricted, nearly all civilian GPS users use the SPS.

Using GPS in One-Way Mode

GPS has the best price-performance ratio of any current time transfer system. Receivers range in price from less than \$500 for an OEM timing board, to \$20,000 or more for the most sophisticated models. The price often depends on the quality of the receiver's timebase oscillator. Lower priced models have a low-quality timebase that must be constantly steered to follow the GPS signal. Higher priced receivers have better timebases (some have internal rubidium oscillators), and can ignore many of the GPS path variations because their oscillator allows them to coast for longer intervals.

TABLE 18.3 Timing Uncertainty of GPS in One-Way Mode

Service	Uncertainty (ns) 50th percentile	Uncertainty (ns) 1σ	Uncertainty (ns) 2σ
SPS	± 115	± 170	± 340
PPS	± 68	± 100	± 200

To use most receivers, you simply mount the antenna, connect the antenna to the receiver, and turn the receiver on. The antenna is often a small cone or disk (normally about 15 cm in diameter) and must be mounted outdoors where it has a clear, unobstructed view of the sky. Once the receiver is turned on, it performs a sky search to find out which satellites are currently above the horizon and visible from the antenna site. The receiver then collects two blocks of data (called the *almanac* and *ephemeris*) from the satellites it finds. Once this is done, it can compute a 3-dimensional coordinate (latitude, longitude, and altitude) as long as four satellites are in view. The receiver can then compensate for path delay, and synchronize its on-time pulse.

If the antenna has a clear view of the sky, at least four satellites should be in view at all times, and the receiver should always be able to compute its position. The simplest GPS receivers have just one channel and look at multiple satellites using a sequencing scheme that rapidly switches between satellites. More sophisticated models have parallel tracking capability and can assign a separate channel to each satellite in view. These receivers typically track from 5 to 12 satellites at once (although more than 8 will only be available in rare instances). By averaging data from multiple satellites, a receiver can remove some of the effects of SA and reduce the timing uncertainty.

GPS Performance in One-Way Mode

Most GPS timing receivers provide a 1 pps on-time pulse. GPS also broadcasts three pieces of time code information: the number of weeks since GPS time began (January 5, 1980); the current second in the current week; and the number of leap seconds since GPS time began. By using the first two pieces of information, a GPS receiver can recover GPS time. By adding the leap second information, the receiver can recover UTC. GPS time differs from UTC by the number of leap seconds that have occurred since January 5, 1980.

Most GPS receivers output UTC in the traditional time-of-day format: month, day, year, hour, minute, and second. Table 18.3 lists the UTC uncertainty specifications for both the SPS and PPS.

Since nearly all GPS receivers are limited to using the SPS, the top row in the table is of most interest. It shows there is a 50% probability that a given on-time pulse from GPS will be within ± 115 ns of UTC. The 1σ uncertainty of GPS (~68% probability) is ± 170 ns, and the 2σ uncertainty (95%) is ± 340 ns.

To achieve the uncertainties shown in Table 18.3, one must calibrate receiver and antenna delays, and estimate synchronization errors. For this reason, some manufacturers of GPS equipment quote a timing uncertainty of ± 1 μ s. This specification should be easy to support, even if receiver and antenna delays are roughly estimated or ignored. Other manufacturers use averaging techniques or algorithms that attempt to “remove” SA. These manufacturers might quote an uncertainty specification of ± 100 ns or less [17, 18].

Using GPS in Common-View Mode

The *common-view* mode is used to synchronize or compare time standards or time scales at two or more locations. Common-view GPS is the method used by the BIPM to collect data from laboratories who contribute to TAI.

Common-view time transfer requires a specially designed GPS receiver that can read a tracking schedule. This schedule tells the receiver when to start making measurements and which satellite to track. Another user at another location uses the same schedule and makes simultaneous measurements from

TABLE 18.4 Performance of Radio Time Transfer Signals

Radio Time Transfer Signal	Performance without Path Calibration	Typical Limit of System	Items Needed to Reach Performance Limit
HF (WWV/WWVH)	-30 ms (signal delay depends on distance from transmitter)	± 1 ms	Path delay estimate, radio propagation model
GOES Satellite	± 16 ms	± 100 μ s	Receiver that corrects for path delay
WWVB	-10 ms (signal delay depends upon distance from transmitter)	± 100 μ s	Path delay estimate, knowledge of equipment and antenna delays
LORAN-C	± 10 μ s	± 500 ns	Path delay estimate, receiver that is TOC capable, TOC table, knowledge of equipment and antenna delays
GPS (one-way mode)	± 340 ns	± 100 ns	Commercially available GPS receiver that averages data from multiple satellites. Knowledge of equipment and antenna delays.
GPS (common-view mode)	± 20 ns	± 5 ns	Common-view receiver, tracking schedule, and another user or laboratory that will exchange data; knowledge of equipment and antenna delays

the same satellite. The tracking schedule must be designed so that it chooses satellites visible to both users at reasonable elevation angles.

Each site measures the difference between its local clock and the satellite. Typically, measurements are made during a satellite pass lasting for less than 15 min. The individual measurements at each site are estimates of (Clock A – GPS) and (Clock B – GPS). If these results are subtracted, the GPS clock drops out and an estimate of (Clock A – Clock B) remains. Since GPS clock errors (including SA) do not influence the results, the uncertainty of GPS common view can be as small as ± 5 ns [19].

Although common view is important for international timing comparisons, it is impractical for the average user for several reasons. First, it requires exchanging data with another user. Second, common view does not provide continuous data. It only provides data during comparisons lasting for less than 15 min. And finally, common view does not work in real time; one will not know the timing uncertainty until after the data exchange.

Table 18.4 summarizes the various radio time transfer signals.

Table 18.5 lists some manufacturers of radio clocks. It includes radio clocks that use high-frequency (HF) radio signals, WWVB or other low-frequency (LF) radio signals, LORAN-C (LORAN), the Global Positioning System (GPS), and GPS common-view (GPS-CV). A wide variety of equipment is available for a wide variety of applications. Contact the manufacturer for specific details.

18.7 Computer Time Transfer Signals

One of the most common time transfer problems involves synchronizing computer clocks. Radio clocks like those described in the last section are often used for computer timekeeping. However, using a dial-up or Internet time service is often more convenient and less expensive than purchasing a radio clock [20].

Dial-Up Time Setting Services

Dial-up time services allow computers to synchronize their clocks using an ordinary telephone line. To illustrate how these services work, take a look at NIST's Automated Computer Time Service (ACTS), which went online in 1988.

TABLE 18.5 Sources of Radio Clocks

Radio Clock Manufacturer	Location	Type of Receivers Sold
Absolute Time	San Jose, CA	GPS
Arbiter	Paso Robles, CA	GPS
Allen Osborne	Westlake Village, CA	GPS, GPS-CV
Ashtech	Sunnyvale, CA	GPS
Austron	Austin, TX	LORAN, GPS, GPS-CV
Bancomm	San Jose, CA	GPS
Chrono-Log	Havertown, PA	HF, GPS
Datum	Anaheim, CA	GPS
Efratom	Irvine, CA	GPS
ESE	El Segundo, CA	GPS
Franklin Instrument	Warminster, PA	LF
Frequency and Time Systems	Beverly, MA	GPS
Garmin	Lenexa, KS	GPS
Heath	Benton Harbor, MI	HF
Hewlett-Packard	Santa Clara, CA	GPS
Macrodyne	Clifton Park, NY	GPS
Magellan	San Dimas, CA	GPS
Motorola	Northbrook, IL	GPS
Odetics	Anaheim, CA	GPS
Rockwell	Newport Beach, CA	GPS

Stanford Telecomm	Santa Clara, CA	GPS
Telecom Solutions	San Jose, CA	GPS
Tracor	Austin, TX	LF
Trak Systems	Tampa, FL	GPS
Trimble	Sunnyvale, CA	GPS
True Time	Santa Rosa, CA	HF, LF, GPS

ACTS requires a computer, a modem, and some simple software. When a computer connects to ACTS by telephone, it receives an ASCII time code. The information in this time code is used to synchronize the computer clock. ACTS is usable at modem speeds up to 9600 baud with 8 data bits, 1 stop bit, and no parity. To receive the full time code, one must connect at 1200 baud or higher. The full time code is transmitted once per second and contains more information than the 300 baud time code, which is transmitted every 2 s. Table 18.6 describes the full ACTS time code.

The last character in the time code is the on-time marker (OTM). The values enclosed in the time code refer to the arrival time of the OTM. In other words, if the time code states it is 12:45:45, it means it is 12:45:45 when the OTM arrives. To compensate for the path delay between NIST and the user, ACTS sends the OTM out 45 ms early. The 45 ms advance was chosen based on experiments conducted using 1200 baud modems. It allows 8 ms for sending the OTM at 1200 baud, 7 ms for transmission time between NIST and a typical user, and 30 ms for modem processing delay.

Advancing the OTM by 45 ms always reduces the amount of path delay. However, ACTS can calibrate the actual path by using the *loop-back* method. The loop-back method is implemented if the user's software returns the OTM to ACTS after it is received. Each time the OTM is returned, ACTS measures the round-trip path delay, and divides this quantity by 2 to get the one-way path delay. Then, after three consistent measurements, ACTS advances the OTM by the amount of the one-way path delay. For example, if the one-way path delay is 50.4 ms, ACTS sends the OTM out 50.4 ms (instead of 45 ms) early. At this point, the path is calibrated, and the OTM changes from an asterisk to a pound sign (#). If the loop-back option is used, the uncertainty of ACTS is ± 5 ms [21].

TABLE 18.6 The Automated Computer Time Service (ACTS) Time Code

Code	Meaning
JJJJ	The Modified Julian Date (MJD). The MJD is the last five digits of the Julian Date, which is a count of the number of days since January 1, 4713 B.C.
YR-MO-DA	The year, month, and day.
HH:MM:SS	Hour, minute, and second. The time is always transmitted as UTC, and an offset must be applied to obtain local time.
TT	A two-digit code that indicates whether the United States is on Standard Time (ST) or Daylight Saving Time (DST). It also indicates when ST or DST is approaching. The code is set to 00 when ST is in effect, or to 50 when DST is in effect. During the month in which a time change occurs, this number will begin deincrementing by 1 each day until the change occurs. For example, if TT is set to 5, it means the change from DST to ST will take place in 5 days.
L	A one-digit code that indicates whether a leap second will be added or subtracted at midnight on the last day of the current month. If the code is 0, no leap second will occur this month. If the code is 1, a positive leap second will be added at the end of the month. If the code is 2, a second will be deleted at the end of the month.
DUT1	The current difference between the UT1 time scale and UTC. This number can be added to UTC to obtain UT1. The correction ranges from -0.8 to 0.8 s.
msADV	A five-digit code that displays the number of milliseconds that NIST advances the time code. It defaults to 45.0 ms, but will change to reflect the actual one-way line delay if the on-time marker (OTM) is echoed back to NIST.
UTC(NIST)	A label that indicates one is receiving UTC from the National Institute of Standards and Technology (NIST).
<OTM>	A single character sent at the end of each time code. The OTM is originally an asterisk (*) and changes to a pound sign (#) if ACTS has successfully calibrated the path.

TABLE 18.7 Dial-Up Time Setting Services

Organization	Location	Telephone Number

Telecommunications Laboratory (TL)	Taiwan	011-886-3-424-5490
United States Naval Observatory (USNO)	Washington, D.C.	(202) 762-1594

Some dial-up services similar to ACTS are listed in [Table 18.7](#). These services all transmit time codes in ASCII, but several different formats are used. Due to this lack of standardization, software that accesses multiple services must be able to interpret several different time code formats.

Network Time Setting Services

Computers connected to the Internet can be synchronized without the expense of using a dial-up service. The Internet time servers provide a higher level of standardization than the dial-up services. Several standard timing protocols are defined in a series of RFC (Request for Comments) documents. One can obtain these documents from a number of Internet sites. The four major timing protocols are the Time Protocol, the Daytime Protocol, the Network Time Protocol (NTP), and the Simple Network Time Protocol (SNTP). [Table 18.8](#) summarizes the various protocols and their port assignments, or the port on which the time server “listens” for a request from the client [22–26].

TABLE 18.8 Internet Time Protocols

Protocol Name	Document	Format	Port Assignments
Time Protocol	RFC-868	Unformatted 32-bit binary number contains time in UTC seconds since January 1, 1900.	Port 37 tcp/ip, udp/ip
Daytime Protocol	RFC-867	Exact format not specified in standard. Only requirement is that time code is sent as ASCII characters. Often is similar to time codes sent by dial-up services like ACTS.	Port 13 tcp/ip, udp/ip
Network Time Protocol (NTP)	RFC-1305	Server responds to each query with a data packet in NTP format. The data packet includes a 64-bit timestamp containing the time in UTC seconds since January 1, 1900, with a resolution of 200 ps, and an uncertainty of 1 to 50 ms. NTP software runs continuously on the client machine as a background task that periodically gets updates from the server.	Port 123 udp/ip
Simple Network Time Protocol (SNTP)	RFC-1769	A version of NTP that does not change the specification, but simplifies some design features. It is intended for machines where the full performance of NTP is “not needed or justified.”	Port 123 udp/ip

NIST operates a Network Time Service that distributes time using the Time, Daytime, and NTP formats from multiple servers [27]. Small computers (PCs) normally use the Daytime Protocol. Large computers and workstations normally use NTP, and NTP software is often included with the operating system. The Daytime Protocol time code is very similar to ACTS. Like ACTS, the Daytime Protocol time code is sent early (by 50 ms), but the server does not calibrate the path. However, the timing uncertainty should be ± 50 ms at most locations.

Computer software to access the various dial-up and network time services is available for all major operating systems. One can often obtain evaluation copies (shareware) from the Internet or another on-line service.

18.8 Future Developments

Both the realization of the SI second and the performance of time transfer techniques will continue to improve. One promising development is the increased use of *cesium-fountain* standards. These devices work by laser cooling the atoms and then lofting them vertically. The resonance frequency is detected as the atoms rise and fall under the influence of gravity. Many laboratories are working on this concept, which should lead to substantial improvement over existing atomic-beam cesium standards [28]. In the longer term, a *trapped-ion* standard could lead to improvements of several orders of magnitude. This standard derives its resonance frequency from the systematic energy shifts in transitions in certain ions. The frequency uncertainty of such a device could eventually reach $\pm 1 \times 10^{-18}$ [29].

The future of time transfer should involve more and more reliance on satellite-based systems. Ground-based systems such as LORAN-C are expected to be phased out [30]. The timing uncertainty of GPS will improve if the Selective Availability (SA) program is discontinued (as expected) in the early part of the next century [31]. GLONASS, the Russian counterpart to GPS, might become more widely used [32]. And, in the near future, a time transfer service from the geostationary INMARSAT satellites could be available. This service uses technology similar to GPS, but should provide better performance.

and Technology*

Frequency is the rate of occurrence of a repetitive event. If T is the period of a repetitive event, then the frequency $f = 1/T$. The International System of Units (SI) states that the period should always be expressed in units of seconds (s), and the frequency should always be expressed in hertz (Hz). The frequency of electric signals often is measured in units of kilohertz (kHz) or megahertz (MHz), where 1 kHz equals 1000 (10^3) cycles per second, and 1 MHz equals 1 million (10^6) cycles per second.

Average frequency over a time interval can be measured very precisely. Time interval is one of the four basic standards of measurement (the others are length, mass, and temperature). Of these four basic standards, time interval (and frequency) can be measured with the most resolution and the least uncertainty. In some fields of metrology, 1 part per million (1×10^{-6}) is considered quite an accomplishment. In frequency metrology, measurements of 1 part per billion (1×10^{-9}) are routine, and even 1 part per trillion (1×10^{-12}) is commonplace.

Devices that produce a known frequency are called *frequency standards*. These devices must be calibrated so that they remain within the tolerance required by the user's application. The discussion begins with an overview of frequency calibrations.

19.1 Overview of Frequency Measurements and Calibration

Frequency calibrations measure the performance of frequency standards. The frequency standard being calibrated is called the *device under test* (DUT). In most cases, the DUT is a *quartz*, *rubidium*, or *cesium* oscillator. In order to perform the calibration, the DUT must be compared to a *standard* or *reference*. The standard should outperform the DUT by a specified ratio in order for the calibration to be valid. This ratio is called the *test uncertainty ratio* (TUR). A TUR of 10:1 is preferred, but not always possible. If a smaller TUR is used (5:1, for example), then the calibration will take longer to perform.

Once the calibration is completed, the metrologist should be able to state how close the DUT's output is to its *nameplate frequency*. The nameplate frequency is labeled on the oscillator output. For example, a DUT with an output labeled "5 MHz" is supposed to produce a 5 MHz frequency. The calibration measures the difference between the actual frequency and the nameplate frequency. This difference is called the *frequency offset*. There is a high probability that the frequency offset will stay within a certain range of values, called the *frequency uncertainty*. The user specifies a frequency offset and an associated uncertainty requirement that the DUT must meet or exceed. In many cases, users base their requirements on the specifications published by the manufacturer. In other cases, they may "relax" the requirements and use a less demanding specification. Once the DUT meets specifications, it has been successfully calibrated. If the DUT cannot meet specifications, it fails calibration and is repaired or removed from service.

The reference used for the calibration must be *traceable*. The International Organization for Standardization (ISO) definition for *traceability* is:

The property of the result of a measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties [1].

In the United States, the "unbroken chain of comparisons" should trace back to the National Institute of Standards and Technology (NIST). In some fields of calibration, traceability is established by sending the standard to NIST (or to a NIST-traceable laboratory) for calibration, or by sending a set of reference materials (such as a set of artifact standards used for mass calibrations) to the user. Neither method is practical when making frequency calibrations. Oscillators are sensitive to changing environmental conditions and especially to being turned on and off. If an oscillator is calibrated and then turned off, the calibration could be invalid when the oscillator is turned back on. In addition, the vibrations and temperature changes encountered during shipment can also change the results. For these reasons, laboratories should make their calibrations on-site.

Fortunately, one can use *transfer standards* to deliver a frequency reference from the national standard to the calibration laboratory. Transfer standards are devices that receive and process radio signals that provide frequency traceable to NIST. The radio signal is a link back to the national standard. Several different types of signals are available, including NIST radio stations WWV and WWVB, and radionavigation signals from LORAN-C and GPS. Each signal delivers NIST traceability at a known level of uncertainty. The ability to use transfer standards is a tremendous advantage. It allows traceable calibrations to be made simultaneously at a number of sites as long as each site is equipped with a radio receiver. It also eliminates the difficult and undesirable practice of moving frequency standards from one place to another.

Once a traceable transfer standard is in place, the next step is developing the technical procedure used to make the calibration. This procedure is called the *calibration method*. The method should be defined and documented by the laboratory, and ideally a measurement system that automates the procedure should be built. ISO/IEC Guide 25, *General Requirements for the Competence of Calibration and Testing Laboratories*, states:

The laboratory shall use appropriate methods and procedures for all calibrations and tests and related activities within its responsibility (including sampling, handling, transport and storage, preparation of items, estimation of uncertainty of measurement, and analysis of calibration and/or test data). They shall be consistent with the accuracy required, and with any standard specifications relevant to the calibrations or test concerned.

In addition, Guide 25 states:

The laboratory shall, wherever possible, select methods that have been published in international or national standards, those published by reputable technical organizations or in relevant scientific texts or journals [2,3].

Calibration laboratories, therefore, should automate the frequency calibration process using a well-documented and established method. This helps guarantee that each calibration will be of consistently high quality, and is essential if the laboratory is seeking ISO registration or laboratory accreditation.

Having provided an overview of frequency calibrations, we can take a more detailed look at the topics introduced. This chapter begins by looking at the specifications used to describe a frequency calibration, followed by a discussion of the various types of frequency standards and transfer standards. A discussion of some established calibration methods concludes this chapter.

19.2 The Specifications: Frequency Uncertainty and Stability

This section looks at the two main specifications of a frequency calibration: uncertainty and stability.

Frequency Uncertainty

As noted earlier, a frequency calibration measures whether a DUT meets or exceeds its uncertainty requirement. According to ISO, uncertainty is defined as:

Parameter, associated with the result of a measurement, that characterizes the dispersion of values that could reasonably be attributed to the measurand [1].

When we make a frequency calibration, the measurand is a DUT that is supposed to produce a specific frequency. For example, a DUT with an output labeled 5 MHz is supposed to produce a 5 MHz frequency. Of course, the DUT will actually produce a frequency that is not exactly 5 MHz. After calibration of the DUT, we can state its frequency offset and the associated uncertainty.

Measuring the frequency offset requires comparing the DUT to a reference. This is normally done by making a *phase comparison* between the frequency produced by the DUT and the frequency produced by the reference. There are several calibration methods (described later) that allow this determination. Once the amount of phase deviation and the *measurement period* are known, we can estimate the frequency offset of the DUT. The measurement period is the length of time over which phase comparisons are made. Frequency offset is estimated as follows, where Δt is the amount of phase deviation and T is the measurement period:

$$f(\text{offset}) = \frac{-\Delta t}{T} \quad (19.1)$$

If we measure +1 μs of phase deviation over a measurement period of 24 h, the equation becomes:

$$f(\text{offset}) = \frac{-\Delta t}{T} = \frac{1 \mu\text{s}}{86,400,000,000 \mu\text{s}} = -1.16 \times 10^{-11} \quad (19.2)$$

The smaller the frequency offset, the closer the DUT is to producing the same frequency as the reference. An oscillator that accumulates +1 μs of phase deviation per day has a frequency offset of about -1×10^{-11} with respect to the reference. Table 19.1 lists the approximate offset values for some standard units of phase deviation and some standard measurement periods.

The frequency offset values in Table 19.1 can be converted to units of frequency (Hz) if the nameplate frequency is known. To illustrate this, consider an oscillator with a nameplate frequency of 5 MHz that is high in frequency by 1.16×10^{-11} . To find the frequency offset in hertz, multiply the nameplate frequency by the dimensionless offset value:

$$(5 \times 10^6) (1.16 \times 10^{-11}) = 5.80 \times 10^{-5} = +0.0000580 \text{ Hz} \quad (19.3)$$

TABLE 19.1 Frequency Offset Values for Given Amounts of Phase Deviation

Measurement		
Period	Phase Deviation	Frequency Offset
1 s	±1 ms	$\pm 1.00 \times 10^{-3}$
1 s	±1 μs	$\pm 1.00 \times 10^{-6}$
1 s	±1 ns	$\pm 1.00 \times 10^{-9}$
1 h	±1 ms	$\pm 2.78 \times 10^{-7}$
1 h	±1 μs	$\pm 2.78 \times 10^{-10}$
1 h	±1 ns	$\pm 2.78 \times 10^{-13}$
1 day	±1 ms	$\pm 1.16 \times 10^{-8}$
1 day	±1 μs	$\pm 1.16 \times 10^{-11}$
1 day	±1 ns	$\pm 1.16 \times 10^{-14}$

The nameplate frequency is 5 MHz, or 5,000,000 Hz. Therefore, the actual frequency being produced by the frequency standard is:

$$5,000,000 \text{ Hz} + 0.0000580 \text{ Hz} = 5,000,000.0000580 \text{ Hz} \quad (19.4)$$

To do a complete uncertainty analysis, the measurement period must be long enough to ensure that one is measuring the frequency offset of the DUT, and that other sources are not contributing a significant amount of uncertainty to the measurement. In other words, must be sure that Δt is really a measure of the DUT's phase deviation from the reference and is not being contaminated by noise from the reference or the measurement system. This is why a 10:1 TUR is desirable. If a 10:1 TUR is maintained, many frequency calibration systems are capable of measuring a 1×10^{-10} frequency offset in 1 s [4].

Of course, a 10:1 TUR is not always possible, and the simple equation given for frequency offset (Equation 19.1) is often too simple. When using transfer standards such as LORAN-C or GPS receivers (discussed later), radio path noise contributes to the phase deviation. For this reason, a measurement period of at least 24 h is normally used when calibrating frequency standards using a transfer standard. This period is selected because changes in path delay between the source and receiver often have a cyclical variation that averages out over 24 h. In addition to averaging, curve-fitting algorithms and other statistical methods are often used to improve the uncertainty estimate and to show the *confidence level* of the measurement [5]. [Figure 19.1](#) shows two simple graphs of phase comparisons between a DUT and a reference frequency. Frequency offset is a linear function, and the top graph shows no discernible variation in the linearity of the phase. This indicates that a TUR of 10:1 or better is being maintained. The bottom graph shows a small amount of variation in the linearity, which could mean that a TUR of less than 10:1 exists and that some uncertainty is being contributed by the reference.

To summarize, frequency offset indicates how accurately the DUT produces its nameplate frequency. Notice that the term *accuracy* (or *frequency accuracy*) often appears on oscillator specification sheets instead of the term frequency offset, since frequency accuracy and frequency offset are nearly equivalent terms. Frequency uncertainty indicates the limits (upper and lower) of the measured frequency offset. Typically, a 2σ uncertainty test is used. This indicates that there is a 95.4% probability that the frequency offset will remain within the stated limits during the measurement period. Think of frequency offset as the result of a measurement made at a given point in time, and frequency uncertainty as the possible dispersion of values over a given measurement period.

Stability

Before beginning a discussion of *stability*, it is important to mention a distinction between frequency offset and stability. Frequency offset is a measure of how well an oscillator produces its nameplate frequency, or how well an oscillator is adjusted. It does not tell us about the inherent quality of an oscillator. For example, a high-quality oscillator that needs adjustment could produce a frequency with

FIGURE 19.1 Simple phase comparison graphs.

FIGURE 19.2 Comparison of unstable and stable frequencies.

a large offset. A low-quality oscillator may be well adjusted and produce (temporarily at least) a frequency very close to its nameplate value.

Stability, on the other hand, indicates how well an oscillator can produce the same frequency over a given period of time. It does not indicate whether the frequency is “right” or “wrong,” only whether it stays the same. An oscillator with a large frequency offset could still be very stable. Even if one adjusts the oscillator and moves it closer to the correct frequency, the stability usually does not change. Figure 19.2 illustrates this by displaying two oscillating signals that are of the same frequency between t_1 and t_2 . However, it is clear that signal 1 is unstable and is fluctuating in frequency between t_2 and t_3 .

Stability is defined as the statistical estimate of the frequency fluctuations of a signal over a given time interval. *Short-term stability* usually refers to fluctuations over intervals less than 100 s. *Long-term stability* can refer to measurement intervals greater than 100 s, but usually refers to periods longer than 1 day. A typical oscillator specification sheet might list stability estimates for intervals of 1, 10, 100, and 1000 s [6, 7].

Stability estimates can be made in the *frequency domain* or *time domain*, but time domain estimates are more widely used. To estimate stability in the time domain, one must start with a set of frequency offset measurements y_i that consists of individual measurements, y_1, y_2, y_3 , etc. Once this dataset is obtained, one needs to determine the dispersion or scatter of the y_i as a measure of oscillator noise. The larger the dispersion, or scatter, of the y_i , the greater the instability of the output signal of the oscillator.

Normally, classical statistics such as *standard deviation* (or *variance*, the square of the standard deviation) are used to measure dispersion. Variance is a measure of the numerical spread of a dataset with respect to the average or mean value of the data set. However, variance works only with stationary data, where the results must be time independent. This assumes the noise is *white*, meaning that its power is evenly distributed across the frequency band of the measurement. Oscillator data is usually nonstationary, because it contains time-dependent noise contributed by the frequency offset. For stationary data, the mean and variance will converge to particular values as the number of measurements increases. With nonstationary data, the mean and variance never converge to any particular values. Instead, there is a moving mean that changes each time a new measurement is added.

For these reasons, a nonclassical statistic is used to estimate stability in the time domain. This statistic is often called the *Allan variance*, but because it is actually the square root of the variance, its proper name is the *Allan deviation*. By recommendation of the Institute of Electrical and Electronics Engineers (IEEE), the Allan deviation is used by manufacturers of frequency standards as a standard specification for stability. The equation for the Allan deviation is:

$$\sigma_y(\tau) = \sqrt{\frac{1}{2(M-1)} \sum_{i=1}^{M-1} (\bar{y}_{i+1} - \bar{y}_i)^2} \quad (19.5)$$

where M is the number of values in the y_i series, and the data are equally spaced in segments τ seconds long. Note that while classical deviation subtracts the mean from each measurement before squaring their summation, the Allan deviation subtracts the previous data point. Since stability is a measure of frequency fluctuations and not of frequency offset, the differencing of successive data points is done to remove the time-dependent noise contributed by the frequency offset. Also, note that the \bar{y} values in the equation do not refer to the average or mean of the dataset, but instead imply that the individual measurements in the dataset are obtained by averaging.

Table 19.2 shows how stability is estimated. The first column is a series of phase measurements recorded at 1 s intervals. Each measurement is larger than the previous measurement. This indicates that the DUT is offset in frequency from the reference and this offset causes a phase deviation. By differencing the raw phase measurements, the phase deviations shown in the second column are obtained. The third column divides the phase deviation (Δt) by the 1 s measurement period to get the frequency offset. Since the phase deviation is about 4 ns^{-1} , it indicates that the DUT has a frequency offset of about 4×10^{-9} . The frequency offset values in the third column form the y_i data series. The last two columns show the first differences of the y_i and the squares of the first differences. Since the sum of the squares equals 2.2×10^{-21} , the equation (where $\tau = 1 \text{ s}$) becomes:

$$\sigma_y(\tau) = \sqrt{\frac{2.2 \times 10^{-21}}{2(9-1)}} = 1.17 \times 10^{-11} \quad (19.6)$$

TABLE 19.2 Using Phase Measurements to Estimate Stability (data recorded at 1 s intervals)

Phase Measurements (ns)	Phase Deviation (ns), Δt	Frequency Offset $\Delta f/1 \text{ s } (y_i)$	First Differences $(y_{i+1} - y_i)$	First Difference Squared $(y_{i+1} - y_i)^2$
3321.44	—	—	—	—
3325.51	4.07	4.07×10^{-9}	—	—
3329.55	4.04	4.04×10^{-9}	-3×10^{-11}	9×10^{-22}
3333.60	4.05	4.05×10^{-9}	$+1 \times 10^{-11}$	1×10^{-22}
3337.65	4.05	4.06×10^{-9}	$+2 \times 10^{-11}$	4×10^{-22}
3341.69	4.04	4.04×10^{-9}	-2×10^{-11}	4×10^{-22}
3345.74	4.05	4.05×10^{-9}	$+1 \times 10^{-11}$	1×10^{-22}
3349.80	4.06	4.06×10^{-9}	$+1 \times 10^{-11}$	1×10^{-22}
3353.85	4.05	4.05×10^{-9}	-1×10^{-11}	1×10^{-22}
3357.89	4.04	4.04×10^{-9}	-1×10^{-11}	1×10^{-22}

Using the same data, the Allan deviation for $\tau = 2 \text{ s}$ can be computed by averaging pairs of adjacent values and using these new averages as data values. For $\tau = 4 \text{ s}$, take the average of each set of four adjacent values and use these new averages as data values. More data must be acquired for longer averaging times. Keep in mind that the confidence level of a stability estimate improves as the averaging time increases. In the above example, we have eight samples for our $\tau = 1 \text{ s}$ estimate. However, one would have only two samples for an estimate of $\tau = 4 \text{ s}$. The confidence level of the estimate (1σ) can be roughly estimated as:

$$\frac{1}{\sqrt{M}} \times 100\% \tag{19.7}$$

In the example, where $M = 9$, the error margin is 33%. With just two samples, the estimate could be in error by as much as 70%. With 10^4 samples, the error margin is reduced to 1%.

A sample Allan deviation graph is shown in [Figure 19.3](#). It shows the stability improving as the measurement period gets longer. Part of this improvement is because measurement system noise becomes less of a factor as the measurement period gets longer. At some point, however, the oscillator will reach its *flicker floor*, and from a practical point of view, no further gains will be made by averaging. The flicker floor is the point where the white noise processes begin to be dominated by nonstationary processes such as frequency drift. Most quartz and rubidium oscillators reach their flicker floor at a measurement period of 10^3 s or less, but cesium oscillators might not reach their flicker floor for 10^5 s (more than 1 day). [Figure 19.3](#) shows a sample Allan deviation graph of a quartz oscillator that is stable to about 5×10^{-12} at 100 s and is approaching its flicker floor [8-10].

Do not confuse stability with frequency offset when reading a specifications sheet. For example, a DUT with a frequency offset of 1×10^{-8} might still reach a stability of 1×10^{-12} in 1000 s. This means that the output frequency of the DUT is stable, even though it is not particularly close to its nameplate frequency. To help clarify this point, [Figure 19.4](#) is a graphical representation of the relationship between frequency offset (accuracy) and stability.

19.3 Frequency Standards

Frequency standards all have an internal device that produces a periodic, repetitive event. This device is called the *resonator*. Of course, the resonator must be driven by an energy source. Taken together, the energy source and the resonator form an *oscillator*. There are two main types of oscillators used as frequency standards: quartz oscillators and atomic oscillators.

FIGURE 19.3 A sample Allan deviation graph.

FIGURE 19.4 The relationship between frequency uncertainty (accuracy) and stability.

Quartz Oscillators

Quartz crystal oscillators first appeared during the 1920s and quickly replaced pendulum devices as laboratory standards for time and frequency [11]. Today, more than 10^9 quartz oscillators are manufactured annually for applications ranging from inexpensive wristwatches and clocks to communications networks and space tracking systems [12]. However, calibration and standards laboratories usually calibrate only the more expensive varieties of quartz oscillators, such as those found inside electronic instruments (like frequency counters) or those designed as standalone units. The cost of a high-quality quartz oscillator ranges from a few hundred to a few thousand dollars.

The quartz crystal inside the oscillator can be made of natural or synthetic quartz, but all modern devices are made of synthetic material. The crystal serves as a mechanical resonator that creates an oscillating voltage due to the *piezoelectric effect*. This effect causes the crystal to expand or contract as voltages are applied. The crystal has a *resonance frequency* that is determined by its physical dimensions and the type of crystal used. No two crystals can be exactly alike or produce exactly the same frequency. The output frequency of a quartz oscillator is either the fundamental resonance frequency or a multiple

FIGURE 19.5 Block diagram of quartz oscillator.

of that frequency. Figure 19.5 is a simplified circuit diagram that shows the basic elements of a quartz oscillator. The amplifier provides the energy needed to sustain oscillation.

Quartz oscillators are sensitive to environmental parameters such as temperature, humidity, pressure, and vibration [12, 13]. When environmental parameters change, the fundamental resonance frequency also changes. There are several types of quartz oscillator designs that attempt to reduce the environmental problems. The *oven-controlled crystal oscillator* (OCXO) encloses the crystal in a temperature-controlled chamber called an oven. When an OCXO is first turned on, it goes through a “warm-up” period while the temperatures of the crystal resonator and its oven stabilize. During this time, the performance of the oscillator continuously changes until it reaches its normal operating temperature. The temperature within the oven then remains constant, even when the outside temperature varies. An alternative solution to the temperature problem is the *temperature-compensated crystal oscillator* (TCXO). In a TCXO, the output signal from a special temperature sensor (called a thermistor) generates a correction voltage that is applied to a voltage-variable reactance (called a varactor). The varactor then produces a frequency change equal and opposite to the frequency change produced by temperature. This technique does not work as well as oven control, but is much less expensive. Therefore, TCXOs are normally used in small, usually portable units when high performance over a wide temperature range is not required. A third type of quartz oscillator is the *microcomputer-compensated crystal oscillator* (MCXO). The MCXO uses a microprocessor and compensates for temperature using digital techniques. The MCXO falls between a TCXO and an OCXO in both price and performance.

All quartz oscillators are subject to *aging*, which is defined as “a systematic change in frequency with time due to internal changes in the oscillator.” Aging is usually observed as a nearly linear change in the resonance frequency. Aging can be positive or negative and, occasionally, a reversal in aging direction is observed. Often, the resonance frequency decreases, which may indicate that the crystal is getting larger. Aging has many possible causes, including contamination of the crystal due to deposits of foreign material, changes in the oscillator circuitry, or changes in the quartz material or crystal structure. The vibrating motion of the crystal can also contribute to aging. High-quality quartz oscillators age at a rate of 5×10^{-9} per year or less.

In spite of the temperature and aging problems, the best OCXOs can achieve frequency offsets as small as 1×10^{-10} . Less expensive oscillators produce less impressive results. Small ovenized oscillators (such as those used as timebases in frequency counters) typically are offset in frequency by $\pm 1 \times 10^{-9}$ and cost just a few hundred dollars. The lowest priced quartz oscillators, such as those found in wristwatches and electronic circuits, cost less than \$1. However, because they lack temperature control, these oscillators have a frequency offset of about $\pm 1 \times 10^{-6}$ in the best case and may be offset as much as $\pm 1 \times 10^{-4}$.

Since the frequency offset of a quartz oscillator changes substantially over long periods of time, regular adjustments might be needed to keep the frequency within tolerance. For example, even the best quartz

oscillators need regular adjustments to maintain frequency within $\pm 1 \times 10^{-10}$. On the other hand, quartz oscillators have excellent short-term stability. An OCXO might be stable to 1×10^{-12} at 1 s. The limitations in short-term stability are mainly due to noise from electronic components in the oscillator circuits.

Atomic Oscillators

Atomic oscillators use the quantized energy levels in atoms and molecules as the source of their resonance frequency. The laws of quantum mechanics dictate that the energies of a bound system, such as an atom, have certain discrete values. An electromagnetic field can boost an atom from one energy level to a higher one. Or, an atom at a high energy level can drop to a lower level by emitting electromagnetic energy. The resonance frequency (f) of an atomic oscillator is the difference between the two energy levels divided by Planck's constant (h) [14]:

$$f = \frac{E_2 - E_1}{h} \quad (19.8)$$

All atomic oscillators are *intrinsic standards*, since their frequency is inherently derived from a fundamental natural phenomenon. There are three main types of atomic oscillators: rubidium standards, cesium standards, and hydrogen masers (discussed individually in the following sections). All three types contain an internal quartz oscillator that is locked to a resonance frequency generated by the atom of interest. Locking the quartz oscillator to the atomic frequency is advantageous. Most of the factors that degrade the long-term performance of a quartz oscillator disappear, because the atomic resonance frequency is much less sensitive to environmental conditions than the quartz resonance frequency. As a result, the long-term stability and uncertainty of an atomic oscillator are much better than those of a quartz oscillator, but the short-term stability is unchanged.

Rubidium Oscillators

Rubidium oscillators are the lowest priced members of the *atomic* oscillator group. They offer perhaps the best price/performance ratio of any oscillator. They perform much better than a quartz oscillator and cost much less than a cesium oscillator.

A rubidium oscillator operates at the resonance frequency of the rubidium atom (^{87}Rb), which is 6,834,682,608 Hz. This frequency is synthesized from a lower quartz frequency (typically 5 MHz) and the quartz frequency is steered by the rubidium resonance. The result is a very stable frequency source with the short-term stability of quartz, but much better long-term stability. Since rubidium oscillators are more stable than quartz oscillators, they can be kept within tolerance with fewer adjustments. The initial price of a rubidium oscillator (typically from \$3000 to \$8000) is higher than that of a quartz oscillator, but because fewer adjustments are needed, labor costs are reduced. As a result, a rubidium oscillator might be less expensive to own than a quartz oscillator in the long run.

The frequency offset of a rubidium oscillator ranges from 5×10^{-10} to 5×10^{-12} after its warm-up period. Maintaining frequency within $\pm 1 \times 10^{-11}$ can be done routinely with a rubidium oscillator but is impractical with even the best quartz oscillators. The performance of a well-maintained rubidium oscillator can approach the performance of a cesium oscillator, and a rubidium oscillator is much smaller, more reliable, and less expensive.

Cesium Oscillators

Cesium oscillators are *primary frequency standards* because the SI second is based on the resonance frequency of the cesium atom (^{133}Cs), which is 9,192,631,770 Hz. This means that a cesium oscillator that is working properly should be very close to its nameplate frequency without any adjustment, and there should be no change in frequency due to aging. The time scale followed by all major countries, Coordinated Universal Time (UTC), is derived primarily from averaging the performance of a large ensemble of cesium oscillators.

Cesium oscillators are the workhorses in most modern time and frequency distribution systems. The primary frequency standard for the United States is a cesium oscillator named NIST-7 with a frequency uncertainty of about $\pm 5 \times 10^{-15}$. Commercially available cesium oscillators differ in quality, but their frequency uncertainty should still be $\pm 5 \times 10^{-12}$ or less.

The two major drawbacks of cesium oscillators involve reliability and cost. Reliability is a major issue. The major component of a cesium oscillator, called the *beam tube*, has a life expectancy of about 3 years to 10 years. The beam tube is needed to produce the resonance frequency of the cesium atom, and this frequency is then used to discipline a quartz oscillator. When the beam tube fails, the cesium oscillator performs like an undisciplined quartz oscillator. For this reason, a cesium oscillator needs to be constantly monitored to make sure that it is still delivering a cesium-derived frequency. Cost is also a major issue. The initial purchase price of a cesium oscillator ranges from \$30,000 to \$80,000 and maintenance costs are high. The cost of a replacement beam tube is a substantial fraction of the cost of the entire oscillator. Laboratories that use cesium oscillators need to budget not only for their initial purchase, but for the cost of maintaining them afterward.

Hydrogen Masers

The *hydrogen maser* is the most elaborate and most expensive commercially available frequency standard. Few masers are built and most are owned by observatories or national standards laboratories. The word “maser” is an acronym that stands for Microwave Amplification by Stimulated Emission of Radiation. Masers derive their frequency from the resonance frequency of the hydrogen atom, which is 1,420,405,752 Hz.

There are two types of hydrogen masers. The first type, called an *active maser*, oscillates spontaneously and a quartz oscillator is phase-locked to this active oscillation. The second type, called a *passive maser*, frequency-locks a quartz oscillator to the atomic reference. The “passive” technique is also used by rubidium and cesium oscillators. Since active masers derive the output frequency more directly from the atomic resonance, they have better short-term stability than passive masers. However, both types of maser have better short-term stability than a cesium oscillator. Even so, the frequency uncertainty of a maser is still greater than that of a cesium oscillator because its operation is more critically dependent on a complex set of environmental conditions. Although the performance of a hydrogen maser is excellent, its cost is still very high, typically \$200,000 or more [15, 16].

Table 19.3 summarizes the characteristics of the different types of oscillators.

19.4 Transfer Standards

To briefly review, a frequency calibration compares the *device under test* (DUT) to a reference. The DUT is usually a quartz, rubidium, or cesium oscillator. The reference is an oscillator of higher performance than the DUT or a *transfer standard* that receives a radio signal. All transfer standards receive a signal that has a cesium oscillator at its source, and this signal delivers a cesium-derived frequency to the user. This benefits many users, because cesium oscillators are expensive both to buy and maintain, and not all calibration laboratories can afford them. Even if a laboratory already has a cesium oscillator, it still needs to check its performance. The only practical way to do this is by comparing the cesium to a transfer standard.

Transfer standards also provide *traceability*. Most transfer standards receive signals traceable to the national frequency standard maintained by NIST. Some signals, such as those transmitted by HF (high frequency) radio stations WWV and WWVH and the LF (low frequency) station WWVB, are traceable because they are directly controlled by NIST. Other signals, like the LORAN-C and Global Positioning System (GPS) satellite broadcasts, are traceable because their reference is regularly compared to NIST. Some signals broadcast from outside the United States are also considered to be traceable. This is because NIST compares its frequency standard to the standards maintained in other countries.

Some compromises are made when using a transfer standard. Even if the radio signal is referenced to a nearly perfect frequency, its performance is degraded as it travels along the radio path between the transmitter and receiver. To illustrate, consider a laboratory that has a rack-mounted frequency standard

TABLE 19.3 Summary of Oscillator Types

Oscillator type	Quartz (TCXO)	Quartz (MCXO)	Quartz (OCXO)	Rubidium	Cesium	Hydrogen maser
Primary standard	No	No	No	No	Yes	No
Intrinsic standard	No	No	No	Yes	Yes	Yes
Resonance frequency	Mechanical (varies)	Mechanical (varies)	Mechanical (varies)	6.834682608 GHz	9.19263177 GHz	1.420405752 GHz
Leading cause of failure	None	None	None	Rubidium lamp (15 years)	Cesium beam tube (3 to 10 years)	Hydrogen depletion (7 years +)
Power (W)	0.05	0.04	0.6	20	30	>100
Stability, $\sigma_y(\tau)$, $\tau = 1$ s	1×10^{-9}	3×10^{-10}	1×10^{-12}	5×10^{-11} – 5×10^{-12}	5×10^{-11} – 5×10^{-12}	$\leq 1 \times 10^{-12}$
Aging/year	5×10^{-7}	3×10^{-8}	5×10^{-9}	2×10^{-10}	None	$\leq 1 \times 10^{-13}$
Frequency Offset after Warm-up	1×10^{-6}	1×10^{-8}	1×10^{-8} – 1×10^{-10}	5×10^{-10} – 5×10^{-12}	5×10^{-12} – 1×10^{-14}	1×10^{-12} – 1×10^{-13}
Warm-up time	<10 s– 1×10^{-6}	<10 s– 1×10^{-8}	<5 min– 1×10^{-8}	<5 min– 5×10^{-10}	30 min– 5×10^{-12}	24 h– 1×10^{-12}
Cost	\$100	\$1000	\$2000	\$3000–\$8000	\$30,000–\$80,000	\$200,000–\$300,000

TABLE 19.4 Traceability Levels Provided by Various Transfer Standards

Transfer standard	Frequency uncertainty over 24 h measurement period (with respect to NIST)
HF receiver (WWV and WWVH)	$\pm 1 \times 10^{-7}$
LF receiver (LORAN-C and WWVB)	$\pm 1 \times 10^{-12}$
Global Positioning System (GPS) Receiver	$\pm 5 \times 10^{-13}$

that produces a 5 MHz signal. Metrologists need to use this signal on their work bench, so they run a length of coaxial cable from the frequency standard to their bench. The signal is delayed as it travels from the standard to the bench, but because the cable is of fixed length, the delay is constant. Constant delays do not change the frequency. The frequency that goes into one end of the cable is essentially the same frequency that comes out the other end. However, what if the cable length were constantly changing? This would generally cause the frequency to fluctuate. Over long periods of time, these fluctuations will average out, but the short-term frequency stability would still be very poor. This is exactly what happens when one uses a transfer standard. The “cable” is actually a radio path that might be thousands of kilometers in length. The length of the radio path is constantly changing and appears to introduce frequency fluctuations, even though the source of the frequency (a cesium oscillator) is not changing. This makes transfer standards unsuitable as a reference when making short-term stability measurements. However, transfer standards are well suited for measuring frequency uncertainty, because one can minimize and even eliminate the effects of these frequency fluctuations if one averages for a long enough measurement interval. Eventually, the performance of a cesium oscillator will be recovered.

Some radio signals have path variations that are so pronounced that they are not well suited for high-level frequency calibrations. To illustrate this, consider the signal broadcast from WWV, located in Fort Collins, CO. WWV is an HF radio station (often called a *shortwave* station) that transmits on 2.5, 5, 10, 15, and 20 MHz. WWV is referenced to the national frequency standard at NIST, but by the time the signal gets to the receiver, much of its potential performance has been lost. Most shortwave users receive the *skywave*, or the part of the signal that travels up to the ionosphere and is reflected back to Earth. Since the height of the ionosphere constantly changes, the path delay constantly changes, often by as much as 500 μs to 1000 μs . Because there is so much variability in the path, averaging leads to only limited improvement. Therefore, even though WWV is traceable to NIST, its frequency uncertainty is limited to $\pm 1 \times 10^{-7}$ when averaged for 1 day.

Other radio signals have more stable paths and much lower uncertainty values. Low-frequency (LF) radio stations (like NIST radio station WWVB and LORAN-C) can provide traceability to NIST with a frequency uncertainty of $\pm 1 \times 10^{-12}$ per day. An LF path is much more stable than an HF path, but still experiences a path delay change when the height of the ionosphere changes at sunrise and sunset. Currently, the most widely used signals originate from the Global Positioning System (GPS) satellites. GPS signals have the advantage of an unobstructed path between the transmitter and receiver. The frequency uncertainty of GPS is about $\pm 5 \times 10^{-13}$ /day. WWVB, LORAN-C, and GPS are described in the next three sections.

Table 19.4 shows some of the transfer standards available and the level of NIST traceability they provide when averaged for a measurement period of at least 24 h [17].

WWVB

Many countries broadcast time and frequency signals in the LF band from 30 kHz to 300 kHz, as well as in the VLF (very low frequency) band from 3 kHz to 30 kHz. Because part of the LF signal is *groundwave* and follows the curvature of the Earth, the path stability of these signals is acceptable for many applications. One such station is WWVB, which is operated by NIST. WWVB transmits on 60 kHz from the same site as WWV in Fort Collins, CO. The signal currently covers most of North America, and a power increase (6 dB, scheduled for 1998) will increase the coverage area and improve the signal-to-noise ratio within the United States.

Although far more stable than an HF path, the WWVB path length is influenced by environmental conditions along the path and by daily and seasonal changes. Path length is important because part of the signal travels along the ground (*groundwave*) and another part is reflected from the ionosphere (*skywave*). The groundwave path is far more stable than the skywave path. If the path is relatively short (less than 1000 km), the receiver might continuously track the groundwave signal because it always arrives first. For longer paths, a mixture of groundwave and skywave is received. And over a very long path, the groundwave might become so weak that it will only be possible to receive the skywave. In this instance, the path becomes much less stable.

The characteristics of an LF path are different at different times of day. During the daylight and nighttime hours, the receiver might be able to distinguish between groundwave and skywave, and path stability might vary by only a few hundred nanoseconds. However, if some skywave is being received, *diurnal* phase shifts will occur at sunrise and sunset. For example, as the path changes from all darkness to all daylight, the ionosphere lowers and the path gets shorter. The path length then stabilizes until either the transmitter or receiver enters darkness. At this point, the ionosphere rises and the path gets longer.

WWVB receivers have several advantages when used as a transfer standard. They are low cost and easy to use, and the received signals are directly traceable to NIST. With a good receiver and antenna system, one can achieve a frequency uncertainty of $\pm 1 \times 10^{-12}$ by averaging for 1 day [18].

LORAN-C

LORAN-C is a radionavigation system that operates in the LF band. Most of the system is operated by the U.S. Department of Transportation (DOT), but some stations are operated by other governments. The system consists of groups of stations called *chains*. Each chain has one master station and from two to five secondary stations. The stations operate at high power, typically 275 kW to 800 kW, and broadcast on a carrier frequency of 100 kHz using the 90 kHz to 110 kHz band.

Since all LORAN-C chains use the same carrier frequency, the chains transmit pulses so that individual stations can be identified. Each chain transmits a pulse group that includes pulses from all of the individual stations. The pulse group is sent at a unique Group Repetition Interval (GRI). For example, the 7980 chain transmits pulses every 79.8 ms. When the pulses leave the transmitter, they radiate in all directions. The *groundwave* travels parallel to the surface of the Earth. The *skywave* travels upward and is reflected off the ionosphere. The pulse shape was designed so that the receiver can distinguish between groundwave and skywave and lock onto the more stable groundwave signal. Most receivers stay locked to the groundwave by tracking the third cycle of the pulse. The third cycle was chosen for two reasons. First, it arrives early in the pulse so we know that it is groundwave. Second, it has more amplitude than the first and second cycles in the pulse, which makes it easier for the receiver to stay locked. Generally, a receiver within 1500 km of the transmitter can track the same groundwave cycle indefinitely and avoid skywave reception. The variations in groundwave path delay are typically quite small (<500 ns per day). However, if the path length exceeds 1500 km, the receiver might lose lock, and jump to another cycle of the carrier. Each cycle jump introduces a 10 μ s phase step, equal to the period of 100 kHz.

Commercially available LORAN-C receivers designed as transfer standards range in price from about \$3000 to \$10,000. These receivers typically provide several different frequency outputs (usually 10 MHz, 1 Hz, and the GRI pulse). LORAN-C navigation receivers are mass produced and inexpensive but do not provide a frequency output. However, it is sometimes possible to find and amplify the GRI pulse on the circuit board and use it as a reference frequency.

LORAN-C Performance

The frequency uncertainty of LORAN-C is degraded by variations in the radio path. The size of these variations depends on the signal strength, the distance between the receiver and the transmitter, the weather and atmospheric conditions, and the quality of the receiver and antenna. [Figure 19.6](#) shows the type of path variations one can typically expect. It shows a 100 s phase comparison between the LORAN-C

FIGURE 19.6 LORAN-C path variations during 100 s measurement period.

8970 chain as received in Boulder, CO, and the NIST national frequency standard. The 8970 signal is broadcast from the master station in Dana, IN, a site about 1512 km from Boulder. The frequency offset between the NIST frequency standard and the cesium standard at the LORAN-C transmitter would produce a phase shift of <1 ns per 100 s. Therefore, the graph simply shows the LORAN-C path noise or the difference in the arrival times of the GRI pulses due to path variations. The range of this path noise is about 200 ns.

The path variations cause the short-term stability of LORAN-C to be poor. However, because the path variations average out over time, the long-term stability is much better. This means that we can use LORAN-C to calibrate nearly any frequency standard if we average for a long enough interval. The better the frequency standard, the longer it takes to obtain a TUR approaching 10:1. For example, a quartz oscillator with a frequency uncertainty of 1×10^{-7} could be calibrated in 100 s. The quartz would accumulate $10 \mu\text{s}$ of phase shift in 100 s, and this would completely hide the path noise shown in Figure 19.6. However, a rubidium oscillator with a frequency uncertainty of 1×10^{-11} would accumulate only 1 ns of phase shift in 100 s, or about $1 \mu\text{s}$ per day. For this reason, a measurement period of at least 24 h is recommended when using LORAN-C to calibrate atomic oscillators. Figure 19.7 shows the results of a 96 h calibration of a cesium oscillator using LORAN-C. The thick line is a least squares estimate of the frequency offset. Although the path noise is clearly visible, the slope of the line indicates that the cesium oscillator is low in frequency by $\approx 3.4 \times 10^{-12}$.

Global Positioning System (GPS)

The Global Positioning System (GPS) is a radionavigation system developed and operated by the U.S. Department of Defense (DOD). The system consists of a constellation of 24 Earth orbiting satellites (21 primary satellites and 3 in-orbit spares). Each satellite carries four atomic frequency standards (two

FIGURE 19.7 LORAN-C compared to cesium oscillator over 96 h interval.

rubidiums and two cesiums) that are referenced to the United States Naval Observatory (USNO) and traceable to NIST. The 24 satellites orbit the Earth in six fixed planes inclined 55° from the equator. Each satellite is 20,200 km above the Earth and has an 11 h, 58 min orbital period, which means a satellite will pass over the same place on Earth 4 min earlier each day. Since the satellites continually orbit the Earth, GPS should be usable anywhere on the Earth's surface.

Each GPS satellite broadcasts on two carrier frequencies: L1 at 1575.42 MHz and L2 at 1227.6 MHz. Each satellite broadcasts a spread spectrum waveform called a *pseudo-random noise* (PRN) code on L1 and L2, and each satellite is identified by the PRN code it transmits. There are two types of PRN codes. The first type is a *coarse acquisition* code (called the C/A code) with a chip rate of 1023 chips per millisecond. The second is a *precision* code (called the P code) with a chip rate of 10230 chips per millisecond. The C/A code repeats every millisecond. The P code repeats only every 267 days, but for practical reasons is reset every week. The C/A code is broadcast on L1, and the P code is broadcast on both L1 and L2 [19, 20].

For national security reasons, the DOD started the *Selective Availability* (SA) program in 1990. SA intentionally increases the positioning and timing uncertainty of GPS by adding about 300 ns of noise to both the C/A code and the P code. The resulting signal is distributed through the *Standard Positioning Service* (SPS). The SPS is intended for worldwide use, and can be used free of charge by anyone with a GPS receiver. The *Precise Positioning Service* (PPS) is available only to users authorized by the United States military. PPS users require a special receiver that employs cryptographic logic to remove the effects of SA. Because PPS use is restricted, nearly all civilian GPS users use the SPS.

GPS Receiving Equipment

At this writing (1996), GPS receivers have become common-place in the consumer electronics market, and some models cost \$200 or less. However, receivers suitable for use as a transfer standard are much

less common, and more expensive. Receivers range in price from less than \$100 for an OEM timing board, to \$20,000 or more for the most sophisticated models. The price often depends on the quality of the receiver's timebase oscillator. Lower priced models have a low-quality timebase that must be constantly steered to follow the GPS signal. Higher priced receivers have better timebases (some have internal rubidium oscillators) and can ignore many of the GPS path variations because their oscillator allows them to coast for longer intervals [21].

Most GPS receivers provide a 1 *pulse per second* (pps) output. Some receivers also provide a 1 kHz output (derived from the C/A code) and at least one standard frequency output (1, 5, or 10 MHz). To use these receivers, one simply mounts the antenna, connects the antenna to the receiver, and turns the receiver on. The antenna is often a small cone or disk (normally about 15 cm in diameter) that must be mounted outdoors where it has a clear, unobstructed view of the sky. Once the receiver is turned on, it performs a sky search to find out which satellites are currently above the horizon and visible from the antenna site. It then computes its three-dimensional coordinate (latitude, longitude, and altitude as long as four satellites are in view) and begins producing a frequency signal. The simplest GPS receivers have just one channel and look at multiple satellites using a sequencing scheme that rapidly switches between satellites. More sophisticated models have parallel tracking capability and can assign a separate channel to each satellite in view. These receivers typically track from 5 to 12 satellites at once (although more than 8 will only be available in rare instances). By averaging data from multiple satellites, a receiver can remove some of the effects of SA and reduce the frequency uncertainty.

GPS Performance

GPS has many technical advantages over LORAN-C. The signals are usually easier to receive, the equipment is often less expensive, and the coverage area is much larger. In addition, the performance of GPS is superior to that of LORAN-C. However, like all transfer standards, the short-term stability of a GPS receiver is poor (made worse by SA), and it lengthens the time required to make a calibration. As with LORAN-C, a measurement period of at least 24 h is recommended when calibrating atomic frequency standards using GPS.

To illustrate this, [Figure 19.8](#) shows a 100 s comparison between GPS and a cesium oscillator. The cesium oscillator has a frequency offset of $\approx 1 \times 10^{-13}$, and its accumulated phase shift during the 100 s measurement period is < 1 ns. Therefore, the noise on the graph can be attributed to GPS path variations and SA.

[Figure 19.9](#) shows a 1-week comparison between a GPS receiver and the same cesium oscillator used in [Figure 19.8](#). The range of the data is 550 ns. The thick line is a least squares estimate of the frequency offset. Although the GPS path noise is still clearly visible, one can see the linear trend contributed by the frequency offset of the cesium; this trend implies that the cesium oscillator is low in frequency by $\approx 5 \times 10^{-13}$.

19.5 Calibration Methods

To review, frequency standards are normally calibrated by comparing them to a traceable reference frequency. In this section, a discussion of how this comparison is made, is presented. To begin, look at the electric signal produced by a frequency standard. This signal can take several forms, as illustrated in [Figure 19.10](#). The dashed lines represent the supply voltage inputs (ranging from 5 V to 15 V for CMOS), and the bold solid lines represent the output voltage.

If the output frequency is an oscillating sine wave, it might look like the one shown in [Figure 19.11](#). This signal produces one cycle (2π radians of phase) in one period. Frequency calibration systems compare a signal like the one shown in [Figure 19.11](#) to a higher quality reference signal. The system then measures and records the change in phase between the two signals. If the two frequencies were exactly the same, their phase relationship would not change. Because the two frequencies are not exactly the same, their phase relationship will change; and by measuring the rate of change, one can determine the frequency offset of the DUT. Under normal circumstances, the phase changes in an orderly, predictable fashion. However, external factors like power outages, component failures, or human errors can cause a sudden

FIGURE 19.8 GPS compared to cesium oscillator over 100 s interval.

phase change, or *phase step*. A calibration system measures the total amount of phase shift (caused either by the frequency offset of the DUT or a phase step) over a given measurement period.

Figure 19.12 shows a phase comparison between two sinusoidal frequencies. The top sine wave represents a signal from the DUT, and the bottom sine wave represents a signal from the reference. Vertical lines have been drawn through the points where each sine passes through zero. The bottom of the figure shows “bars” that indicate the size of the phase difference between the two signals. If the phase relationship between the signals is changing, the phase difference will either increase or decrease to indicate that the DUT has a frequency offset (high or low) with respect to the reference. Equation 19.1 estimates the frequency offset. In Figure 19.12, both Δt and T are increasing at the same rate and the phase difference “bars” are getting wider. This indicates that the DUT has a constant frequency offset.

There are several types of calibration systems that can be used to make a phase comparison. The simplest type of system involves directly counting and displaying the frequency output of the DUT with a device called a *frequency counter*. This method has many applications but is unsuitable for measuring high-performance devices. The DUT is compared to the counter’s timebase (typically a TCXO), and the uncertainty of the system is limited by the performance of the timebase, typically $\approx 1 \times 10^{-8}$. Some counters allow use of an external timebase, which can improve the results. The biggest limitation is that frequency counters display frequency in hertz and have a limited amount of resolution. Detecting small changes in frequency could take many days or weeks, which makes it difficult or impossible to use this method to adjust a precision oscillator or to measure stability [22]. For this reason, most high-performance calibration systems collect time series data that can be used to estimate both frequency uncertainty and stability. A discussion follows on how phase comparisons are made using two different methods, the *time interval method* and the *dual mixer time difference method* [9, 10].

The time interval method uses a device called a *time interval counter* (TIC) to measure the time interval between two signals. A TIC has inputs for two electrical signals. One signal starts the counter and the

FIGURE 19.9 GPS compared to cesium oscillator over 1 week interval.

FIGURE 19.10 Oscillator outputs.

other signal stops it. If the two signals have the same frequency, the time interval will not change. If the two signals have different frequencies, the time interval will change, although usually very slowly. By looking at the rate of change, one can calibrate the device. It is exactly as if there were two clocks. By reading them each day, one can determine the amount of time one clock gained or lost relative to the other clock. It takes two time interval measurements to produce any useful information. By subtracting the first measurement from the second, one can tell whether time was gained or lost.

TICs differ in specification and design details, but they all contain several basic parts known as the *timebase*, the *main gate*, and the *counting assembly*. The timebase provides evenly spaced pulses used to measure time interval. The timebase is usually an internal quartz oscillator that can often be phase locked to an external reference. It must be stable because timebase errors will directly affect the measurements.

FIGURE 19.11 An oscillating signal.

FIGURE 19.12 Two signals with a changing phase relationship.

The main gate controls the time at which the count begins and ends. Pulses that pass through the gate are routed to the counting assembly, where they are displayed on the TIC's front panel or read by computer. The counter can then be reset (or *armed*) to begin another measurement. The stop and start inputs are usually provided with level controls that set the amplitude limit (or *trigger level*) at which the counter responds to input signals. If the trigger levels are set improperly, a TIC might stop or start when it detects noise or other unwanted signals and produce invalid measurements.

FIGURE 19.13 Measuring time interval.

Figure 19.13 illustrates how a TIC measures the interval between two signals. Input A is the start pulse and Input B is the stop pulse. The TIC begins measuring a time interval when the start signal reaches its trigger level and stops measuring when the stop signal reaches its trigger level. The time interval between the start and stop signals is measured by counting cycles from the timebase. The measurements produced by a TIC are in time units: milliseconds, microseconds, nanoseconds, etc. These measurements assign a value to the phase difference between the reference and the DUT.

The most important specification of a TIC is *resolution*; that is, the degree to which a measurement can be determined. For example, if a TIC has a resolution of 10 ns, it can produce a reading of 3340 ns or 3350 ns, but not a reading of 3345 ns. Any finer measurement would require more resolution. In simple TIC designs, the resolution is limited to the period of the TIC's timebase frequency. For example, a TIC with a 10 MHz timebase is limited to a resolution of 100 ns if the unit cannot resolve time intervals smaller than the period of one cycle. To improve this situation, some TIC designers have multiplied the timebase frequency to get more cycles and thus more resolution. For example, multiplying the timebase frequency to 100 MHz makes 10 ns resolution possible, and 1 ns counters have even been built using a 1 GHz timebase. However, a more common way to increase resolution is to detect parts of a timebase cycle through interpolation and not be limited by the number of whole cycles. Interpolation has made 1 ns TICs commonplace, and 10 ps TICs are available [23].

A time interval system is shown in Figure 19.14. This system uses a TIC to measure and record the difference between two signals. Low-frequency start and stop signals must be used (typically 1 Hz). Since oscillators typically produce frequencies like 1, 5, and 10 MHz, the solution is to use a *frequency divider* to convert them to a lower frequency. A frequency divider could be a stand-alone instrument, a small circuit, or just a single chip. Most divider chips divide by multiples of 10, so it is common to find circuits that divide by a thousand, a million, etc. For example, dividing a 1 MHz signal by 10^6 produces a 1 Hz signal. Using low-frequency signals reduces the problem of counter overflows and underflows and helps prevent errors that could be made if the start and stop signals are too close together. For example, a TIC might make errors when attempting to measure a time interval of <100 ns.

The time interval method is probably the most common method in use today. It has many advantages, including low cost, simple design, and excellent performance when measuring long-term frequency uncertainty or stability. There are, however, two problems that can limit its performance when measuring short-term stability. The first problem is that after a TIC completes a measurement, the data must be processed before the counter can reset and prepare for the next measurement. During this delay, called *dead time*, some information is lost. Dead time has become less of a problem with modern TICs where

FIGURE 19.14 Time interval system.

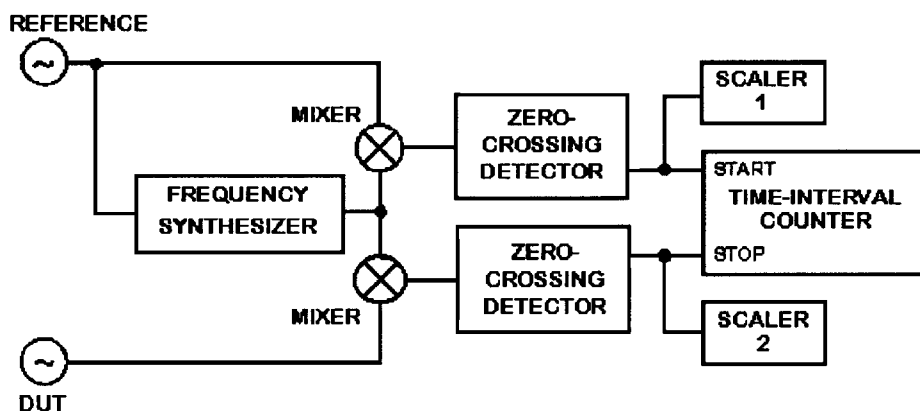

FIGURE 19.15 Dual mixer time difference system.

faster hardware and software has reduced the processing time. A more significant problem when measuring short-term stability is that the commonly available frequency dividers are sensitive to temperature changes and are often unstable to ± 1 ns. Using more stable dividers adds to the system cost [10, 22].

A more complex system, better suited for measuring short-term stability, uses the Dual Mixer Time Difference (DMTD) method, shown in Figure 19.15. This method uses a frequency synthesizer and two mixers in parallel. The frequency synthesizer is locked to the reference oscillator and produces a frequency lower than the frequency output of the DUT. The synthesized frequency is then heterodyned (or mixed) both with the reference frequency and the output of the DUT to produce two beat frequencies. The beat frequencies are out of phase by an amount proportional to the time difference between the DUT and reference. A *zero crossing detector* is used to determine the zero crossing of each beat frequency cycle. An event counter (or *scaler*) accumulates the coarse phase difference between the oscillators by counting the number of whole cycles. A TIC provides the fine-grain resolution needed to count fractional cycles. The resulting system is much better suited for measuring short-term stability than a time interval system. The oscillator, synthesizer, and mixer combination provides the same function as a divider, but the noise is reduced, often to ± 5 ps or less.

Other variations of these calibration methods are used and might be equally valid for a particular application [9, 10, 21, 22]. Keep in mind that a well-defined and documented calibration method is mandatory for a laboratory seeking ISO registration or compliance with a laboratory accreditation program.

19.6 Future Developments

In future years, the performance of frequency standards will continue to improve. One promising development is the *cesium-fountain* standard. This device works by laser cooling cesium atoms and then lofting them vertically through a microwave cavity. The resonance frequency is detected as the atoms rise and fall under the influence of gravity. Many laboratories are working on this concept, which should reduce the frequency uncertainty realized with existing atomic-beam cesium standards [24]. Eventually, a *trapped-ion* standard could lead to improvements of several orders of magnitude. This standard derives its resonance frequency from the systematic energy shifts in transitions in certain ions that are held motionless in an electromagnetic trap. The frequency uncertainty of such a device could be as small as $\pm 1 \times 10^{-18}$ [25]. Also, new statistical tools could improve the ability to estimate oscillator stability, particularly at long term [26].

The future of transfer standards should involve more and more reliance on satellite receivers, and their performance should continue to improve. Ground-based systems such as LORAN-C are expected to be phased out [27]. The frequency uncertainty of GPS receivers will improve when the Selective Availability (SA) program is discontinued in the early part of the next century [28].

20.1 Weighing Instruments

20.2 Weighing Techniques

Mass and weight are often used interchangeably; however, they are different. Mass is a quantitative measure of inertia of a body at rest. As a physical quantity, mass is the product of density and volume.

Weight or weight force is the force with which a body is attracted toward the Earth. Weight force is determined by the product of the mass and the acceleration of gravity.

$$M = V \times D \quad (20.1)$$

where M = mass

V = volume

D = density

Note: In most books, the symbol for density is the Greek letter ρ .

$$W = M \times G \quad (20.2)$$

where W = weight

G = gravity

The embodiment of units of mass are called weights; this increases the confusion between mass and weight. In the International System of Units (SI), the modernized metric measurement system, the unit for mass is called the kilogram and the unit for force is called the newton. In the United States, the customary system the unit for mass is called the slug and the unit for force is called the pound. When using the U.S. customary units of measure, people are using the unit pound to designate the mass of an object because, in the United States, the pound has been defined in terms of the kilogram since 1893.

20.1 Weighing Instruments

Weighing is one of the oldest known measurements, dating back to before written history. The equal arm balance was probably the first instrument used for weighing. It is a simple device in which two pans are suspended from a beam equal distance from a central pivot point. The standard is placed in one pan and the object to be measured is placed in the second pan; when the beam is level, the unknown is equal to the standard. This method of measurement is still in wide use throughout the world today. [Figure 20.1](#) shows an Ainsworth equal arm balance.

FIGURE 20.1 Ainsworth FV series equal arm balance. (Courtesy Denver Instrument Company.)

A balance is a measuring instrument used to determine the mass of an object by measuring the force exerted by the object on its support within the gravitational field of the Earth. One places a standard of known value on one pan of the balance. One then adds the unknown material to the second pan, until the gravitational force on the unknown material equals the gravitational force on the standard. This can be expressed mathematically as:

$$S \times G = U \times G \quad (20.3)$$

where S = mass of the standard
 G = gravity
 U = mass of the unknown

Given the short distance between pans, one assumes that the gravitational forces acting on them are equal. Another assumption is that the two arms of the balance are equal.

Since the gravitational force is equal, it can be removed from the equation and the standard and the unknown are said to be equal. This leads to one of the characteristics of the equal arm balance as well as of other weighing devices, the requirement to have a set of standards that allows for every possible measured value. The balance can only indicate if objects are equal and has a limited capability to determine how much difference there is between two objects.

Probably, the first attempt to produce direct reading balances was the introduction of the single pan substitution balance. A substitution balance is, in principle, similar to an equal arm balance. The object to be measured is placed in the weighing pan; inside the balance are a series of calibrated weights that can be added to the standard side of the balance, through the use of dials and levers. The standard weights can be added and subtracted through the use of the balance's mechanical system, to equal a large variety of weighing loads. Very small differences between the standard weights and the load are read out on an optical scale.

The spring scale is probably the least expensive device for making mass measurements. The force of gravity is once again used as the reference. The scale is placed so that the unknown object is suspended by the spring and the force of gravity can freely act on the object. The elasticity of the spring is assumed to be linear and the force required to stretch it is marked on the scale. When the force of gravity and the elastic force of the spring balance, the force is read from the scale, which has been calibrated in units of mass. Capacity can be increased by increasing the strength of the spring. However, as the strength of the spring increases, the resolution of the scale decreases. This decrease in resolution limits spring scales to relatively small loads of no more than a few kilograms. There are two kinds of springs used: spiral and cantilevered springs.

The torsion balance is a precise adaptation of the spring concept used to determine the mass indirectly. The vertical force produced by the load produces a torque on a wire or beam. This torque produces an angular deflection. As long as the balance is operated in the linear range, the angular deflection is proportional to the torque. Therefore, the angular deflection is also proportional to the applied load. When the torsion spring constant is calibrated, the angular deflection can be read as a mass unit. Unlike the crude spring scales, it is possible to make torsion balances capable of measuring in the microgram region. The torsion element could be a band, a wire, or a string.

The beam balance is probably the next step in accuracy and cost. The beam balance uses the same principle of operation as the equal arm balance. However, it normally has only one pan and the beam is offset. A set of sliding weights are mounted on the beam. As the weights slide out the beam, they gain a mechanical advantage due to the inequality of the distance from the pivot point of the balance. The weights move out along the beam until the balance is in equilibrium. Along the beam, there are notched positions that are marked to correspond to the force applied by the sliding weights. By adding up the forces indicated by the position of each weight, the mass of the unknown material is determined. Beam balances and scales are available in a wide range of accuracy's load capacities. Beam balances are available to measure in the milligram range and large beam scales are made with capacities to weigh trucks and trains. Once again, the disadvantage is that as load increases the resolution decreases. [Figure 20.2](#) shows an example of a two pan beam balance.

The next progression in cost and accuracy is the strain gage load cell. A strain gage is an electrically resistive wire element that changes resistance when the length of the wire element changes. The gage is bonded to a steel cylinder that will shorten when compressed or lengthen when stretched. Because the gage is bonded to the cylinder, the length of the wire will lengthen or contract with the cylinder. The electrical resistance is proportional to the length of the wire element of the gage. By measuring the resistance of the strain gage, it is possible to determine the load on the load cell. The electric resistance is converted into a mass unit readout by the electric circuitry in the readout device.

The force restorative load cell is the heart of an electronic balance, shown in [Figure 20.3](#). The force restorative load cell uses the principle of the equal arm balance. However, in most cases, the fulcrum is offset so it is no longer an equal arm balance, as one side is designed to have a mechanical advantage. This side of the balance is attached to an electric coil. The coil is suspended in a magnetic field. The other side is still connected to a weighing pan. Attached to the beam is a null indicating device, consisting of a photodiode and a light-emitting diode (LED) that are used to determine when the balance is in equilibrium. When a load is placed on the weighing pan, the balance goes out of equilibrium. The LED photodiode circuit detects that the balance is no longer in equilibrium, and the electric current in the coil is increased to bring the balance back to equilibrium. The electric current is then measured across a precision sense resistor and converted into a mass unit reading and displayed on the digital readout.

FIGURE 20.2 Beam balance. (Courtesy Denver Instrument Company.)

FIGURE 20.3 Force restorative load cell. (Courtesy Denver Instrument Company.)

A variation of the latter is the new generation of industrial scales, laboratory balances, and mass comparators. Mass comparators are no longer called balances because they always perform a comparison between known masses (standards) and unknown masses. These weighing devices are employing the electromagnetic force compensation principle in conjunction with joint flexures elements replacing the

traditional knife-edge joints. Some of the advantages include a computer interfacing capability and a maintenance-free feature because there are no moving parts.

Another measuring method used in the weighing technology is the vibrating cord. A wire or cord of known length, which vibrates transversely, is tensioned by the force F . The vibration frequency changes in direct proportion to the load F . The piezoelectric effect is also used in weighing technology. Such weighing devices consist of the presence of an electric voltage at the surface of a crystal when the crystal is under load. Balances employing the gyroscopic effect are also used. This measuring device uses the output signal of a gyrodynamic cell similar to the frequency. Balances wherein the weight force of the load changes the reference distance of the capacitive or inductive converters are also known. As well, balances using the radioactivity changes of a body as a function of its mass under certain conditions exist.

20.2 Weighing Techniques

When relatively low orders of accuracy are required, reading mass or weight values directly from the weighing instrument are adequate. Except for the equal arm balance and some torsion balances, most modern weighing instruments have direct readout capability. For most commercial transactions and for simple scientific experiments, this direct readout will provide acceptable results.

In the case of equal arm balances, the balance will have a pointer and a scale. When relatively low accuracy is needed, the pointer and scale are used to indicate when the balance is close to equilibrium. The same is true when using a torsion balance. However, the equal arm balances of smaller (e.g., 30 g) or larger (e.g., 900 kg) capacity are also used for high-accuracy applications. Only the new generation of electronic balances are equal or better in terms of accuracy and benefit from other features.

Weighing is a deceptively simple process. Most people have been making and using weighing measurements for most of their lives. We have all gone to the market and purchased food that is priced by weight. We have weighed ourselves many times, and most of us have made weight or mass measurements in school. What could be simpler? One places an object on the weighing pan or platform and reads the result.

Unfortunately, the weighing process is very susceptible to error. There are errors caused by imperfections in the weighing instrument; errors caused by biases in the standards used; errors caused by the weighing method; errors caused by the operator; and errors caused by environmental factors. In the case of the equal arm balance, any difference between the lengths of the arms will result in a bias in the measurement result. Nearly all weighing devices will have some degree of error caused by small amounts of nonlinearity in the device. All standards have some amount of bias and uncertainty. Mass is the only base quantity in the International System of Units (SI) defined in relation with a physical artifact. The international prototype of the kilogram is kept at Sevres in France, under the custody of the International Bureau of Weights and Measures. All weighing measurements originate from this international standard. The international prototype of the kilogram is, by international agreement, exact; however, over the last century, it has changed in value. What one does not know is the exact magnitude or direction of the change. Finally, environmental factors such as temperature, barometric pressure, and humidity can affect the weighing process.

There are many weighing techniques used to reduce the errors in the weighing process. The simplest technique is *substitution weighing*. The substitution technique is used to eliminate some of the errors introduced by the weighing device. The single-substitution technique is one where a known standard and an unknown object are both weighed on the same device. The weighing device is only used to determine the difference between the standard and the unknown. First, the standard is weighed and the weighing device's indication is noted. (In the case of an equal arm balance, tare weights are added to the second pan to bring the balance to equilibrium.) The standard is then removed from the weighing device and the unknown is placed in the same position. Again, the weighing device's indication is noted. The first noted indication is subtracted from the second indication. This gives the difference between the standard and the unknown. The difference is then added to the known value of the standard to calculate the value of the unknown object. A variation of this technique is to use a small weight of known value

to offset the weighing device by a small amount. The amount of offset is then divided by the known value of the small weight to calibrate the readout of the weighing device. The weighing results of this measurement is calculated as follows:

$$U = S + (O_2 - O_1)(SW) / (O_3 - O_2) \quad (20.4)$$

where U = value of the unknown

S = known value of the standard

SW = small sensitivity weight used to calibrate the scale divisions

O_1 = first observation (standard)

O_2 = second observation (unknown)

O_3 = third observation (unknown + SW)

These techniques remove most of the errors introduced by the weighing device, and are adequate when results to a few tenths of a gram are considered acceptable.

If results better than a few tenths of a gram are required, environmental factors begin to cause significant errors in the weighing process. Differences in density between the standard and the unknown object and air density combine together to cause significant errors in the weighing process.

It is the buoyant force that generates the confusion in weighing. What is called the “true mass” of an object is the mass determined in vacuum. The terms “true mass” and “mass in vacuum” are referring to the same notion of inertial mass or mass in the Newtonian sense. In practical life, the measurements are performed in the surrounding air environment. Therefore, the objects participating in the measurement process adhere to the Archimedean principle being lifted with a force equal to the weight of the displaced volume of air. Applying the buoyancy correction to the measurement requires the introduction of the term “apparent mass.” The “apparent mass” of an object is defined in terms of “normal temperature” and “normal air density,” conventionally chosen as 20°C and 1.2 mg cm⁻³, respectively. Because of these conventional values, the “apparent mass” is also called the “conventional mass.” The reference material is either brass (8.4 g cm⁻³) or stainless steel (8.0 g cm⁻³), for which one obtains an “apparent mass versus brass” and an “apparent mass versus stainless steel,” respectively. The latter is preferred for reporting the “apparent mass” of an object.

Calibration reports from the National Institute of Standards and Technology will report mass in three ways: True Mass, Apparent Mass versus Brass, and Apparent Mass versus Stainless Steel. Conventional mass is defined as the mass of an object with a density of 8.0 g cm⁻³, at 20°C, in air with a density of 1.2 mg cm⁻³. However, most scientific weighings are of materials with densities that are different from 8.0 g cm⁻³. This results in significant measurement errors.

As an example, use the case of a chemist weighing 1 liter of water. The chemist will first weigh a mass standard, a 1 kg weight made of stainless steel; then the chemist will weigh the water. The 1 kg mass standard made of 8.0 g cm⁻³ stainless steel will have a volume of 125 cm³. The same mass of water will have a volume approximately equal to 1000 cm³ (Volume = Mass/Density). The mass standard will displace 125 cm³ of air, which will exert a buoyant force of 150 mg (125 cm³ × 1.2 mg cm⁻³). However, the water will displace 1000 cm³ air, which will exert a buoyant force of 1200 mg (1000 cm³ × 1.2 mg cm⁻³). Thus, the chemist has introduced a significant error into the measurement by not taking the differing densities and air buoyancy into consideration.

Using 1.2 mg cm⁻³ for the density of air is adequate for measurements made close to sea level; it must be noted that air density decreases with altitude. For example, the air density in Denver, CO, is approximately 0.98 mg cm⁻³. Therefore, to make accurate mass measurements, one must measure the air density at the time of the measurement if environmental errors in the measurement are to be reduced.

Air density can be calculated to an acceptable value using the following equations:

$$\rho_A \cong 0.0034848 / (t + 273.15) (P - 0.0037960 \times U \times e_s) \quad (20.5)$$

where ρ_A = air density in mg cm^{-3}
 t = temperature in $^{\circ}\text{C}$
 P = barometric pressure in pascals
 U = relative humidity in percent
 e_s = saturation vapor pressure

$$e_s \cong (1.7526 \times 10^{11}) \times e^{(-5315.56/(273.15+t))} \quad (20.6)$$

where $e \cong 2.7182818$
 t = temperature in $^{\circ}\text{C}$

To apply an air buoyancy correction to the single substitution technique, use the following formulae:

$$M_u = \left(M_s \left(1 - \rho_A / \rho_s \right) + (O_2 - O_1) \left(M_{sw} \left(1 - \rho_A / \rho_{sw} \right) / (O_3 - O_2) \right) \right) / \left(1 - \rho_A / \rho_u \right) \quad (20.7)$$

where M_u = mass of the unknown (in a vacuum)
 M_s = mass of the standard (in a vacuum)
 M_{sw} = mass of the sensitivity weight
 ρ_A = air density
 ρ_s = density of the standard
 ρ_u = density of the unknown
 ρ_{sw} = density of the sensitivity weight
 O_1 = first observation (standard)
 O_2 = second observation (unknown)
 O_3 = third observation (unknown + SW)

$$\text{CM} = M_u \left(1 - 0.0012 / \rho_u \right) / 0.99985 \quad (20.8)$$

where CM = conventional mass
 M_u = mass of the unknown in a vacuum
 ρ_u = density of the unknown

When very precise measurements are needed, the double-substitution technique coupled with an air buoyancy correction will provide acceptable results for nearly all scientific applications. The double-substitution technique is similar to the single-substitution technique using the sensitivity weight. In the double-substitution technique, the sensitivity weight is weighed with both the mass standard and the unknown. The main advantage of this technique over single substitution is that any drift in the weighing device is accounted for in the technique. Because of the precision of this weighing technique, it is only appropriate to use it on precision balances or mass comparators. As in the case of single substitution, one places the standard on the balance pan and takes a reading. The standard is then removed and the unknown object is placed on the balance pan and a second reading is taken. The third step is to add the small sensitivity weight to the pan with the unknown object and take a third reading. Then remove the unknown object and return the standard to the pan with the sensitivity weight and take a fourth reading. The mass is calculated using the following formulae:

$$M_u = \frac{\left(M_s \left(1 - \rho_A / \rho_s \right) + (O_2 - O_1 + O_3 - O_4) \right) / 2 \left(M_{sw} \left(1 - \rho_A / \rho_{sw} \right) / (O_3 - O_2) \right)}{\left(1 - \rho_A / \rho_u \right)} \quad (20.9)$$

where M_u = mass of the unknown (in a vacuum)
 M_s = mass of the standard (in a vacuum)
 M_{sw} = mass of the sensitivity weight
 ρ_A = air density
 ρ_s = density of the standard
 ρ_u = density of the unknown
 ρ_{sw} = density of the sensitivity weight
 O_1 = first observation (standard)
 O_2 = second observation (unknown)
 O_3 = third observation (unknown + sensitivity weight)
 O_4 = fourth observation (standard + sensitivity weight)

$$CM = M_u \left(1 - 0.0012/\rho_u\right) / 0.99985 \quad (20.10)$$

where CM = conventional mass

M_u = mass of the unknown in a vacuum
 ρ_u = density of the unknown

To achieve the highest levels of accuracy, advanced weighing designs have been developed. These advanced weighing designs incorporate redundant weighing, drift compensation, statistical checks, and multiple standards. The simplest of these designs is the three-in-one design. It uses two standards to calibrate one unknown weight. In its simplest form, one would perform three double substitutions. The first compares the first standard and the unknown weight; the second double substitution compares the first standard against the second standard, which is called the check standard; and the third and final comparison compares the second (or check standard) against the unknown weight. These comparisons would then result in the following:

O_1 = reading with standard on the balance
 O_2 = reading with unknown on the balance
 O_3 = reading with unknown and sensitivity weight on the balance
 O_4 = reading with standard and sensitivity weight on the balance
 O_5 = reading with standard on the balance
 O_6 = reading with check standard on the balance
 O_7 = reading with check standard and sensitivity weight on the balance
 O_8 = reading with standard and sensitivity weight on the balance
 O_9 = reading with check standard on the balance
 O_{10} = reading with unknown on the balance
 O_{11} = reading with unknown and sensitivity weight on the balance
 O_{12} = reading with check standard and sensitivity weight on the balance

The measured differences are calculated using the following formulae:

$$a = \left[\left(O_1 - O_2 + O_4 - O_3 \right) / 2 \right] \times \left[M_{sw} \left(1 - \rho_A / \rho_{sw} \right) / O_3 - O_2 \right] \quad (20.11)$$

$$b = \left[\left(O_5 - O_6 + O_8 - O_7 \right) / 2 \right] \times \left[M_{sw} \left(1 - \rho_A / \rho_{sw} \right) / O_7 - O_6 \right] \quad (20.12)$$

$$c = \left[\left(O_9 - O_{10} + O_{12} - O_{11} \right) / 2 \right] \times \left[M_{sw} \left(1 - \rho_A / \rho_{sw} \right) / O_{11} - O_{10} \right] \quad (20.13)$$

where a = difference between standard and unknown
 b = difference between standard and check standard
 c = difference between check standard and unknown
 M_{sw} = mass of sensitivity weight
 ρ_A = air density calculated using Equations 20.5 and 20.6
 ρ_{sw} = density of sensitivity weight

The least-squares measured difference is computed for the unknown from:

$$d_u = (-2a - b - c) / 3 \quad (20.14)$$

Using the least-squares measured difference, the mass of the unknown is computed as:

$$U = \left(S \left(1 - \rho_A / \rho_S \right) + d_u \right) / \left(1 - \rho_A / \rho_U \right) \quad (20.15)$$

where U = mass of unknown
 S = mass of the standard
 d_u = least-squares measured difference of the unknown
 ρ_A = air density calculated using Equations 20.5 and 20.6
 ρ_S = density of the standard
 ρ_U = density of the unknown

The conventional mass of the unknown is now calculated as:

$$CU = U \left(1 - 0.0012 / \rho_U \right) / 0.99985 \quad (20.16)$$

where CU = conventional mass
 U = mass of unknown
 ρ_U = density of unknown

The least-squares measured difference is now computed for the check standard as:

$$d_{CS} = (-a - 2b - c) / 3 \quad (20.17)$$

Using the least-squares measured difference, the mass of the check standard is computed from:

$$CS = \left(S \left(1 - \rho_A / \rho_S \right) + d_{CS} \right) / \left(1 - \rho_A / \rho_{CS} \right) \quad (20.18)$$

where CS = mass of check standard
 s = mass of the standard
 d_{CS} = least-squares measured difference of the check standard
 ρ_A = air density calculated using Equations 20.5 and 20.6
 ρ_S = density of the standard
 ρ_{CS} = density of unknown

The mass of the check standard must lie within the control limits for the check standard. If it is out of the control limits, the measurement must be repeated.

The short-term standard deviation of the process is now computed:

$$\text{Short-term standard deviation} = 0.577(a - b + c) \quad (20.19)$$

The short-term standard deviation is divided by the historical pooled short-time standard deviation to calculate the F -statistic:

$$F\text{-statistic} = \text{short-term standard deviation/pooled short-time standard deviation}$$

The F -statistic must be less than the value obtained from the student t -variant at the 99% confidence level for the number of degrees of freedom of the historical pooled standard deviation. If this test fails, the measurement is considered to be out of statistical control and must be repeated.

By measuring a check standard and by computing the short-term standard deviation of the process and comparing them to historical results, one obtains a high level of confidence in the computed value of the unknown.

There are many different weighing designs that are valid; the three-in-one (three equal weights) and four equal weights are the ones that can be easily calculated without the use of a computer. Primary calibration laboratories — private and government — are using these multiple intercomparisons, state-of-the-art mass calibration methods under the Mass Measurement Assurance Program using the Mass Code computer program provided by the National Institute of Standards and Technology. A full discussion of these designs can be found in the *National Bureau of Standards Technical Note 952*.

Halit Eren

Curtin University of Technology

Density is a significant part of measurement and instrumentation. Density measurements are made for at least two important reasons: (1) for the determination of mass and volume of products, and (2) the quality of the product. In many industrial applications, density measurement ascertains the value of the product.

Density is defined as the mass of a given volume of a substance under fixed conditions. However, ultimate care must be exercised in measurements because density varies with pressure and temperature. The variation is much greater in gases.

In many modern applications, the densities of products are obtained by sampling techniques. In measurements, there are two basic concepts: *static density measurements* and *dynamic (on-line) density measurements*. Within each concept, there are many different methods employed. These methods are based on different physical principles. In many cases, the application itself and the characteristics of the process determine the best suitable method to be used. Generally, static methods are well developed, lower in cost, and more accurate. Dynamic samplers are expensive, highly automated, and use micro-processor-based signal processing devices. Nevertheless, nowadays, many static methods are also computerized, offering easy to use, flexible, and self-calibrating features.

There is no single universally applicable density measurement technique. Different methods must be employed for different products and materials. In many cases, density is normalized under reference conditions.

The density of a substance is determined by dividing the density of that substance by the density of a standard substance obtained under the same conditions. This dimensionless ratio is called the *specific gravity* (SG), also termed the *relative density*. The specific gravities of liquid and gases under reference conditions are given by:

$$\text{Liquid SG} = \text{density of liquid} / \text{density of water} \quad (21.1)$$

$$\text{Gas SG} = \text{density of gas} / \text{density of air} \quad (21.2)$$

Commonly accepted sets of conditions are *normal temperature and pressure* (NTP) and *standard temperature and pressure* (STP). NTP is usually taken as the temperature of 0.00°C and a pressure of 760 mm Hg. The NTP is accepted as 15.00 or 15.56°C and 101.325 kPa.

21.1 Solid Density

If the uniformity is maintained, the determination of density of solids is a simple task. Once the volume of the solid and its mass are known, the density can be found using the basic ratio: density = mass/volume (kg m^{-3}).

However, in many applications, solids have different constituents and are made up from different materials having different ratios. Their volumes can also change often. In these cases, dynamic methods are employed, such as radioactive absorption types, ultrasonic, and other techniques. Some of these methods are described below.

21.2 Fluid Density

The measurement of densities of fluids is much more complex than for solids. For fluid densities, many different techniques are available. This is mainly due to complexities in processes, variations of fluid densities during the processes, and diverse characteristics of the process and the fluids themselves. Some of these methods are custom designed and applicable to special cases only. Others are very similar in principles and technology, and applicable to many different type of fluids. At present, apart from conventional methods, there are many novel and unusual techniques undergoing extensive development and research. For example, densitometers based on electromagnetic principles [1] can be given as part of an intelligent instrumentation system.

Fluids can be divided to liquids and gases. Extra care and further considerations are necessary in gas density measurements. For example, perfect gases contain an equal number of molecules under the same conditions and volumes. Therefore, molecular weights can be used in density measurements.

Depending on the application, fluid densities can be measured both in *static* and *dynamic* forms. In general, static density measurements of fluids are well developed, precise, and have greater resolution than most dynamic techniques. Pycnometers and buoyancy are examples of static techniques that can be adapted to cover small density ranges with a high resolution and precision. Nowadays, many manufacturers offer dynamic instruments previously known to be static. Also, many static density measurement devices are computerized and come with appropriate hardware and software. In general, static-type measurements are employed in laboratory conditions, and dynamic methods are employed for real-time measurements where the properties of a fluid vary from time to time.

In this chapter, the discussion will concentrate on the commonly applied, modern density measuring devices. These devices include:

1. Pycnometric densitometers
2. Buoyancy-type densitometers
3. Hydrometers
4. Hydrostatic weighing densitometers
5. Balance-type densitometers
6. Column-type densitometers
7. Vibrating element densitometers
8. Radioactive densitometers
9. Refractometer and index of reflection densitometers
10. Coriolis densitometers
11. Absorption-type densitometers

FIGURE 21.1 A pycnometer. A fixed volume container is filled with liquid and weighed accurately; capillary is used to determine the exact volume of the liquid.

Pycnometric Densitometers

Pycnometers are static devices. They are manufactured as fixed volume vessels that can be filled with the sample liquid. The density of the fluid is measured by weighing the sample. The simplest version consists of a vessel in the shape of a bottle with a long stopper containing a capillary hole, as shown in [Figure 21.1](#). The capillary is used to determine the exact volume of the liquid, thus giving high resolution when filling the pycnometer. The bottle is first weighed empty, and then with distilled-aerated water to determine the volume of the bottle. The bottle is then filled with the process fluid and weighed again. The density is determined by dividing the mass by the volume. The specific gravity of the liquid is found by the ratio of the fluid mass to water mass. When pycnometers are used, for good precision, ultimate care must be exercised during the measurements; that is, the bottle must be cleaned after each measurement, the temperature must be kept constant, and precision balances must be used. In some cases, to ensure filling of the pycnometer, twin capillary tubes are used. The two capillaries, made of glass, are positioned such that the fluid can be driven into the vessel under vacuum conditions. Accurate filling to graduation marks on the capillary is then made.

The pycnometers have to be lightweight, strong enough to contain samples, and they need to be nonmagnetic for accurate weighing to eliminate possible ambient magnetic effects. Very high-resolution balances must be used to detect small differences in weights of gases and liquids. Although many pycnometers are made of glass, they are also made of metals to give enough strength for the density measurements of gases and liquids at extremely high pressures. In many cases, metal pycnometers are necessary for taking samples from the line of some rugged processes.

Pycnometers have advantages and disadvantages. Advantages are that if used correctly, they are accurate; and they can be used for both density and specific gravity measurements. The disadvantages include:

1. Great care must be exercised for accurate results.
2. The sample must be taken off-line, with consequent time lag in results. This creates problems of relating samples to the materials that exist in the actual process.
3. High-precision pycnometers are expensive. They require precision weighing scales and controlled laboratory conditions. Specialized techniques must be employed to take samples in high-pressure processes and hostile conditions, such as offshore installations.
4. Their good performances might depend on the skill of operator.

Buoyancy-Type Densitometers

The buoyancy method basically uses Archimedes principle. A suspended sinker, with a known mass and volume attached to a fine wire, is totally immersed in the sample liquid. A precision force balance is used to measure the force to support the sinker. Once the mass, volume, and supporting weight of the sinker

FIGURE 21.2 Hydrometer. A fixed weight and volume bulb is placed into the liquid. The bulb sinks in the liquid, depending on its density. The density is read directly from the scale. Temperature correction is necessary.

are known, the density of the liquid can be calculated. However, some corrections need to be made for surface tension on the suspension wire, the cubicle expansion coefficient of the sinker, and the temperature of process. Buoyancy-type densitometers give accurate results and are used for the calibration of the other liquid density transducers.

One advanced version of the buoyancy technique is the magnetic suspension system. The sinker is fully enclosed in a pressure vessel, thus eliminating surface tension errors. Their uses can also be extended to applications such as the specific gravity measurements under low vapor pressures and density measurements of hazardous fluids.

Hydrometers

Hydrometers are the most commonly used devices for measurement of the density of liquids. They are so commonly used that their specifications and procedure of use are described by national and international standards, such as ISO 387. The buoyancy principle is used as the main technique of operation. The volume of fixed mass is converted to a linear distance by a sealed bulb-shaped glass tube containing a long stem measurement scale, shown in [Figure 21.2](#). The bulb is ballasted with a lead shot and pitch, the mass of which depends on the density range of the liquid to be measured. The bulb is simply placed into the liquid and the density is read from the scale. The scale is graduated in density units such as kg m^{-3} . However, many alternative scales are offered by manufacturers, such as specific gravity, API gravity, Brix, Brine, etc. Hydrometers can be calibrated for different ranges for surface tensions and temperatures. Temperature corrections can be made for set temperature such as 15°C, 20°C, or 25°C. ISO 387 covers a density range of 600 kg m^{-3} to 2000 kg m^{-3} . Hydrometers have a number of advantages and disadvantages. The advantages include:

1. Relatively low cost and easy to use
2. Good resolution for small range
3. Traceable to national and international standards

The disadvantages include:

1. They have small span; therefore, a number of meters are required to cover a significant range.
2. They are made from glass and fragile. Metal and plastic versions are not as accurate.
3. The fluid needs to be an off-line sample, not representing the exact conditions of the process. There are pressure hydrometers for low vapor pressure hydrocarbons, but this adds a need for accurately determining the pressure too.
4. If good precision is required, they are difficult to use, needing surface tension and temperature corrections. Further corrections could be required for opaque fluids.

FIGURE 21.3 Hydrostatic weighing. The total weight of a fixed-volume tube containing liquid is determined accurately. The density is calculated using mass: volume ratio.

Hydrostatic Weighing Densitometers

The most common device using a hydrostatic weighing method consists of a U-tube that is pivoted on flexible end couplings. A typical example is shown in [Figure 21.3](#). The total weight of the tube changes, depending on the density of fluid flowing through it. The change in the weight needs to be measured accurately, and there are a number of methods employed to do this. The most common commercial meters use a force balance system. The connectors are stainless steel bellows. In some cases, rubber or PTFE are used, depending on the process fluid characteristics and the accuracy required. There are temperature and pressure limitations due to bellows, and the structure of the system may lead to a reading offset. The meter must be securely mounted on a horizontal plane for optimal accuracy.

The advantages of this method include:

1. They give continuous reading and can be calibrated accurately.
2. They are rugged and can be used for two-phase liquids such as slurries, sugar solutions, powders, etc.

The disadvantages of these meters include:

1. They must be installed horizontally on a solid base. These meters are not flexible enough to adapt to any process; thus, the process must be designed around it.
2. They are bulky and cumbersome to use.
3. They are unsuitable for gas density measurements.

Balance-Type Densitometers

Balance-type densitometers are suitable for liquid and gas density measurements. Manufacturers offer many different types; four of the most commonly used ones are discussed below.

Balanced-Flow Vessel

A fixed volume vessel as shown in [Figure 21.4](#) is employed for the measurements. While the liquid is flowing continuously through the vessel, it is weighed automatically by a sensitive scale — a spring balance system or a pneumatic force balance transmitter. Because the volume and the weight of the liquid are known, the density or specific gravity can easily be calculated and scaled in respective units. In the design process, extra care must be exercised for the flexible end connections.

FIGURE 21.4 Balanced flow vessel. An accurate spring balance or force balance system is used to weigh the vessel as the liquid flows through it.

FIGURE 21.5 Chain balance float. The fixed volume and weight plummet totally suspended in the liquid assumes equilibrium position, depending on the density. The force exerted by the chains on the plummet is a function of plummet position; hence, the measured force is proportional to the density of the liquid.

Chain Balanced Float

In this system, a self-centering, fixed-volume, submerged plummet is used for density measurements, as illustrated in [Figure 21.5](#). The plummet is located entirely under the liquid surface. At balance, the plummet operates without friction and is not affected by surface contamination. Under steady-state conditions, the plummet assumes a stable position. The effective weight of the chain on the plummet varies, depending on the position of the plummet, which in turn is a function of the density of the liquid. The plummet contains a metallic transformer core that transmits changes in the position to be measured by a pickup coil. The voltage differential, a function of plummet displacement, is calibrated as a measure of variations in specific gravity. A resistance thermometer bridge is used for the compensation of temperature effects on density.

Gas Specific Gravity Balance

A tall column of gas is weighed by the floating bottom of the vessel. This weight is translated into the motion of an indicating pointer, which moves over a scale graduated in units of density or specific gravity. This method can be employed for any gas density measurement.

FIGURE 21.6 Buoyancy gas balance. The position of the balance beam is adjusted by a set pressure air, air is then displaced by gas of the same pressure. The difference in the reading of the balance beam gives the SG of the gas. The pressures are read on the manometer.

FIGURE 21.7 Reference column densitometer. Two identical tubes, having the same distance from the surface, are placed in water and liquid. Water with known density characteristics is used as the reference. The pressures necessary to displace the fluids inside the tubes are proportional to the densities of the fluids. The pressure difference at the differential pressure transmitter is translated into relative densities.

Buoyancy Gas Balance

In this instrument, a displacer is mounted on a balance beam in a vessel, as shown in [Figure 21.6](#). The displacer is balanced for air, and the manometer reading is noted at the exact balance pressure. The air is then displaced by gas, and the pressure is adjusted until the same balance is restored. The ratio of the pressure of air to the pressure of gas is then the density of the gas relative to air. This method is commonly applied under laboratory conditions and is not suitable for continuous measurements.

Column-Type Densitometers

There are number of different versions of column methods. As a typical example, a reference column method is illustrated in [Figure 21.7](#). A known head of sample liquid and water from the respective bubbler pipes are used. A differential pressure measuring device compares the pressure differences, proportional to relative densities of the liquid and the water. By varying the depth of immersion of the pipes, a wide

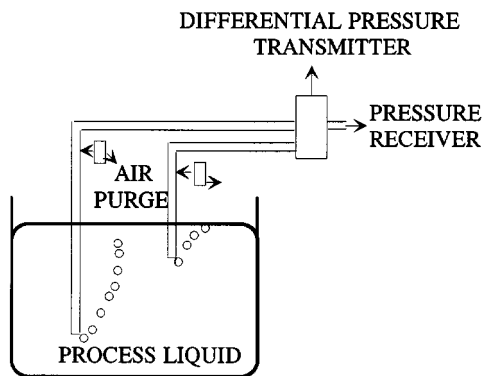

FIGURE 21.8 Two-tube column densitometer. The pressure difference at the differential pressure transmitter depends on the relative positions of the openings of the pipes and the density of liquid. Once the relative positions are fixed, the pressure difference can be related to the equivalent weight of the liquid column at the openings of the pipes, hence the density of the liquid.

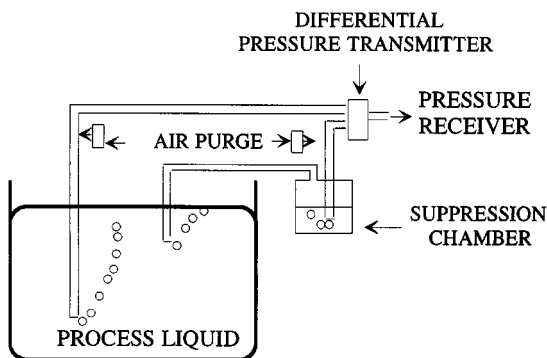

FIGURE 21.9 Suppression-type, two-tube column densitometer. Operation principle is the same as in Figures 21.7 and 21.8. In this case, the suppression chamber affords greater accuracy in readings.

range of measurements can be obtained. Both columns must be maintained at the same temperature to avoid the necessity for corrections of temperature effects.

A simpler and more widely used method of density measurement is achieved by the installation of two bubbler tubes as illustrated in [Figure 21.8](#). The tubes are located in the sample fluid such that the end of one tube is higher than that of the other. The pressure required to bubble air into the fluid from both tubes is equal to the pressure of the fluid at the end of the bubbler tubes. The outlet of one tube higher than the other and the distances of the openings of the tubes are fixed; hence, the difference in the pressure is the same as the weight of a column of liquid between the ends. Therefore, the differential pressure measurement is equivalent to the weight of the constant volume of the liquid, and calibrations can be made that have a direct relationship to the density of the liquid. This method is accurate to within 0.1% to 1% specific gravity. It must be used with liquids that do not crystallize or settle in the measuring chamber during measurements.

Another version is the range suppression type, which has an additional constant pressure drop chamber as shown in [Figure 21.9](#). This chamber is in series with the low-pressure side to give advantages in scaling and accurate readings of densities.

Vibrating Element Densitometers

If a body containing or surrounded by a fluid is set to resonance at its natural frequency, then the frequency of oscillation of the body will vary as the fluid properties and conditions change. The natural frequency is directly proportional to the stiffness of the body and inversely proportional to the combined mass of the body and the fluid. It is also dependent on the shape, size, and elasticity of the material, induced stress, mass, and mass distribution of the body. Basically, the vibration of the body can be equated to motion of a mass attached to a mechanical spring. Hence, an expression for the frequency can be written as:

$$\text{Resonant frequency} = \text{SQRT} \left(K / (M + k\rho) \right) \quad (21.3)$$

where K is the system stiffness, M is the transducer mass, k is the system constant, and ρ is the fluid density.

A factor common to all types of vibrating element densitometers is the problem of setting the element in vibration and maintaining its natural resonance. There are two drives for the purpose.

Magnetic Drives

Magnetic drives of the vibrating element and the pickup sensors of vibrations are usually achieved using small coil assemblies. Signals picked up by the sensors are amplified and fed back as a drive to maintain the disturbing forces on the vibrating body of the meter.

In order to achieve steady drives, the vibrating element sensor can be made from nonmagnetic materials. In this case, small magnetic armatures are attached.

The main advantage of magnetic drive and pickup systems is they are noncontact methods. They use conventional copper windings and they are reliable within the temperature range of -200 to $+200^\circ\text{C}$.

Piezoelectric Drives

A wide range of piezoelectric materials are available to meet the requirements of driving vibrating elements. These materials demonstrate good temperature characteristics as do magnetic drive types. They also have the advantage of being low in cost. They have high impedance, making the signal conditioning circuitry relatively easy. They do not require magnetic sensors.

The piezoelectric drives are mechanically fixed on the vibrating element by adhesives. Therefore, attention must be paid to the careful placement of the mount in order to reduce the strain experienced by the piezo element due to thermal and pressure stresses while the instrument is in service.

A number of different types of densitometers have been developed that utilize this phenomenon. The three main commercial types are introduced here.

Vibrating Tube Densitometers

These devices are suitable for highly viscous liquids or slurry applications. The mode of operation of vibration tube meters is based on the transverse vibration of tubes as shown in [Figure 21.10](#). The tube and the driving mechanisms are constrained to vibrate on a single plane. As the liquid moves inside the tube, the density of the entire mass of the liquid is measured. The tube length is approximately 20 times greater than the tube diameter.

A major design problem with the vibrating tube method is the conflict to limit the vibrating element to a finite length and accurately fix the nodes. Special attention must be paid to avoid any exchange of vibrational energy outside the sensory tube. The single tube has the disadvantage of presenting obstruction to the flow, thus experiencing some pressure losses. The twin tube, on the other hand, offers very small blockage ([Figure 21.11](#)) and can easily be inspected and cleaned. Its compact size is another distinct advantage. In some densitometers, the twin tube is designed to achieve a good dynamic balance, with the two tubes vibrating in antiphase. Their nodes are fixed at the ends, demonstrating maximum sensitivity to installation defects, clamping, and mass loading.

FIGURE 21.10 Vibrating tube densitometer. Tube containing fluid is vibrated at resonant frequency by electromagnetic vibrators. The resonant frequency, which is a function of the density of the fluid, is measured accurately. The tube is isolated from the fixtures by carefully designed bellows.

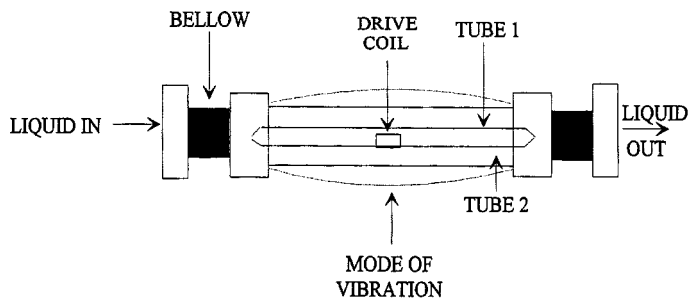

FIGURE 21.11 Two-tube vibrating densitometer. Two tubes are vibrated in antiphase for greater accuracy. Twin-tube densitometers are compact in size and easy to use.

The main design problems of the vibrating tube sensors are in minimizing the influence of end padding and overcoming the effects of pressure and temperature. Bellows are used at both ends of the sensor tubes to isolate the sensors from external vibrations. Bellows also minimize the end loadings due to differential expansions and installation stresses.

The fluid runs through the tubes; therefore, no pressure balance is required. Nevertheless, in some applications, the pressure stresses the tubes, resulting in stiffness changes. Some manufacturers modify the tubes to minimize the pressure effects. In these cases, corrections are necessary only when high accuracy is mandatory. The changes in the Young's modulus with temperature can be reduced to near-zero using Ni-span-C materials whenever corrosive properties of fluids permit. Usually, manufacturers provide pressure and temperature correction coefficients for their products.

It is customary to calibrate each vibration element densitometer against others as a transfer of standards. Often, the buoyancy method is used for calibration purposes. The temperature and pressure coefficients are normally found by exercising the transducer over a range of temperatures and pressures on a liquid with well-known properties. Prior to calibration, the vibration tube densitometers are subjected to a programmed burn-in cycle to stabilize them against temperatures and pressures.

Vibrating Cylinder Densitometers

A thin-walled cylinder, with a 3:1 length:diameter ratio, is fixed with stiff ends. The thickness of the cylinder wall varies from 25 μm to 300 μm , depending on the density range and type of fluid used. The cylinder can be excited to vibrate in a hoop mode by magnetic drives mounted either in or outside the cylinder.

For good magnetic properties, the cylinder is made of corrosion-resistant magnetic materials. Steel such as FV520 is often used for this purpose. Such materials have good corrosion-resistance characteristics; unfortunately, due to their poor thermoelastic properties, they need extensive temperature corrections.

FIGURE 21.12 Tuning fork densitometer. Twin forks are inserted into the fluid and the natural frequencies are measured accurately. The natural frequency of the forks is a function of the density of the fluid.

Nickel-iron alloys such as Ni-span-C are often used to avoid temperature effects. Once correctly treated, the Ni-span-C alloy has near-zero Young's modulus properties. Because the cylinder is completely immersed in the fluid, there are no pressure coefficients.

The change in the resonant frequency is determined by the local mass loading of the fluid in contact with the cylinder. The curve of frequency against density is nonlinear and has a parabolic shape, thus requiring linearization to obtain practical outputs. The resonant frequency range varies from 2 kHz to 5 kHz, depending on the density range of the instrument. The cylinders need precision manufacturing and thus are very expensive to construct. Each meter needs to be calibrated individually for different temperatures and densities to suit specific applications. In the case of gas density applications, gases with well-known properties (e.g., pure argon or nitrogen) are used for calibrations. In this case, the meters are subjected to a gas environment with controlled temperature and pressure. The calibration curves are achieved by repetitions to suit the requirements of individual customers for particular applications. In the case of liquids, the meters are calibrated with liquids of known density, or they are calibrated against another standard (e.g., pycnometer or buoyancy type densitometers).

Vibration cylinder-type densitometers have zero pressure coefficients and they are ideal for liquefied gas products or refined liquids. Due to relatively small clearances between cylinder and housing, they require regular cleaning. They are not suitable for liquids or slurries with high viscous properties.

Tuning Fork Densitometers

These densitometers make use of the natural frequency of low-mass tuning forks, shown in [Figure 21.12](#). In some cases, the fluid is taken into a small chamber in which the electromechanically driven forks are situated. In other cases, the fork is inserted directly into the liquid. Calibration is necessary in each application.

The advantages of vibrating element meters include:

1. They are suitable for both liquids and gases with reasonable accuracy.
2. They can be designed for real-time measurements.
3. They can easily be interfaced because they operate on frequencies and are inherently digital.
4. They are relatively robust and easy to install.
5. Programmable and computerized versions are available. Programmed versions make all the corrections automatically. They provide the output of live density, density at reference conditions, relative density, specific gravity, concentration, solid contents, etc.

The disadvantages include:

1. They do not relate directly to primary measurements; therefore, they must be calibrated.
2. They all have problems in measuring multiphase liquids.

Radioactive Densitometers

As radioactive isotopes decay, they emit radiation in the form of particles or waves. This physical phenomenon can be used for the purposes of density measurement. For example, γ rays are passed

through the samples and their rate of arrivals are measured using ion- or scintillation-based detection [2]. Generally, γ -ray mass absorption rate is independent of material composition; hence they can be programmed for a wide range materials. Densitometers based on radiation methods can provide accuracy up to $+0.0001 \text{ g mL}^{-1}$. Many of these devices have self-diagnostic capabilities and are able to compensate for drift caused by source decay, thus pinpointing any signaling problems.

If γ rays of intensity J_0 penetrate a material of a density ρ and thickness d then the intensity of the radiation after passing through the material can be expressed by:

$$J = J_0 \exp(-n \rho d) \quad (21.4)$$

where n is the mass absorption coefficient.

The accuracy of the density measurement depends on the accuracy of the measurement of the intensity of the radiation and the path length d . A longer path length through the material gives a stronger detection signal.

For accurate operations, there are many arrangements for relative locations of transmitters and detectors, some of which are illustrated in Figures 21.13 and 21.14. Generally, the source is mounted in a lead container clamped onto the pipe or the container wall. In many applications, the detector is also clamped onto the wall.

FIGURE 21.13 Fixing radioactive densitometer on an enlarged pipe. The pipe is enlarged to give longer beam length through the liquid, and hence better attenuation of the radioactive energy.

FIGURE 21.14 Fixing radioactive densitometer on an elongated pipe. Elongated path yields a longer path length of the radioactive energy through the liquid; hence, a stronger attenuation.

The advantages of using radioactive methods include:

1. The sensor does not touch the sample; hence, there is no blockage to the path of the liquid.
2. Multiphase liquids can be measured.
3. They come in programmable forms and are easy to interface.
4. They are most suitable in difficult applications, such as mining and heavy process industries.

The disadvantages include:

1. A radioactive source is needed; hence, there is difficulty in handling.
2. For reasonable accuracy, a minimum path length is required.
3. There could be long time constants, making them unsuitable in some applications.
4. They are suitable only for solid and liquid density measurements.

Refractometer and Index of Refraction Densitometers

Refractometers are essentially optical instruments operating on the principles of refraction of light traveling in liquid media. Depending on the characteristics of the samples, measurement of refractive index can be made in a variety of ways (e.g., critical angle, collimation, and displacement techniques). Usually, an in-line sensing head is employed, whereby a sensing window (commonly known as a prism) is wetted by the product to be measured. In some versions, the sensing probes must be installed inside the pipelines or in tanks and vessels. They are most effective in reaction-type process applications where blending and mixing of liquids take place. For example, refractometers can measure dissolved soluble solids accurately.

Infrared diodes, lasers, and other lights may be used as sources. However, this measurement technique is not recommended in applications in processes containing suspended solids, high turbidity, entrained air, heavy colors, poor transparency and opacity, or extremely high flow rates. The readings are automatically corrected for variations in process temperature. The processing circuitry can include signal outputs adjustable in both frequency and duration.

Another version of a refractometer is the index of refraction type densitometer. For example, in the case of position-sensitive detectors, the index of refraction of liquid under test is determined by measuring the lateral displacement of a laser beam. When the laser beam impinges on the cell at an angle of incidence, as in [Figure 21.15](#), the axis of the emerging beam is displaced by the cell wall and by the inner liquid. The lateral displacement can accurately be determined by position-sensitive detectors. For maximum sensitivity, the devices need to be calibrated with the help of interferometers.

Refractometers are often used for the control of adulteration of liquids of common use (e.g., edible oils, wines, and gasoline). They also find application in pulp and paper, food and beverage, sugar, dairy, and other chemical industries.

Coriolis Densitometers

The Coriolis density metering systems are similar to vibrating tube methods, but with slight variations in the design. They are comprised of a sensor and a signal-processing transmitter. Each sensor consists of one or two flow tubes enclosed in a sensor housing. They are manufactured in various sizes and shapes [3]. The sensor tubes are securely anchored at the fluid inlet and outlet points and force is vibrated at the free end, as shown in [Figure 21.16](#). The sensor operates by applying Newton's second law of motion ($F = ma$).

Inside the housing, the tubes are vibrated in their natural frequencies using drive coils and a feedback circuit. This resonant frequency of the assembly is a function of the geometry of the element, material of construction, and mass of the tube assembly. The tube mass comprises two parts: the mass of the tube itself and the mass of the fluid inside the tube. The mass of the tube is fixed for a given sensor. The mass of fluid in the tube is equal to the fluid density multiplied by volume. Because the tube volume is constant, the frequency of oscillation can be related directly to the fluid density. Therefore, for a given geometry

FIGURE 21.15 Index of refraction-type densitometer. The angle of refraction of the beam depends on the shape, size, and thickness of the container, and the density of fluid in the container. Because the container has the fixed characteristics, the position of the beam can be related to density of the fluid. Accurate measurement of the position of the beam is necessary.

FIGURE 21.16 Coriolis densitometer. Vibration of the tube is detected and related to the mass and flow rate of the fluid. Further calibrations and calculations must be made to determine the densities.

of tube and the material of the construction, the density of the fluid can be determined by measuring the resonant frequency of vibration. Temperature sensors are used for overcoming the effects of changes in modulus of elasticity of the tube. The fluid density is calculated using a linear relationship between the density and the tube period and calibration constants.

Special peripherals, based on microprocessors, are offered by various manufacturers for a variety of measurements. However, all density peripherals employ the natural frequency of the sensor coupled with the sensor temperature to calculate on-line density of process fluid. Optional communication, interfacing facilities, and appropriate software are also offered.

Absorption-Type Densitometers

Absorption techniques are also used for density measurements in specific applications. X-rays, visible light, UV light, and sonic absorptions are typical examples of this method. Essentially, attenuation and

phase shift of a generated beam going through the sample is sensed and related to the density of the sample. Most absorption-type densitometers are custom designed for applications having particular characteristics. Two typical examples are: (1) UV absorption or X-ray absorptions are used for determining the local densities of mercury deposits in arc discharge lamps, and (2) ultrasonic density sensors are used in connection with difficult density measurements (e.g., density measurement of slurries). The lime slurry, for example, is a very difficult material to handle. It has a strong tendency to settle out and coat all equipment with which it comes in contact. An ultrasonic density control sensor can fully be emerged into an agitated slurry, thus avoiding the problems of coating and clogging. Inasmuch as the attenuation of the ultrasonic beam is proportional to the suspended solids, the resultant electronic signal is proportional to the specific gravity of the slurry. Such devices can give accuracy up to 0.01%. The ultrasonic device measures the percentage of the suspended solids in the slurry by providing a close approximation of the specific gravity.

 - Piezoresistive Foil Gages • Piezoresistive Semiconducting Gages • Piezoelectric Gages • Fiber Optic Strain Gages • Birefringent Film Strain Sensing • Moiré Strain Sensing

This chapter begins with a review of the fundamental definitions of strain and ways it can be measured. This is followed by a review of the many types of strain sensors and their application, and sources for strain sensors and signal conditioners. Next, a more detailed look is taken at operating principles of various strain measurement techniques and the associated signal conditioning.

22.1 Fundamental Definitions of Strain

Stress and strain are defined in many elementary textbooks about the mechanics of deformable bodies [1, 2]. The terms *stress* and *strain* are used to describe loads on and deformations of solid materials. The simplest types of solids to describe are homogeneous and isotropic. *Homogeneous* means the material properties are the same at different locations and *isotropic* means the material properties are independent of direction in the material. An annealed steel bar is homogeneous and isotropic, whereas a human femur is not homogeneous because the marrow has very different properties from the bone, and it is not isotropic because its properties are different along the length and along the cross-section.

The concepts of stress and strain are introduced in the context of a long homogeneous isotropic bar subjected to a tensile load (Figure 22.1). The stress σ , is the applied force F divided by the cross-sectional area A . The resulting strain ϵ , is the length change ΔL , divided by the initial length L . The bar elongates in the direction the force is pulling (longitudinal strain ϵ_l) and contracts in the direction perpendicular to the force (transverse strain ϵ_t).

When the strain is not too large, many solid materials behave like linear springs; that is, the displacement is proportional to the applied force. If the same force is applied to a thicker piece of material, the spring is stiffer and the displacement is smaller. This leads to a relation between force and displacement that depends on the dimensions of the material. Material properties, such as the density and specific heat, must be defined in a manner that is independent of the shape and size of the specimen. Elastic material properties are defined in terms of stress and strain. In the linear range of material response, the stress is proportional to the strain (Figure 22.2). The ratio of stress to strain for the bar under tension is an elastic constant called the Young's modulus E . The negative ratio of the transverse strain to longitudinal strain is the Poisson's ratio ν .

Forces can be applied to a material in a manner that will cause distortion rather than elongation (Figure 22.3). A force applied tangent to a surface divided by the cross-sectional area is described as a shear stress τ . The distortion can be measured by the angle change produced. This is the shear strain γ

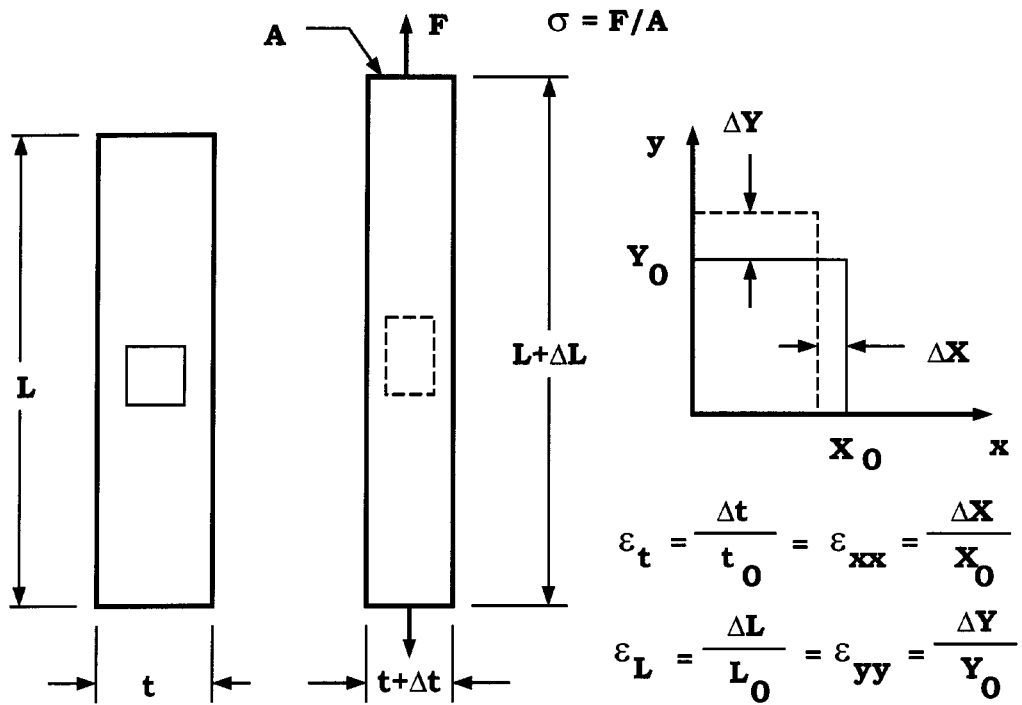

FIGURE 22.1 When a homogeneous isotropic bar is stretched by a uniaxial force, it elongates in the direction of the force and contracts perpendicular to the force. The relative elongation and contraction are defined as the longitudinal and transverse strains, respectively.

FIGURE 22.2 The uniaxial force shown in Figure 22.1 produces uniaxial stress in the bar. When the material response is linear, the slope of the stress vs. strain curve is the Young's modulus. The negative ratio of the transverse to longitudinal strain is the Poisson's ratio.

when the angle change is small. When the relation between shear stress and shear strain is linear, the ratio of the shear stress to shear strain is the shear modulus G .

Temperature change also induces strain. This is thermal expansion. In most materials, thermal strain increases with temperature. Over a limited temperature range, the relationship between thermal strain

FIGURE 22.3 When a block of material is subjected to forces parallel to the sides as shown, it distorts. The force per unit area is the shear stress τ , and the angle change is the shear strain γ .

FIGURE 22.4 Some elements of a bar under uniaxial tension undergo elongation and contraction. These elements lie in principal directions. Other elements undergo distortion as well.

and temperature is linear. In this case, the strain divided by the temperature change is the thermal expansion coefficient α . In isotropic materials, thermal expansion only produces elongation strain, no shear strain.

Principal directions in a material are directions that undergo elongation but no shear. On any particular surface of a solid, there are always at least two principal directions in which the strain is purely elongation. This is seen if two squares are drawn on the bar under uniform tension (Figure 22.4). When the bar is stretched, the square aligned with the load is elongated, whereas the square at 45° is distorted (angles have changed) and elongated. If the principal directions are known, as with the bar under tension, then strain gages can be applied in these directions. If the principal directions are not known, such as near a hole or notch, in an anisotropic specimen, or in a structure with complicated geometry, then additional strain gages are needed to fully characterize the strain state.

The elastic and thermal properties can be combined to give Hooke's law, Equations 22.1 to 22.6.

$$\epsilon_{xx} = \frac{\sigma_{xx}}{E} - \frac{\nu}{E}(\sigma_{yy} + \sigma_{zz}) \quad (22.1)$$

$$\epsilon_{yy} = \frac{\sigma_{yy}}{E} - \frac{\nu}{E}(\sigma_{xx} + \sigma_{zz}) \quad (22.2)$$

$$\epsilon_{zz} = \frac{\sigma_{zz}}{E} - \frac{\nu}{E}(\sigma_{xx} + \sigma_{yy}) \quad (22.3)$$

$$\gamma_{xy} = \frac{\tau_{xy}}{G} \quad (22.4)$$

$$\gamma_{xz} = \frac{\tau_{xz}}{G} \quad (22.5)$$

$$\gamma_{yz} = \frac{\tau_{yz}}{G} \quad (22.6)$$

Several types of sensors are used to measure strain. These include piezoresistive gages (foil or wire strain gages and semiconductor strain gages), piezoelectric gages (polyvinylidene fluoride (PVDF) film and quartz), fiber optic gages, birefringent films and materials, and Moiré grids. Each type of sensor requires its own specialized signal conditioning. Selection of the best strain sensor for a given measurement is based on many factors, including specimen geometry, temperature, strain rate, frequency, magnitude, as well as cost, complexity, accuracy, spatial resolution, time resolution, sensitivity to transverse strain, sensitivity to temperature, and complexity of signal conditioning. [Table 22.1](#) describes typical characteristics of several sensors. [Table 22.2](#) lists some manufacturers and the approximate cost of the sensors and associated signal conditioning electronics.

The data in [Table 22.1](#) are to be taken as illustrative and by no means complete. The sensor description section describes only the type of sensor, not the many sizes and shapes. The longitudinal strain sensitivity is given as sensor output per unit longitudinal strain in the sensor direction. If the signal conditioning is included, the sensitivities can all be given in volts out per unit strain [3, 4], but this is a function of amplification and the quality of the signal conditioner. The temperature sensitivity is given as output change due to a temperature change. In many cases, higher strain resolution can be achieved, but resolving smaller strain is more difficult and may require vibration and thermal isolation. For the Moiré technique, the strain resolution is a function of the length of the viewing area. This technique can resolve a displacement of 100 nm (1/4 fringe order). This is divided by the viewing length to obtain the strain resolution. The spatial resolution corresponds to the gage length for most of the sensor types. The measurable strain range listed is the upper limit for the various sensors. Accuracy and reliability are usually reduced when sensors are used at the upper limit of their capability.

Manufacturers of the various sensors provide technical information that includes details of using the sensors, complete calibration or characterization data, and details of signal conditioning. The extensive technical notes and technical tips provided by Measurements Group, Inc. address such issues as thermal effects [5], transverse sensitivity corrections [6], soldering techniques [7], Rosettes [8], and gage fatigue [9]. Strain gage catalogs include information about gage materials, sizes, and selection. Manufacturers of other sensors provide similar information.

TABLE 22.1 Comparison of Strain Sensors

Description	Longitudinal strain sensitivity	Transverse strain sensitivity	Temperature sensitivity	Strain resolution	Spatial resolution	Time resolution	Measurable strain range
Piezoresistive constantan foil	$\Delta R/R/\Delta \epsilon_L = 2.1$	$\Delta R/R/\Delta \epsilon_t = <0.02$	$\Delta R/R/\Delta T = 2 \times 10^{-6}/^\circ\text{C}$	$<1 \mu\text{strain}^a$	5–100 mm ^b	$<1 \mu\text{s}^c$	0–3%
Annealed constantan foil ^d	$\Delta R/R/\Delta \epsilon_L = 2.1$	$\Delta R/R/\Delta \epsilon_t = <0.02$	$\Delta R/R/\Delta T = 2 \times 10^{-6}/^\circ\text{C}$	$<11 \mu\text{strain}$	5–100 mm	$<1 \mu\text{s}$	0–10%
Piezoresistive semiconductor	$\Delta R/R/\Delta \epsilon_L = 150$	$\Delta R/R/\Delta \epsilon_t = ???$	$\Delta R/R/\Delta T = 1.7 \times 10^{-3}/^\circ\text{C}$	$<0.1 \mu\text{strain}$	1–15 mm	$<1 \mu\text{s}$	0–0.1%
Piezoelectric PVDF	$\Delta Q/A/\Delta \epsilon_L = 120 \text{ nC/m}^2/\mu\epsilon$	$\Delta Q/A/\Delta \epsilon_t = 60 \text{ nC/m}^2/\mu\epsilon$	$\Delta Q/A/\Delta T = -27 \mu\text{C/m}^2/^\circ\text{C}$	1–10 μstrain	Gage size	$<1 \mu\text{s}$	0–30%
Piezoelectric quartz	$\Delta Q/A/\Delta \epsilon_L = 150 \text{ nC/m}^2/\mu\epsilon$ bonded to steel		$\Delta Q/A/\Delta T = 0$	$<0.01 \mu\text{strain}$ 20 mm gage	Gage size	$<10 \mu\text{s}$	0–0.1%
Fiber optic Fabry–Perot	2 to 1000 $\mu\text{strain}/\text{V}$	Near zero		$<1 \mu\text{strain}$	2–10 mm	$<20 \mu\text{s}$	
Birefringent Film	$K^e = 0.15\text{--}0.002$				0.5 mm ^f	$<5 \mu\text{s}$	0.05–5%
Moiré	1 fringe order/417 nm displ.	1 fringe order/417 nm displ.	Not defined	41.7 $\mu\epsilon$ over 10 mm	full field ^g	Limited by signal conditioning	0.005–5%

^a With good signal conditioning.

^b Equal to grid area.

^c Gage response is within 100 ns. Most signal conditioning limits response time to far less than this.

^d Annealed foil has a low yield stress and a large strain to failure. It also has hysteresis in the unload and a zero shift under cyclic load.

^e This technique measures a difference in principal strains. $\epsilon_2 - \epsilon_1 = N\lambda/2tK$

^f Approximately the film thickness.

^g The spatial strain resolution depends on the strain level. This is a displacement measurement technique.

TABLE 22.2 Sources and Prices of Strain Sensors

Supplier	Address	Sensor Types	Sensor Cost	Signal Conditioning	Cost
Micro Measurements	P.O. Box 27777 Raleigh, NC 27611	Piezoresistive foil Birefringent film	From \$5.00 From \$10.00	Wheatstone bridge Polariscope	From \$500 \$5000 to 10,000

22.2 Principles of Operation of Strain Sensors

Piezoresistive Foil Gages

Piezoresistive foil and wire gages comprise a thin insulating substrate (usually polyimide film), a foil or wire grid (usually constantan) bonded to the substrate, lead wires to connect the grid to a resistance measuring circuit, and often an insulating encapsulation (another sheet of polyimide film) (Figure 22.5). The grid is laid out in a single direction so that strain will stretch the legs of the grid in the length direction. The gages are designed so that strain in the width or transverse direction separates the legs of the grid without straining them. This makes the gage sensitive to strain only along its length. There is always some sensitivity to transverse strain, and almost no sensitivity to shear strain. In most cases, the transverse sensitivity can be neglected.

When piezoresistive foil or wire strain gages are bonded to a specimen and the specimen is strained, the gage strains as well. The resistance change is related to the strain by a gage factor, Equation 22.7.

FIGURE 22.5 Gage construction of a foil or wire piezoresistive gage.

$$\frac{\Delta R}{R} = G_L \epsilon_L \quad (22.7)$$

where $\Delta R/R$ = Relative resistance change

G = Gage factor

ϵ = Strain

These gages respond to the average strain over the area covered by the grid [10]. The resistance change is also sensitive to temperature. If the temperature changes during the measurement period, a correction must be made to distinguish the strain response from the thermal response. The gage response to longitudinal strain, transverse strain, and temperature change is given by Equation 22.8.

$$\frac{\Delta R}{R} = G_L \epsilon_L + G_t \epsilon_t + G_T \Delta T \quad (22.8)$$

where G_L , G_t , and G_T are the longitudinal, transverse, and temperature sensitivity, respectively. Micromea-
 surements, Inc. uses a different notation. Their gage data is provided as $G_L = F_G$, $G_t = K_t F_G$, $G_T = \beta_g$.
 When a strain gage is bonded to a specimen and the temperature changes, the strain used in Equation 22.8
 is the total strain, thermal plus stress induced, as given by Equation 22.7.

The temperature contribution to gage output must be removed if the gages are used in tests where
 the temperature changes. A scheme referred to as self-temperature compensation (STC) can be used.
 This is accomplished by selecting a piezoresistive material whose thermal output can be canceled by the
 strain induced by thermal expansion of the test specimen. Gage manufacturers specify STC numbers that
 match the thermal expansion coefficients of common specimen materials.

Strain of piezoresistive materials produces a relative resistance change. The resistance change is the
 result of changes in resistivity and dimensional changes. Consider a single leg of the grid of a strain gage
 with a rectangular cross-section (Figure 22.6). The resistance is given by Equation 22.9.

$$R = \rho \frac{L}{A} \quad (22.9)$$

where R = Resistance

ρ = Resistivity

L = Length

A = Area of the cross-section

FIGURE 22.6 A single leg of a piezoresistive gage is used to explain the source of the relative resistance change that occurs in response to strain.

A small change in resistance is given by the first-order terms of a Taylor's series expansion, Equation 22.10.

$$\Delta R = \frac{\partial R}{\partial \rho} \Delta \rho + \frac{\partial R}{\partial L} \Delta L + \frac{\partial R}{\partial A} \Delta A \quad (22.10)$$

Differentiating Equation 22.9 to obtain each term of Equation 22.10 and then dividing by the initial resistance leads to Equation 22.11.

$$\frac{\Delta R}{R_0} = \frac{\Delta \rho}{\rho_0} + \frac{\Delta L}{L_0} - \frac{\Delta A}{A_0} \quad (22.11)$$

The relative resistance change is due to a change in resistivity, a change in length strain, and a change in area strain.

The strain gage is a composite material. The metal in a strain gage is like a metal fiber in a polymer matrix. When the polymer matrix is deformed, the metal is dragged along in the length direction; but in the width and thickness directions, the strain is not passed to the metal. This results in a stress state called uniaxial stress. This state was discussed in the examples above. The mathematical details involve an inclusion problem [11, 12]. Accepting that the stress state is uniaxial, the relationship between the area change and the length change in Equation 22.11 is found from the Poisson's ratio. The area strain is the sum of the width and thickness strain, Equation 22.12.

$$\frac{\Delta A}{A_0} = \frac{\Delta w}{w_0} + \frac{\Delta t}{t_0} \quad (22.12)$$

The definition of the Poisson's ratio gives Equation 22.13.

$$\frac{\Delta A}{A_0} = -2\nu \frac{\Delta L}{L_0} \quad (22.13)$$

where $\Delta w/w =$ width strain and $\Delta t/t =$ thickness strain. Substitution of Equation 22.13 into Equation 22.11 gives Equation 22.14 for the relative resistance change.

$$\frac{\Delta R}{R_0} = \frac{\Delta \rho}{\rho_0} + \frac{\Delta L}{L_0} (1 + 2\nu) \quad (22.14)$$

The relative resistivity changes in response to stress. The resistivity is a second-order tensor [13], and the contribution to the overall resistance change can be found in terms of strain using the elastic

constitutive law [14]. The results lead to an elastic gage factor just over 2 for constantan gages. If the strain is large, the foil or wire in the gage will experience plastic deformation. When the deformation is plastic, the resistivity change is negligible and the dimensional change dominates. In this case, Poisson's ratio is 0.5 and the gage factor is 2. This effect is utilized in manufacturing gages for measuring strains larger than 1.5%. In this case, annealed foil is used. The annealed foil undergoes plastic deformation without failure. These gages are capable of measuring strain in excess of 10%. When metals undergo plastic deformation, they do not unload to the initial strain. This shows up as hysteresis in the gage response, that is, on unload, the resistance does not return to its initial value.

Foil and wire strain gages can be obtained in several configurations. They can be constructed with different backing materials, and left open faced or fully encapsulated. Backing materials include polyimide and glass fiber-reinforced phenolic resin. Gages can be obtained with solder tabs for attaching lead wires, or with lead wires attached. They come in many sizes, and in multiple gage configurations called rosettes.

Strain gages are mounted to test specimens with adhesives using a procedure that is suitable for bonding most types of strain sensors. This is accomplished in a step-by-step procedure [15] that starts with surface preparation. An overview of the procedure is briefly described. To successfully mount strain gages, the surface is first degreased. The surface is abraded with a fine emery cloth or 400 grit paper to remove any loose paint, rust, or deposits. Gage layout lines are drawn (not scribed) on the surface in a cross pattern with pen or pencil, one line in the grid direction and one in the transverse direction. The surface is then cleaned with isopropyl alcohol. This can be done with an ultrasonic cleaner or with wipes. If wiped, the paper or gauze wipe should be folded and a small amount of alcohol applied. The surface should be wiped with one pass and the wipe discarded. This should be repeated, wiping in the other direction. The final step is to neutralize the surface, bringing the alkalinity to a pH of 7 to 7.5. A surface neutralizer is available from most adhesive suppliers. The final step is to apply the gage.

Gage application is accomplished with cellophane tape, quick-set glue, and a catalyst. The gage is placed on a clean glass or plastic surface with bonding side down, using tweezers. (Never touch the gage. Oils from skin prevent proper adhesion.) The gage is then taped down with a 100 mm piece of cellophane tape. The tape is then peeled up with the gage attached. The gage can now be taped onto its desired location on the test specimen. Once the gage has been properly aligned, the tape is peeled back from one side, lifting the gage from the surface. The tape should remain adhered to the surface about 1 cm from the gage. Note that one side of the tape is still attached to the specimen so that the gage can be easily returned to its desired position. A thin coating of catalyst is applied to the exposed gage surface. A drop of glue is placed at the joint of the tape and the specimen. Holding the tape at about a 30° angle from the surface, the tape can be slowly wiped down onto the surface. This moves the glue line forward. After the glue line has passed the gage, the gage should be pressed in place and held for approximately 1 min. The tape can now be peeled back to expose the gage, and lead wires can be attached.

The relative resistance change of piezoresistive gages is usually measured using a Wheatstone bridge [16]. This allows a small change of resistance to be measured relative to an initial zero value, rather than relative to a large resistance value, with a corresponding increase in sensitivity and resolution. The Wheatstone bridge is a combination of four resistors and a voltage source (Figure 22.7). One to four of the resistors in the bridge can be strain gages. The output of the bridge is the difference between the voltage at points B and D. Paths ABC and ADC are voltage dividers so that V_B and V_D are given by Equations 22.15a and b.

$$V_B = V_{in} \frac{R_2}{R_1 + R_2} \quad (22.15a)$$

$$V_D = V_{in} \frac{R_3}{R_3 + R_4} \quad (22.15b)$$

FIGURE 22.7 The Wheatstone bridge is used to measure the relative resistance change of piezoresistive strain gages.

The bridge output, Equation 22.16, is zero when the balance condition, Equation 22.17, is met.

$$V_0 = V_B - V_D \quad (22.16)$$

$$R_1 R_3 = R_2 R_4 \quad (22.17)$$

Wheatstone bridge signal conditioners are constructed with a way to “balance” the bridge by adjusting the ratio of the resistances so that the bridge output is initially zero.

The balance condition is no longer met if the resistance values undergo small changes ΔR_1 , ΔR_2 , ΔR_3 , ΔR_4 . If the values $R_1 + \Delta R_1$, etc. are substituted into Equation 22.15, the results substituted into Equation 22.16, condition (22.17) used, and the higher order terms neglected, the result is Equation 22.18 for the bridge output.

$$V_{out} = V_{in} \frac{R_1 R_3}{(R_1 + R_2)(R_3 + R_4)} \left(-\frac{\Delta R_1}{R_1} + \frac{\Delta R_2}{R_2} - \frac{\Delta R_3}{R_3} + \frac{\Delta R_4}{R_4} \right) \quad (22.18)$$

The Wheatstone bridge can be used to directly cancel the effect of thermal drift. If R_1 is a strain gage bonded to a specimen and R_2 is a strain gage held onto a specimen with heat sink compound (a thermally conductive grease available at any electronics store), then R_1 will respond to strain plus temperature, and R_2 will only respond to temperature. Since the bridge subtracts the output of R_1 from that of R_2 , the temperature effect cancels.

The sensitivity of a measuring system is the output per unit change in the quantity to be measured. If the resistance change is from a strain gage, the sensitivity of the Wheatstone bridge system is proportional to the input voltage. Increasing the voltage increases the sensitivity. There is a practical limitation to increasing the voltage to large values. The power dissipated (heat) in the gage is $P = I^2 R$, where I , the current through the gage, can be found from the input voltage and the bridge resistances. This heat must go somewhere or the temperature of the gage will continuously rise and the resistance will change due to heating. If the gage is mounted on a good thermal conductor, more power can be conducted away than if the gage is mounted on an insulator. The specimen must act as a heat sink.

Heat sinking ability is proportional to the thermal conductivity of the specimen material. A reasonable temperature gradient to allow the gage to induce in a material is 40°C per meter (about 1°C per 25 mm).

For thick specimens (thickness several times the largest gage dimension), this can be conducted away to the grips or convected to the surrounding atmosphere. If the four bridge resistances are approximately equal, the power to the gage in terms of the bridge voltage is given by Equation 22.19.

$$P_g = \frac{V_{in}^2}{4R} \quad (22.19)$$

The power per unit grid area, A_g , or power density to the gage can be equated to the thermal conductivity of the specimen and the allowable temperature gradient in the specimen by Equation 22.20.

$$\frac{P_g}{A_g} = \frac{V_{in}^2}{4RA_g} = K\nabla T \quad (22.20)$$

Thermal conductivities of most materials can be found in tables or on the Web. Some typical values are Al: $K = 204 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$, steel: $K = 20 \text{ to } 70 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$, glass: $K = 0.78 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$ [17].

The acceptable bridge voltage can be calculated from Equation 22.21.

$$V_{in} = \sqrt{K\nabla T 4RA_g} \quad (22.21)$$

A sample calculation shows that for a $0.010 \text{ m} \times 0.010 \text{ m}$ $120 \text{ } \Omega$ grid bonded to a thick piece of aluminum with a thermal conductivity of $204 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$ and an acceptable temperature gradient of 40°C per meter, the maximum bridge voltage is 19 V. If thin specimens are used, the allowable temperature gradient will be smaller. If smaller gages are used for better spatial resolution, the bridge excitation voltage must be reduced with a corresponding reduction in sensitivity.

A considerably higher bridge voltage can be used if the bridge voltage is pulsed for a short duration. This dissipates substantially less energy in the gage and thus increases the sensitivity by a factor of 10 to 100. Wheatstone bridge pulse power supplies with variable pulse width from $10 \text{ } \mu\text{s}$ and excitation of 350 V are commercially available [18].

The strain measurement required is often in a complex loading situation where the directions of principal strain are not known. In this case, three strain gages must be bonded to the test specimen at three angles. This is called a strain rosette. The angle between the rosette and the principal directions, as well as the magnitude of the principal strains, can be determined from the output of the rosette gages. This is most easily accomplished using the construct of a Mohr's circle (Figure 22.8).

A common rosette is the 0–45–90° pattern. The rosette is bonded to the specimen with relative rotations of 0°, 45°, and 90°. These will be referred to as the x , x' , and y directions. The principal directions are labeled the 1 and 2 directions. The unknown angle between the x direction and the 1 direction is labeled θ . The Mohr's circle is drawn with the elongational strain on the horizontal axis and the shear strain on the vertical axis. The center of the circle is labeled C and the radius R . The principal directions correspond to zero shear strain. The principal values are given by Equations 22.22 and 22.23.

$$\epsilon_1 = C + R \quad (22.22)$$

$$\epsilon_2 = C - R \quad (22.23)$$

A rotation through an angle 2θ on the Mohr's circle corresponds to a rotation of the rosette of θ relative to the principal directions. The center of the circle is given by Equation 22.24 and the output of the strain gages is given by Equations 22.25 to 22.27.

FIGURE 22.8 A three-element rosette is used to measure strain when the principal directions are not known. The Mohr's circle is used to find the principal directions and the principal strain values.

$$C = \frac{\epsilon_{xx} + \epsilon_{yy}}{2} \quad (22.24)$$

$$\epsilon_{xx} - C = R \cos 2\theta \quad (22.25)$$

$$\epsilon_{x'x'} - C = -R \sin 2\theta \quad (22.26)$$

$$\epsilon_{yy} - C = -R \cos 2\theta \quad (22.27)$$

Dividing Equation 22.25 by Equation 22.26 leads to θ and then to R , Equations 22.28 and 22.29.

$$R^2 = (\epsilon_{xx} - C)^2 + (\epsilon_{x'x'} - C)^2 \quad (22.28)$$

$$\tan 2\theta = \frac{C - \epsilon_{x'x'}}{\epsilon_{xx} - C} \quad (22.29)$$

The principal directions and principal strain values have been found from the output of the three rosette gages.

Piezoresistive Semiconducting Gages

Piezoresistive semiconductor strain gages, like piezoresistive foil and wire gages, undergo a resistance change in response to strain, but with nearly an order of magnitude larger gage factor [19]. The coupling between resistance change and temperature is very large, so these gages have to be temperature compensated. The change of resistance with a small temperature change can be an order of magnitude larger than that induced by strain. Semiconductor strain gages are typically used to manufacture transducers such as load cells. They are fragile and require great care in their application.

FIGURE 22.9 Typical gage construction of a piezoelectric gage.

Piezoelectric Gages

Piezoelectric strain gages are, effectively, parallel plate capacitors whose dielectric changes polarization in response to strain [14]. When the polarization changes, a charge proportional to the strain is produced on the electrodes. PVDF film strain gages are inexpensive, but not very accurate and subject to depoling by moderate temperature. They make good sensors for dynamic measurements such as frequency and logarithm decrement, but not for quantitative measurements of strain. When used for quasistatic measurements, the charge tends to drain through the measuring instrument. This causes the signal to decay with a time constant dependent on the input impedance of the measuring instrument. Quartz gages are very accurate, but also lose charge through the measuring instrument. Time constants can be relatively long (seconds to hours) with electrometers or charge amplifiers.

The PVDF gage consists of a thin piezoelectric film with metal electrodes (Figure 22.9). Lead wires connect the electrodes to a charge measuring circuit. Gages can be obtained with the electrodes encapsulated between insulating layers of polyimide.

The gage output can be described in terms of a net dipole moment per unit volume. If the net dipole moment is the total charge, Q , on the electrodes multiplied by spacing, d , between the electrodes, then the polarization is given by Equation 22.30.

$$P = \frac{Qd}{V} \quad (22.30)$$

From Equation 22.30, it is seen that the polarization P (approximately equal to the electric displacement D) is the charge per unit electrode area (Figure 22.10).

A Taylor's series expansion of Equation 22.30 gives Equation 22.31.

$$\Delta P = \frac{\partial P}{\partial V} \Delta V + \frac{\partial P}{\partial(Qd)} \Delta Qd \quad (22.31)$$

Which, after differentiating Equation 22.30 and substituting becomes Equation 22.31.

$$\Delta P = \frac{\Delta Qd}{V_0} - \frac{\Delta V}{V_0} P_0 \quad (22.32)$$

FIGURE 22.10 A representative cross-section of a piezoelectric material formed into a parallel plate capacitor. The piezoelectric material is polarized. This results in a charge on the electrodes. When the material is strained, the polarization changes and charge flows.

For PVDF film, the second term in Equation 22.32 dominates. The output is proportional to the remanent polarization P_0 . The remanent polarization slowly decays with time, has a strong dependence on temperature, and decays rapidly at temperatures around 50°C. This makes accuracy a problem. If the sensors are kept at low temperature, accuracy can be maintained within $\pm 3\%$.

Strain sensors can also be constructed from piezoelectric ceramics like lead zirconate titanate (PZT) or barium titanate. Ceramics are brittle and can be depoled by strain so should only be used at strains less than 200 microstrain. PZT loses some of its polarization with time and thus has accuracy problems, but remains polar to temperatures of 150°C or higher. “Hard” PZT (usually iron doped) is the best composition for polarization stability and low hysteresis. Quartz has the best accuracy. It is not polar, but polarization is induced by strain. Quartz has excellent resolution and accuracy over a broad temperature range but is limited to low strain levels. It is also brittle, so is limited to small strain.

Two circuits are commonly used for piezoelectric signal conditioning: the electrometer and the charge amplifier (Figure 22.11). In the electrometer circuit, the piezoelectric sensor is connected to a capacitor with a capacitance value C , at least 1000 times that of the sensor C_g . There is always some resistance in

FIGURE 22.11 The electrometer and charge amplifier are the most common circuits used to measure charge from piezoelectric transducers.

FIGURE 22.12 A schematic of the Fabry–Perot fiber optic strain gage. When the cavity elongates, alternating constructive and destructive interference occur.

the cable that connects the sensor to the capacitor. The circuit is simply two capacitors in parallel connected by a resistance. The charge equilibrates with a time constant given by $R_g C_g$. This time constant limits the fastest risetime that can be resolved to about 50 ns, effectively instantaneous for most applications. The charge is measured by measuring the voltage on the capacitor, then using Equation 22.33.

$$Q = CV \tag{22.33}$$

The difficulty is that measuring devices drain the charge, causing a time decay with a time constant RC . This causes the signal to be lost rapidly if conventional op amps are used. FET input op amps have a very high input impedance and can extend this time constant to many hours. The charge amplifier is another circuit used to measure charge. This is usually an FET input op amp with a capacitor feedback. This does not really amplify charge, but produces a voltage proportional to the input charge. Again, the time constant can be many hours, allowing use of piezoelectric sensors for near static measurements.

High input impedance electrometer and charge amplifier signal conditioners for near static measurements are commercially available [20] as well as low-cost capacitive terminators for high-frequency (high kilohertz to megahertz) measurements [18]. An advantage of piezoelectric sensors is that they are active sensors that do not require any external energy source.

Fiber Optic Strain Gages

Fiber optic strain gages are miniature interferometers [21, 22]. Many commercially available sensors are based on the Fabry–Perot interferometer. The Fabry–Perot interferometer measures the change in the size of a very small cavity.

Fabry–Perot strain sensors (Figure 22.12) comprise a laser light source, single-mode optical fibers, a coupler (the fiber optic equivalent of a beam splitter), a cavity that senses strain, and a photodetector. Light leaves the laser diode. It passes down the fiber, through the coupler, and to the cavity. The end of the fiber is the equivalent of a partially silvered mirror. Some of the light is reflected back up the fiber and some is transmitted. The transmitted light crosses the cavity and then is reflected from the opposite end back into the fiber where it recombines with the first reflected beam. The two beams have a phase difference related to twice the cavity length. The recombined beam passes through the coupler to the photodetector. If the two reflected beams are in phase, there will be constructive interference. If the two

beams are out of phase, there will be destructive interference. The cavity is bonded to a specimen. When the specimen is strained, the cavity stretches. This results in a phase change of the cavity beam, causing a cycling between constructive and destructive interference. For a 1.3 μm light source, each peak in output corresponds to a 650 nm gap displacement. The gap displacement divided by the gap length gives the strain. The output is continuous between peaks so that a 3 mm gage can resolve 1 μstrain .

Birefringent Film Strain Sensing

Birefringent film strain sensors give a full field measurement of strain. A nice demonstration of this effect can be achieved with two sheets of inexpensive Polaroid film, a 6 mm thick, 25 mm \times 200 mm bar of Plexiglas (polymethylmethacrylate or PMMA), and an overhead projector. Place the two Polaroid sheets at 90° to one another so that the light is blocked. Place the PMMA between the Polaroid sheets. Apply a bending moment to the bar and color fringes will appear. Birefringent materials have a different speed of light in different directions. This means that if light is polarized in a particular direction and passed through a birefringent specimen, if the fast direction is aligned with the electric field vector, the light passes through faster than if the slow direction is aligned with the electric field vector. This effect can be used to produce optical interference. In some materials, birefringence is induced by strain. The fast and slow directions correspond to the directions of principal strain, and the amount of birefringence corresponds to the magnitude of the strain. One component of the electric field vector travels through the specimen faster than the other. They emerge with a phase difference. This changes the relative amplitude and thus rotates the polarization of the light. If there is no birefringence, no light passes through the second polarizer. As the birefringence increases with strain, light passes through. As it further increases, the polarization rotation will be a full 180° and again no light will pass through. This produces a fringe that corresponds to a constant difference in principal strains. The difference in principal strains is given by Equation 22.34.

$$\varepsilon_2 - \varepsilon_1 = \frac{N\lambda}{tK} \quad (22.34)$$

where $\varepsilon_1, \varepsilon_2$ = Principal strains

N = Fringe order

λ = Wavelength

t = Specimen thickness

K = Strain-optical coefficient of the photoelastic material

A similar technique can be used with a birefringent plastic film with a silvered backing laminated to the surface of a specimen. Polarized light is passed through the film; it reflects from the backing, passes back through the film, and through the second polarizer. In this case, because light passes twice through the film, the equation governing the difference in principal strains is Equation 22.35.

$$\varepsilon_2 - \varepsilon_1 = \frac{N\lambda}{2tK} \quad (22.35)$$

If the polarizers align with principal strain directions, no birefringence is observed. Rotation of both polarizers allows the principal directions to be found at various locations on the test specimen. If a full view of the fringes is desired, quarter wave plates are used (Figure 22.13). In this arrangement, light is passed through the first polarizer, resulting in plane polarization; through the quarter wave plate, resulting in circular polarization; through the test specimen, resulting in phase changes; through the second quarter wave plate to return to plane polarization; and then through the final polarizer.

The optical systems for viewing birefringence are commercially available as “Polariscopes” [23]. Optical components to construct custom systems are available from many optical components suppliers.

FIGURE 22.13 A schematic of the polariscope, a system for measuring birefringence. This technique gives a full field measure of the difference in principal strains.

Moiré Strain Sensing

Moiré interference is another technique that gives a full field measurement, but it measures displacement rather than strain. The strain field must be computed from the displacement field. This technique is based on the interference obtained when two transparent plates are covered with equally spaced stripes. If the plates are held over one another, they can be aligned so that no light will pass through or so that all light will pass through. If one of the plates is stretched, the spacing of the lines is wider on the stretched plate. Now, if one plate is placed over the other, in some regions light will pass through and in some regions it will not (Figure 22.14). The dark and light bands produced give information about the displacement field.

Moiré is defined as a series of broad dark and light patterns formed by the superposition of two regular gratings [24]. The dark or light regions are called fringes. Examples of pure extension and pure rotation are shown. In both cases, some of the light that would emerge from the first grating is obstructed by the superimposed grating. At the centers of the dark fringes, the bar of one grating covers the space of the other and no light comes through. The emergent intensity, I , is zero. Proceeding from there toward the next dark fringe, the amount of obstruction diminishes linearly and the amount of light increases linearly until the bar of one grating falls above the bar of the other. There, the maximum amount of light passes through the gratings.

Both geometric interference and optical interference are used. This discussion is restricted to geometric interference. Geometric moiré takes advantage of the interference of two gratings to determine displacements and rotations in the plane of view. In-plane moiré is typically conducted with two gratings, one applied to the specimen (specimen grating) and the other put in contact with the specimen grating (reference grating). When the specimen is strained, interference patterns or fringes occur. N is the moiré fringe order. Each fringe corresponds to an increase or decrease of specimen displacement by one grating pitch. The relationship between displacement and fringes is $\delta = gN$, where δ is component of the displacement perpendicular to the reference grating lines, g is reference grating pitch, and N is the fringe order.

For convenience, a zero-order fringe is designated assuming the displacement there is zero. With the reference grating at 0° and 90° , the fringe orders N_x and N_y are obtained. The displacements in x , y directions are then obtained from Equations 22.36 and 22.37.

$$u_x(x, y) = gN_x(x, y) \tag{22.36}$$

$$u_y(x, y) = gN_y(x, y) \tag{22.37}$$

Differentiation of Equations 22.36 and 22.37 gives the strains, Equations 22.38 through 22.40.

FIGURE 22.14 A demonstration of moiré fringes formed by overlapping gratings. The fringes are the result of stretching and relative rotation of the gratings. The fringe patterns are used to determine displacement fields.

$$\epsilon_x = \frac{\partial u_x}{\partial x} = g \frac{\partial N_x}{\partial x} \quad (22.38)$$

$$\epsilon_{xy} = \frac{1}{2} \left(\frac{\partial u_y}{\partial x} + \frac{\partial u_x}{\partial y} \right) = \frac{1}{2} \left(g \frac{\partial N_y}{\partial x} + g \frac{\partial N_x}{\partial y} \right) \quad (22.39)$$

$$\epsilon_y = \frac{\partial u_y}{\partial y} = g \frac{\partial N_y}{\partial y} \quad (22.40)$$

In most cases, the sensitivity of geometric moiré is not adequate for determination of strain distributions. Strain analysis should be conducted with high-sensitivity measurement of displacement using moiré interferometry [24, 25]. Moiré interferometers are commercially available [26]. Out-of-plane measurement can be conducted with one grating (the reference grating). The reference grating is made to interfere with either its reflection or its shadow [27, 28].

Force, which is a vector quantity, can be defined as an action that will cause an acceleration or a certain reaction of a body. This chapter will outline the methods that can be employed to determine the magnitude of these forces.

23.1 General Considerations

The determination or measurement of forces must yield to the following considerations: if the forces acting on a body do not produce any acceleration, they must form a *system of forces in equilibrium*. The system is then considered to be in static equilibrium. The forces experienced by a body can be classified into two categories: internal, where the individual particles of a body act on each other, and external otherwise. If a body is supported by other bodies while subject to the action of forces, deformations and/or displacements will be produced at the points of support or contact. The internal forces will be distributed throughout the body until equilibrium is established, and then the body is said to be in a state of tension, compression, or shear. In considering a body at a definite section, it is evident that all the internal forces act in pairs, the two forces being equal and opposite, whereas the external forces act singly.

23.2 Hooke's Law

The basis for force measurement results from the physical behavior of a body under external forces. Therefore, it is useful to review briefly the mechanical behavior of materials. When a metal is loaded in uniaxial tension, uniaxial compression, or simple shear ([Figure 23.1](#)), it will behave elastically until a critical value of normal stress (S) or shear stress (τ) is reached, and then it will deform plastically [1]. In the elastic region, the atoms are temporarily displaced but return to their equilibrium positions when the load is removed. Stress (S or τ) and strain (e or γ) in the elastic region are defined as indicated in [Figure 23.2](#).

$$\nu = -\frac{e_2}{e_1} \quad (23.1)$$

FIGURE 23.1 When a metal is loaded in uniaxial tension (a) uniaxial compression (b), or simple shear (c), it will behave elastically until a critical value of normal stress or shear stress is reached.

FIGURE 23.2 Elastic stress and strain for: (a) uniaxial tension; (b) uniaxial compression; (c) simple shear [1].

Poisson's ratio (ν) is the ratio of transverse (e_2) to direct (e_1) strain in tension or compression. In the elastic region, ν is between 1/4 and 1/3 for metals. The relation between stress and strain in the elastic region is given by Hooke's law:

$$S = E e \text{ (tension or compression)} \quad (23.2)$$

$$\tau = G \gamma \text{ (simple shear)} \quad (23.3)$$

where E and G are the Young's and shear modulus of elasticity, respectively. A small change in specific volume ($\Delta Vol / Vol$) can be related to the elastic deformation, which is shown to be as follows for an isotropic material (same properties in all directions).

$$\frac{\Delta Vol}{Vol} = e_1 (1 - 2\nu) \quad (23.4)$$

The bulk modulus ($K =$ reciprocal of compressibility) is defined as follows:

$$K = \Delta p / \left(\frac{\Delta Vol}{Vol} \right) \quad (23.5)$$

where Δp is the pressure acting at a particular point. For an elastic solid loaded in uniaxial compression (S):

$$K = S / \left(\frac{\Delta Vol}{Vol} \right) = \frac{S}{\epsilon_1(1-2\nu)} = \frac{E}{1-2\nu} \quad (23.6)$$

Thus, an elastic solid is compressible as long as ν is less than 1/2, which is normally the case for metals. Hooke's law (Equation 23.2) for uniaxial tension can be generalized for a three-dimensional elastic condition.

The theory of elasticity is well established and is used as a basis for force measuring techniques. Note that the measurement of forces in separate engineering applications is very application specific, and care must be taken in the selection of the measuring techniques outlined below.

Basic Methods of Force Measurement

An unknown force may be measured by the following means:

1. Balancing the unknown force against a standard mass through a system of levers.
2. Measuring the acceleration of a known mass.
3. Equalizing it to a magnetic force generated by the interaction of a current-carrying coil and a magnet.
4. Distributing the force on a specific area to generate pressure, and then measuring the pressure.
5. Converting the applied force into the deformation of an elastic element.

The aforementioned methods used for measuring forces yield a variety of designs of measuring equipment. The challenge involved with the task of measuring force resides primarily in sensor design. The basics of sensor design can be resolved into two problems:

1. Primary geometric, or physical constraints, governed by the application of the force sensor device.
2. The means by which the force can be converted into a workable signal form (such as electronic signals or graduated displacements).

The remaining sections will discuss the types of devices used for force to signal conversion and finally illustrate some examples of applications of these devices for measuring forces.

23.3 Force Sensors

Force sensors are required for a basic understanding of the response of a system. For example, cutting forces generated by a machining process can be monitored to detect a tool failure or to diagnose the causes of this failure in controlling the process parameters, and in evaluating the quality of the surface produced. Force sensors are used to monitor impact forces in the automotive industry. Robotic handling and assembly tasks are controlled by detecting the forces generated at the end effector. Direct measurement of forces is useful in controlling many mechanical systems.

Some types of force sensors are based on measuring a deflection caused by the force. Relatively high deflections (typically, several micrometers) would be necessary for this technique to be feasible. The excellent elastic properties of helical springs make it possible to apply them successfully as force sensors that transform the load to be measured into a deflection. The relation between force and deflection in the elastic region is demonstrated by Hooke's law. Force sensors that employ strain gage elements or piezoelectric (quartz) crystals with built-in microelectronics are common. Both impulsive forces and slowly varying forces can be monitored using these sensors.

Of the available force measuring techniques, a general subgroup can be defined as that of load cells. Load cells are comprised generally of a rigid outer structure, some medium that is used for measuring

FIGURE 23.3 Different types of load cells [2].

the applied force, and the measuring gage. Load cells are used for sensing large, static or slowly varying forces with little deflection and are a relatively accurate means of sensing forces. Typical accuracies are of the order of 0.1% of the full-scale readings. Various strategies can be employed for measuring forces that are strongly dependent on the design of the load cell. For example, Figure 23.3 illustrates different types of load cells that can be employed in sensing large forces for relatively little cost. The hydraulic load cell employs a very stiff outer structure with an internal cavity filled with a fluid. Application of a load increases the oil pressure, which can be read off an accurate gage.

Other sensing techniques can be utilized to monitor forces, such as piezoelectric transducers for quicker response of varying loads, pneumatic methods, strain gages, etc. The proper sensing technique needs special consideration based on the conditions required for monitoring.

Strain Gage Load Cell

The strain gage load cell consists of a structure that elastically deforms when subjected to a force and a strain gage network that produces an electrical signal proportional to this deformation. Examples of this are beam and ring types of load cells.

Strain Gages

Strain gages use a length of gage wire to produce the desired resistance (which is usually about $120\ \Omega$) in the form of a flat coil. This coil is then cemented (bonded) between two thin insulating sheets of paper or plastic. Such a gage cannot be used directly to measure deflection. It has to be first fixed properly to a member to be strained. After bonding the gage to the member, they are baked at about 195°F (90°C) to remove moisture. Coating the unit with wax or resin will provide some mechanical protection. The resistance between the member under test and the gage itself must be at least $50\ \text{M}\Omega$. The total area of all conductors must remain small so that the cement can easily transmit the force necessary to deform the wire. As the member is stressed, the resulting strain deforms the strain gage and the cross-sectional area diminishes. This causes an increase in resistivity of the gage that is easily determined. In order to measure very small strains, it is necessary to measure small changes of the resistance per unit resistance ($\Delta R/R$). The change in the resistance of a bonded strain gage is usually less than 0.5%. A wide variety of gage sizes and grid shapes are available, and typical examples are shown in Figure 23.4.

The use of strain gages to measure force requires careful consideration with respect to rigidity and environment. By virtue of their design, strain gages of shorter length generally possess higher response frequencies (examples: 660 kHz for a gage of 0.2 mm and 20 kHz for a gage of 60 mm in length). The environmental considerations focus mainly on the temperature of the gage. It is well known that resistance is a function of temperature and, thus, strain gages are susceptible to variations in temperature. Thus, if it is known that the temperature of the gage will vary due to any influence, temperature compensation is required in order to ensure that the force measurement is accurate.

A Wheatstone bridge (Figure 23.5) is usually used to measure this small order of magnitude. In Figure 23.5, no current will flow through the galvanometer (G) if the four resistances satisfy a certain

FIGURE 23.4 Configuration of metal-foil resistance strain gages: (a) single element; (b) two element; and (c) three element.

FIGURE 23.5 The Wheatstone bridge.

condition. In order to demonstrate how a Wheatstone bridge operates [3], a voltage scale has been drawn at points C and D of Figure 23.5. Assume that R_1 is a bonded gage and that initially Equation 23.7 is satisfied. If R_1 is now stretched so that its resistance increases by one unit ($+\Delta R$), the voltage at point D will be increased from zero to plus one unit of voltage ($+\Delta V$), and there will be a voltage difference of one unit between C and D that will give rise to a current through C. If R_4 is also a bonded gage, and at the same time that R_1 changes by $+\Delta R$, R_4 changes by $-\Delta R$, the voltage at D will move to $+2\Delta V$. Also, if at the same time, R_2 changes by $-\Delta R$, and R_3 changes by $+\Delta R$, then the voltage of point C will move to $-2\Delta V$, and the voltage difference between C and D will now be $4\Delta V$. It is then apparent that although a single gage can be used, the sensitivity can be increased fourfold if two gages are used in tension while two others are used in compression.

$$\frac{R_1}{R_4} = \frac{R_2}{R_3} \quad (23.7)$$

The grid configuration of the metal-foil resistance strain gages is formed by a photo-etching process. The shortest gage available is 0.20 mm; the longest is 102 mm. Standard gage resistance are 120 Ω and 350 Ω . A strain gage exhibits a resistance change $\Delta R/R$ that is related to the strain in the direction of the grid lines by the expression in Equation 23.8 (where S_g is the gage factor or calibration constant for the gage).

$$\frac{\Delta R}{R} = S_g \epsilon \quad (23.8)$$

FIGURE 23.6 Beam-type load cells: (a) a selection of beam-type load cells (elastic element with strain gages); and (b) gage positions in the Wheatstone bridge.

Beam-Type Load Cell

Beam-type load cells are commonly employed for measuring low-level loads [3]. A simple cantilever beam (see [Figure 23.6\(a\)](#)) with four strain gages, two on the top surface and two on the bottom surface (all oriented along the axis of the beam) is used as the elastic member (sensor) for the load cell. The gages are wired into a Wheatstone bridge as shown in [Figure 23.6\(b\)](#). The load P produces a moment $M = Px$ at the gage location (x) that results in the following strains:

$$\epsilon_1 = -\epsilon_2 = \epsilon_3 = -\epsilon_4 = \frac{6M}{Ebh^2} = \frac{6Px}{Ebh^2} \quad (23.9)$$

where b is the width of the cross-section of the beam and h is the height of the cross-section of the beam. Thus, the response of the strain gages is obtained from Equation 23.10.

$$\frac{\Delta R_1}{R_1} = -\frac{\Delta R_2}{R_2} = \frac{\Delta R_3}{R_3} = -\frac{\Delta R_4}{R_4} = \frac{6S_g Px}{Ebh^2} \quad (23.10)$$

The output voltage E_o from the Wheatstone bridge, resulting from application of the load P , is obtained from Equation 23.11. If the four strain gages on the beam are assumed to be identical, then Equation 23.11 holds.

$$E_o = \frac{6S_g Px E_1}{Ebh^2} \quad (23.11)$$

The range and sensitivity of a beam-type load cell depends on the shape of the cross-section of the beam, the location of the point of application of the load, and the fatigue strength of the material from which the beam is fabricated.

Ring-Type Load Cell

Ring-type load cells incorporate a proving ring (see [Figure 23.7](#)) as the elastic element. The ring element can be designed to cover a very wide range of loads by varying the diameter D , the thickness t , or the depth w of the ring. Either strain gages or a linear variable-differential transformer (LVDT) can be used as the sensor.

The load P is linearly proportional to the output voltage E_o . The sensitivity of the ring-type load cell with an LVDT sensor depends on the geometry of the ring (R , t , and w), the material from which the ring is fabricated (E), and the characteristics of the LVDT (S and E_i). The range of a ring-type load cell is controlled by the strength of the material used in fabricating the ring.

FIGURE 23.7 Ring-type load cells: (a) elastic element with strain-gage sensors; (b) gage positions in the Wheatstone bridge; and (c) elastic element with an LVDT sensor.

Piezoelectric Methods

A piezoelectric material exhibits a phenomenon known as the *piezoelectric effect*. This effect states that when asymmetrical, elastic crystals are deformed by a force, an electrical potential will be developed within the distorted crystal lattice. This effect is reversible. That is, if a potential is applied between the surfaces of the crystal, it will change its physical dimensions [4]. Elements exhibiting piezoelectric qualities are sometimes known as electrorestrictive elements.

The magnitude and polarity of the induced surface charges are proportional to the magnitude and direction of the applied force [4]:

$$Q = dF \quad (23.12)$$

where d is the charge sensitivity (a constant for a given crystal) of the crystal in C/N . The force F causes a thickness variation Δt meters of the crystal:

$$F = \frac{aY}{t} \Delta t \quad (23.13)$$

where a is area of crystal, t is thickness of crystal, and Y is Young's modulus.

$$Y = \frac{\text{stress}}{\text{strain}} = \frac{Ft}{a\Delta t} \quad (23.14)$$

The charge at the electrodes gives rise to a voltage $E_0 = Q/C$, where C is capacitance in farads between the electrodes and $C = \epsilon a/t$ where ϵ is the absolute permittivity.

FIGURE 23.8 Modes of operation for a simple plate as a piezoelectric device [4].

FIGURE 23.9 Curvature of "twister" and "bender" piezoelectric transducers when voltage applied [4].

$$E_o = \frac{dF}{C} = \frac{d}{\epsilon} \frac{tF}{a} \quad (23.15)$$

The voltage sensitivity = $g = d/\epsilon$ in volt m/N can be obtained as:

$$E_o = g \frac{t}{a} F = gtP \quad (23.16)$$

The piezoelectric materials used are quartz, tourmaline, Rochelle salt, ammonium dihydrogen phosphate (ADP), lithium sulfate, barium titanate, and lead zirconate titanate (PZT) [4]. Quartz and other earthly piezoelectric crystals are naturally polarized. However, synthetic piezoelectric materials, such as barium titanate ceramic, are made by baking small crystallites under pressure and then placing the resultant material in a strong dc electric field [4]. After that, the crystal is polarized, along the axis on which the force will be applied, to exhibit piezoelectric properties. Artificial piezoelectric elements are free from the limitations imposed by the crystal structure and can be molded into any size and shape. The direction of polarization is designated during their production process.

The different modes of operation of a piezoelectric device for a simple plate are shown in Figure 23.8 [4]. By adhering two crystals together so that their electrical axes are perpendicular, bending moments or torque can be applied to the piezoelectric transducer and a voltage output can be produced (Figure 23.9) [4]. The range of forces that can be measured using piezoelectric transducers are from 1 to 200 kN and at a ratio of 2×10^5 .

Piezoelectric crystals can also be used in measuring an instantaneous change in the force (dynamic forces). A thin plate of quartz can be used as an electronic oscillator. The frequency of these oscillations will be dominated by the natural frequency of the thin plate. Any distortion in the shape of the plate caused by an external force, alters the oscillation frequency. Hence, a dynamic force can be measured by the change in frequency of the oscillator.

Resistive Method

The resistive method employs the fact that when the multiple contact area between semiconducting particles (usually carbon) and the distance between the particles are changed, the total resistance is altered. The design of such transducers yields a very small displacement when a force is applied. A transducer might consist of 2 to 60 thin carbon disks mounted between a fixed and a movable electrode. When a force is applied to the movable electrode and the carbon disks move together by 5 to 250 μm per interface, the transfer function of their resistance against the applied force is approximately hyperbolic, that is, highly nonlinear. The device is also subject to large hysteresis and drift together with a high transverse sensitivity.

In order to reduce hysteresis and drift, rings are used instead of disks. The rings are mounted on an insulated rigid core and prestressed. This almost completely eliminates any transverse sensitivity error. The core's resonant frequency is high and can occur at a frequency as high as 10 kHz. The possible measuring range of such a transducer is from 0.1 kg to 10 kg. The accuracy and linear sensitivity of this transducer is very poor.

Inductive Method

The inductive method utilizes the fact that a change in mechanical stress of a ferromagnetic material causes its permeability to alter. The changes in magnetic flux are converted into induced voltages in the pickup coils as the movement takes place. This phenomenon is known as the *Villari effect* or *magnetostriction*. It is known to be particularly strong in nickel–iron alloys.

Transducers utilizing the Villari effect consist of a coil wound on a core of magnetostrictive material. The force to be measured is applied on this core, stressing it and causing a change in its permeability and inductance. This change can be monitored and used for determining the force.

The applicable range for this type of transducer is a function of the cross-sectional area of the core. The accuracy of the device is determined by a calibration process. This transducer has poor linearity and is subject to hysteresis. The permeability of a magnetostrictive material increases when it is subjected to pure torsion, regardless of direction. A flat frequency response is obtained over a wide range from 150 Hz to 15,000 Hz.

Piezotransistor Method

Devices that utilize *anisotropic stress effects* are described as piezotransistors. In this effect, if the upper surface of a *p–n* diode is subjected to a localized stress, a significant reversible change occurs in the current across the junction. These transistors are usually silicon nonplanar type, with an emitter base junction. This junction is mechanically connected to a diaphragm positioned on the upper surface of a typical TO-type can [4]. When a pressure or a force is applied to the diaphragm, an electronic charge is produced. It is advisable to use these force-measuring devices at a constant temperature by virtue of the fact that semiconducting materials also change their electric properties with temperature variations. The attractive characteristic of piezotransistors is that they can withstand a 500% overload.

Multicomponent Dynamometers Using Quartz Crystals As Sensing Elements

The Piezoelectric Effects in Quartz.

For force measurements, the *direct piezoelectric effect* is utilized. The direct longitudinal effect measures compressive force; the direct shear effect measures shear force in one direction. For example, if a disk of crystalline quartz (SiO_2) cut normally to the crystallographic *x*-axis is loaded by a compression force, it will yield an electric charge, nominally 2.26 pC/N. If a disk of crystalline quartz is cut normally to the

FIGURE 23.10 Three-component force transducer.

FIGURE 23.11 Force measuring system to determine the tool-related cutting forces in five-axis milling [6].

crystallographic y -axis, it will yield an electric charge (4.52 pC/N) if loaded by a shear force in one specific direction. Forces applied in the other directions will not generate any output [5].

A charge amplifier is used to convert the charge yielded by a quartz crystal element into a proportional voltage. The range of a charge amplifier with respect to its conversion factor is determined by a feedback capacitor. Adjustment to mechanical units is obtained by additional operational amplifiers with variable gain.

The Design of Quartz Multicomponent Dynamometers.

The main element for designing multicomponent dynamometers is the three-component force transducer (Figure 23.10). It contains a pair of X -cut quartz disks for the normal force component and a pair of Y -cut quartz disks (shear-sensitive) for each shear force component.

Three-component dynamometers can be used for measuring cutting forces during machining. Four three-component force transducers sandwiched between a base plate and a top plate are shown in Figure 23.10. The force transducer is subjected to a preload as shear forces are transmitted by friction. The four force transducers experience a drastic change in their load, depending on the type and position of force application. An overhanging introduction of the force develops a tensile force for some transducers, thus reducing the preload. Bending of the dynamometer top plate causes bending and shearing stresses. The measuring ranges of a dynamometer depend not only on the individual forces, but also on the individual bending stresses.

Measuring Signals Transmitted by Telemetry.

Figure 23.11 shows the newly designed force measuring system RCD (rotating cutting force dynamometer). A ring-shaped sensor (1) is fitted in a steep angle taper socket (2) and a base ring (3) allowing sensing of the three force components F_x , F_y and F_z at the cutting edge as well as the moment M_z . The

Photo not available.

FIGURE 23.12 Capacitive force transducer.

physical operating principle of this measuring cell is based on the piezoelectric effect in quartz plates. The quartz plates incorporated in the sensor are aligned so that the maximum cross-sensitivity between the force components is 1%. As a result of the rigid design of the sensor, the resonant frequencies of the force measuring system range from 1200 Hz to 3000 Hz and the measuring ranges cover a maximum of 10 kN [6].

Force-proportional charges produced at the surfaces of the quartz plates are converted into voltages by four miniature charge amplifiers (7) in hybrid construction. These signals are then filtered by specific electrical circuitry to prevent aliasing effects, and digitized with 8 bit resolution using a high sampling rate (pulse-code modulation). The digitized signals are transmitted by a telemetric unit consisting of a receiver and transmitter module, an antenna at the top of the rotating force measuring system (8), as well as a fixed antenna (9) on the splash cover of the two-axis milling head (10). The electrical components, charge amplifier, and transmitter module are mounted on the circumference of the force measuring system [6].

The cutting forces and the moment measured are digitized with the force measuring system described above. They are modulated on an FM carrier and transmitted by the rotating transmitter to the stationary receiver. The signals transmitted are fed to an external measured-variable conditioning unit.

Measuring Dynamic Forces.

Any mechanical system can be considered in the first approximation as a weakly damped oscillator consisting of a spring and a mass. If a mechanical system has more than one resonant frequency, the lowest one must be taken into consideration. As long as the test frequency remains below 10% of the resonant frequency of the reference transducer (used for calibration), the difference between the dynamic sensitivity obtained from static calibration will be less than 1%. The above considerations assume a sinusoidal force signal. The static calibration of a reference transducer is also valid for dynamic calibration purposes if the test frequency is much lower (at least 10 times lower) than the resonant frequency of the system.

Capacitive Force Transducer

A transducer that uses capacitance variation can be used to measure force. The force is directed onto a membrane whose elastic deflection is detected by a capacitance variation. A highly sensitive force transducer can be constructed because the capacitive transducer senses very small deflections accurately. An electronic circuit converts the capacitance variations into dc-voltage variations [7].

The capacitance sensor illustrated in [Figure 23.12](#) consists of two metal plates separated by an air gap. The capacitance C between terminals is given by the expression:

$$C = \epsilon_0 \epsilon_r \frac{A}{h} \quad (23.17)$$

FIGURE 23.13 Diagram of a typical force sensing resistor (FSR).

FIGURE 23.14 Resistance as a function of force for a typical force sensing resistor.

- where C = Capacitance in farads (F)
 ϵ_0 = Dielectric constant of free space
 ϵ_r = Relative dielectric constant of the insulator
 A = Overlapping area for the two plates
 h = Thickness of the gap between the two plates

The sensitivity of capacitance-type sensors is inherently low. Theoretically, decreasing the gap h should increase the sensitivity; however, there are practical electrical and mechanical conditions that preclude high sensitivities. One of the main advantages of the capacitive transducer is that moving of one of its plate relative to the other requires an extremely small force to be applied. A second advantage is stability and the sensitivity of the sensor is not influenced by pressure or temperature of the environment.

Force Sensing Resistors (Conductive Polymers)

Force sensing resistors (FSRs) utilize the fact that certain polymer thick-film devices exhibit decreasing resistance with the increase of an applied force. A force sensing resistor is made up of two parts. The first is a resistive material applied to a film. The second is a set of digitating contacts applied to another film. Figure 23.13 shows this configuration. The resistive material completes the electrical circuit between the two sets of conductors on the other film. When a force is applied to this sensor, a better connection is made between the contacts; hence, the conductivity is increased. Over a wide range of forces, it turns out that the conductivity is approximately a linear function of force. Figure 23.14 shows the resistance of the sensor as a function of force. It is important to note that there are three possible regions for the sensor to operate. The first abrupt transition occurs somewhere in the vicinity of 10 g of force. In this

region, the resistance changes very rapidly. This behavior is useful when one is designing switches using force sensing resistors.

FSRs should not be used for accurate measurements of force because sensor parts may exhibit 15% to 25% variation in resistance between each other. However, FSRs exhibit little hysteresis and are considered far less costly than other sensing devices. Compared to piezofilm, the FSR is far less sensitive to vibration and heat.

Magneto resistive Force Sensors

The principle of *magneto resistive force sensors* is based on the fact that metals, when cooled to low temperatures, show a change of resistivity when subjected to an applied magnetic field. Bismuth, in particular, is quite sensitive in this respect. In practice, these devices are severely limited because of their high sensitivity to ambient temperature changes.

Magnetoelastic Force Sensors

Magnetoelastic transducer devices operate based on the Joule effect; that is, a ferromagnetic material is dimensionally altered when subjected to a magnetic field. The principle of operation is as follows: Initially, a current pulse is applied to the conductor within the waveguide. This sets up a magnetic field circumference-wise around the waveguide over its entire length. There is another magnetic field generated by the permanent magnet that exists only where the magnet is located. This field has a longitudinal component. These two fields join vectorally to form a helical field near the magnet which, in turn, causes the waveguide to experience a minute torsional strain or twist only at the location of the magnet. This twist effect is known as the *Wiedemann effect* [8].

Magnetoelastic force transducers have a high frequency response (on the order of 20 kHz). Some of the materials that exhibit magnetoelastic include Monel metal, Permalloy, Ceras, Alfer, and a number of nickel-iron alloys. Disadvantages of these transducers include: (1) the fact that excessive stress and aging may cause permanent changes, (2) zero drift and sensitivity changes due to temperature sensitivity, and (3) hysteresis errors.

Torsional Balances

Balancing devices that utilize the deflection of a spring may also be used to determine forces. *Torsional balances* are equal arm scale force measuring devices. They are comprised of horizontal steel bands instead of pivots and bearings. The principle of operation is based on force application on one of the arms that will deflect the torsional spring (within its design limits) in proportion to the applied force. This type of instrument is susceptible to hysteresis and temperature errors and therefore is not used for precise measurements.

Tactile Sensors

Tactile sensors are usually interpreted as a touch sensing technique. Tactile sensors cannot be considered as simple touch sensors, where very few discrete force measurements are made. In tactile sensing, a force “distribution” is measured using a closely spaced array of force sensors.

Tactile sensing is important in both grasping and object identification operations. Grasping an object must be done in a stable manner so that the object is not allowed to slip or damaged. Object identification includes recognizing the shape, location, and orientation of a product, as well as identifying surface properties and defects. Ideally, these tasks would require two types of sensing [9]:

1. Continuous sensing of contact forces
2. Sensing of the surface deformation profile

These two types of data are generally related through stress-strain relations of the tactile sensor. As a result, almost continuous variable sensing of tactile forces (the sensing of the tactile deflection profile) is achieved.

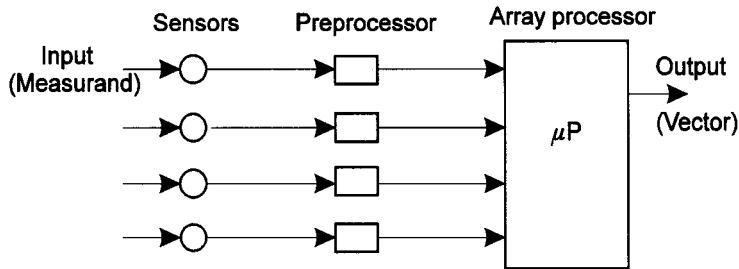

FIGURE 23.15 Tactile array sensor.

Tactile Sensor Requirements.

Significant advances in tactile sensing are taking place in the robotics area. Applications include automated inspection of surface profiles, material handling or parts transfer, parts assembly, and parts identification and gaging in manufacturing applications and fine-manipulation tasks. Some of these applications may need only simple touch (force–torque) sensing if the parts being grasped are properly oriented and if adequate information about the process is already available.

Naturally, the main design objective for tactile sensing devices has been to mimic the capabilities of human fingers [9]. Typical specifications for an industrial tactile sensor include:

1. Spatial resolution of about 2 mm
2. Force resolution (sensitivity) of about 2 g
3. Maximum touch force of about 1 kg
4. Low response time of 5 ms
5. Low hysteresis
6. Durability under extremely difficult working conditions
7. Insensitivity to change in environmental conditions (temperature, dust, humidity, vibration, etc.)
8. Ability to monitor slip

Tactile Array Sensor.

Tactile array sensors (Figure 23.15) consist of a regular pattern of sensing elements to measure the distribution of pressure across the finger tip of a Robot. The 8×8 array of elements at 2 mm spacing in each direction, provides 64 force sensitive elements. Table 23.1 outlines some of the characteristics of early tactile array sensors. The sensor is composed of two crossed layers of copper strips separated by strips of thin silicone rubber. The sensor forms a thin, compliant layer that can be easily attached to a variety of finger-tip shapes and sizes. The entire array is sampled by computer.

A typical tactile sensor array can consist of several sensing elements. Each element or taxel (Figure 23.16) is used to sense the forces present. Since tactile sensors are implemented in applications where sensitivity providing semblance to human touch is desired, an elastomer is utilized to mimic the human skin. The elastomer is generally a conductive material whose electrical conductivity changes locally when pressure is applied. The sensor itself consists of three layers: a protective covering, a sheet of conductive elastomer, and a printed circuit board. The printed circuit board consists of two rows of two “bullseyes,” each with conductive inner and outer rings that compromise the taxels of the sensor. The outer rings are connected together and to a column-select transistor. The inner rings are connected to diodes (D) in Figure 23.16. Once the column in the array is selected, the current flows through the diodes, through the elastomer, and thence through a transistor to ground. As such, it is generally not possible to excite just one taxel because the pressure applied causes a local deformation in neighboring taxels. This situation is called *crossstalk* and is eliminated by the diodes [10].

Tactile array sensor signals are used to provide information about the contact kinematics. Several feature parameters, such as contact location, object shape, and the pressure distribution, can be obtained.

FIGURE 23.16 Typical taxel sensor array.

FIGURE 23.17 General arrangement of an intelligent sensor array system [9].

TABLE 23.1 Summary of Some of the Characteristics of Early Tactile Arrays Sensors

Device parameter	Size of array		
	(4 × 4)	(8 × 8)	(16 × 16)
Cell spacing (mm)	4.00	2.00	1.00
Zero-pressure capacitance (fF)	6.48	1.62	0.40
Rupture force (N)	18.90	1.88	0.19
Max. linear capacitance (fF)	4.80	1.20	0.30
Max. output voltage (V)	1.20	0.60	0.30
Max. resolution (bit)	9.00	8.00	8.00
Readout (access) time (μs)	—	<20	—

The general layout of a sensor array system can be seen in Figure 23.17. An example of this is a contact and force sensing finger. This tactile finger has four contact sensors made of piezoelectric polymer strips on the surface of the fingertip that provide dynamic contact information. A strain gage force sensor provides static grasp force information.

Torque, speed, and power are the defining mechanical variables associated with the functional performance of rotating machinery. The ability to accurately measure these quantities is essential for determining a machine's efficiency and for establishing operating regimes that are both safe and conducive to long and reliable services. On-line measurements of these quantities enable real-time control, help to ensure consistency in product quality, and can provide early indications of impending problems. Torque and power measurements are used in testing advanced designs of new machines and in the development of new machine components. Torque measurements also provide a well-established basis for controlling and verifying the tightness of many types of threaded fasteners. This chapter describes the basic concepts as well as the various methods and apparatus in current use for the measurement of torque and power; the measurement of speed, or more precisely, angular velocity, is discussed elsewhere in this handbook [1].

24.1 Fundamental Concepts

Angular Displacement, Velocity, and Acceleration

The concept of *rotational* motion is readily formalized: all points within a rotating rigid body move in parallel or coincident planes while remaining at fixed distances from a line called the *axis*. In a perfectly rigid body, all points also remain at fixed distances from each other. Rotation is perceived as a change in the angular position of a reference point on the body, i.e., as its *angular displacement*, $\Delta\theta$, over some time interval, Δt . The motion of that point, and therefore of the whole body, is characterized by its

FIGURE 24.1 (a) The off-axis force F at P produces a torque $T = (F \cos \beta)l$ tending to rotate the body in the CW direction. (b) Transmitting torque T over length L twists the shaft through angle ϕ .

clockwise (CW) or counterclockwise (CCW) *direction* and by its *angular velocity*, $\omega = \Delta\theta/\Delta t$. If during a time interval Δt , the velocity changes by $\Delta\omega$, the body is undergoing an *angular acceleration*, $\alpha = \Delta\omega/\Delta t$. With angles measured in radians, and time in seconds, units of ω become radians per second (rad s^{-1}) and of α , radians per second per second (rad s^{-2}). Angular velocity is often referred to as *rotational speed* and measured in numbers of complete revolutions per minute (rpm) or per second (rps).

Force, Torque, and Equilibrium

Rotational motion, as with motion in general, is controlled by *forces* in accordance with Newton's laws. Because a force directly affects only that component of motion in its line of action, forces or components of forces acting in any plane that includes the axis produce no tendency for rotation about that axis. Rotation can be initiated, altered in velocity, or terminated only by a *tangential force* F_t acting at a finite radial distance l from the axis. The effectiveness of such forces increases with both F_t and l ; hence, their product, called a *moment*, is the activating quantity for rotational motion. A moment about the rotational axis constitutes a *torque*. Figure 24.1(a) shows a force F acting at an angle β to the tangent at a point P , distant l (the moment arm) from the axis. The torque T is found from the *tangential component* of F as:

$$T = F_t l = (F \cos \beta)l \quad (24.1)$$

The combined effect, known as the *resultant*, of any number of torques acting at different locations along a body is found from their *algebraic sum*, wherein torques tending to cause rotation in CW and CCW directions are assigned opposite signs. Forces, hence torques, arise from physical contact with other solid bodies, motional interaction with fluids, or via gravitational (including inertial), electric, or magnetic force fields. The *source* of each such torque is subjected to an equal, but oppositely directed, *reaction* torque. With force measured in newtons and distance in meters, Equation 24.1 shows the unit of torque to be a Newton meter (N·m).

A nonzero resultant torque will cause the body to undergo a proportional angular acceleration, found, by application of Newton's second law, from:

$$T_r = I\alpha \quad (24.2)$$

where I , having units of kilogram meter² (kg m^2), is the moment of inertia of the body around the axis (i.e., its *polar* moment of inertia). Equation 24.2 is applicable to any body regardless of its state of motion.

When $\alpha = 0$, Equation 24.2 shows that T_r is also zero; the body is said to be in *equilibrium*. For a body to be in equilibrium, there must be either more than one *applied* torque, or none at all.

Stress, Rigidity, and Strain

Any portion of a rigid body in equilibrium is also in equilibrium; hence, as a condition for equilibrium of the portion, any torques applied thereto from *external* sources must be balanced by equal and directionally opposite *internal* torques from adjoining portions of the body. Internal torques are *transmitted* between adjoining portions by the collective action of *stresses* over their common cross-sections. In a solid body having a round cross-section (e.g., a typical shaft), the *shear stress* τ varies linearly from zero at the axis to a maximum value at the surface. The shear stress, τ_m , at the surface of a shaft of diameter, d , transmitting a torque, T , is found from:

$$\tau_m = \frac{16T}{\pi d^3} \quad (24.3)$$

Real materials are not *perfectly* rigid but have instead a *modulus of rigidity*, G , which expresses the finite ratio between τ and *shear strain*, γ . The maximum strain in a solid round shaft therefore also exists at its surface and can be found from:

$$\gamma_m = \frac{\tau_m}{G} = \frac{16T}{\pi d^3 G} \quad (24.4)$$

Figure 24.1(b) shows the manifestation of shear strain as an angular displacement between axially separated cross-sections. Over the length L , the solid round shaft shown will be *twisted* by the torque through an angle ϕ found from:

$$\phi = \frac{32LT}{\pi d^4 G} \quad (24.5)$$

Work, Energy, and Power

If during the time of application of a torque, T , the body rotates through some angle θ , mechanical work:

$$W = T\theta \quad (24.6)$$

is performed. If the torque acts in the same CW or CCW sense as the displacement, the work is said to be done *on* the body, or else it is done *by* the body. Work done *on* the body causes it to accelerate, thereby appearing as an increase in *kinetic energy* ($KE = I\omega^2/2$). Work done *by* the body causes deceleration with a corresponding decrease in kinetic energy. If the body is not accelerating, any work done on it at one location must be done by it at another location. Work and energy are each measured in units called a joule (J). Equation 24.6 shows that 1 J is equivalent to 1 N·m rad, which, since a radian is a dimensionless ratio, $\equiv 1$ N·m. To avoid confusion with torque, it is preferable to quantify mechanical work in units of m·N, or better yet, in J.

The *rate* at which work is performed is termed *power*, P . If a torque T acts over a small interval of time Δt , during which there is an angular displacement $\Delta\theta$, work equal to $T\Delta\theta$ is performed at the rate $T\Delta\theta/\Delta t$. Replacing $\Delta\theta/\Delta t$ by ω , power is found simply as:

$$P = T\omega \quad (24.7)$$

FIGURE 24.2 Schematic arrangement of devices used for the measurement of torque and power.

The unit of power follows from its definition and is given the special name watt (W). $1 \text{ W} = 1 \text{ J s}^{-1} = 1 \text{ m}\cdot\text{N s}^{-1}$. Historically, power has also been measured in horsepower (Hp), where $1 \text{ Hp} = 746 \text{ W}$. Rotating bodies effectively transmit power between locations where torques from external sources are applied.

24.2 Arrangements of Apparatus for Torque and Power Measurement

Equations 24.1 through 24.7 express the physical bases for torque and power measurement. Figure 24.2 illustrates a generalized measurement arrangement. The actual apparatus used is selected to fulfill the specific measurement purposes. In general, a driving torque originating within a device at one location (B in Figure 24.2), is resisted by an opposing torque developed by a different device at another location (F). The driving torque (from, e.g., an electric motor, a gasoline engine, a steam turbine, muscular effort, etc.) is coupled through connecting members C, transmitting region D, and additional couplings E, to the driven device (an electric generator, a pump, a machine tool, mated threaded fasteners, etc.) within which the resisting torque is met at F. The torque at B or F is the quantity to be measured. These torques may be *indirectly* determined from a correlated physical quantity, e.g., an electrical current or fluid pressure associated with the operation of the driving or driven device, or more directly by measuring either the *reaction* torque at A or G, or the *transmitted* torque through D. It follows from the cause-and-effect relationship between torque and rotational motion that most interest in transmitted torque will involve rotating bodies.

To the extent that the frames of the driving and driven devices and their mountings to the “Earth” are *perfectly rigid*, the reaction at A will *at every instant* equal the torque at B, as will the reaction at G equal the torque at F. Under equilibrium conditions, these equalities are independent of the compliance of any member. Also under equilibrium conditions, and except for usually minor *parasitic* torques (due, e.g., to bearing friction and air drag over rapidly moving surfaces), the driving torque at B will equal the resisting torque at F.

Reaction torque at A or G is often determined, using Equation 24.1, from measurements of the forces acting at known distances fixed by the apparatus. Transmitted torque is determined from measurements, on a suitable member within region D, of τ_m , γ_m , or ϕ and applying Equations 24.3, 24.4, or 24.5 (or analogous expressions for members having other than solid round cross-sections [2]). *Calibration*, the measurement of the stress, strain, or twist angle resulting from the application of a *known* torque, makes it unnecessary to know any details about the member within D. When $\alpha \neq 0$, and is measurable, T may also be determined from Equation 24.2. Requiring only noninvasive, observational measurements, this method is especially useful for determining transitory torques; for example those associated with firing events in multicylinder internal combustion engines [3].

Equations 24.6 and 24.7 are applicable *only* during rotation because, in the absence of motion, no work is done and power transfer is zero. Equation 24.6 can be used to determine *average* torque from calorimetric

measurements of the heat generated (equal to the mechanical work W) during a totalized number of revolutions ($\equiv \theta/2\pi$). Equation 24.7 is routinely applied in power measurement, wherein T is determined by methods based on Equations 24.1, 24.3, 24.4, or 24.5, and ω is measured by any suitable means [4].

F , T , and ϕ are sometimes measured by simple mechanical methods. For example, a “torque wrench” is often used for the controlled tightening of threaded fasteners. In these devices, torque is indicated by the position of a needle moving over a calibrated scale in response to the elastic deflection of a spring member, in the simplest case, the bending of the wrench handle [5]. More generally, instruments, variously called *sensors* or *transducers*, are used to convert the desired (torque or speed related) quantity into a linearly proportional electrical signal. (Force sensors are also known as *load cells*.) The determination of P most usually requires multiplication of the two signals from separate sensors of T and ω . A transducer, wherein the amplitude of a *single* signal proportional to the power being transmitted along a shaft, has also been described [6].

24.3 Torque Transducer Technologies

Various physical interactions serve to convert F , τ , γ , or ϕ into proportional electrical signals. Each requires that some axial portion of the shaft be dedicated to the torque sensing function. Figure 24.3 shows typical features of sensing regions for four sensing technologies in present use.

Surface Strain

Figure 24.3(a) illustrates a sensing region configured to convert surface strain (γ_m) into an electric signal proportional to the transmitted torque. Surface strain became the key basis for measuring both force and torque following the invention of bonded wire strain gages by E. E. Simmons, Jr. and Arthur C. Ruge in 1938 [7]. A modern strain gage consists simply of an elongated electrical conductor, generally formed in a serpentine pattern in a very thin foil or film, bonded to a thin insulating carrier. The carrier is attached, usually with an adhesive, to the surface of the load carrying member. Strain is sensed as a change in gage resistance. These changes are generally too small to be accurately measured directly and so it is common to employ two to four gages arranged in a Wheatstone bridge circuit. Independence from axial and bending loads as well as from temperature variations are obtained by using a four-gage bridge comprised of two diametrically opposite pairs of matched strain gages, each aligned along a *principal strain* direction. In round shafts (and other shapes used to transmit torque), tensile and compressive principal strains occur at 45° angles to the axis. Limiting strains, as determined from Equation 24.4 (with τ_m equal to the shear proportional limit of the shaft material), rarely exceed a few parts in 10^3 . Typical practice is to increase the compliance of the sensing region (e.g., by reducing its diameter or with hollow or specially shaped sections) in order to attain the limiting strain at the highest value of the torque to be measured. This maximizes the measurement sensitivity.

Twist Angle

If the shaft is *slender* enough (e.g., $L > 5d$) ϕ , at limiting values of τ_m for typical shaft materials, can exceed 1° , enough to be resolved with sufficient accuracy for practical torque measurements (ϕ at τ_m can be found by manipulating Equations 24.3, 24.4, and 24.5). Figure 24.3(b) shows a common arrangement wherein torque is determined from the difference in tooth-space phasing between two identical “toothed” wheels attached at opposite ends of a compliant “torsion bar.” The phase displacement of the periodic electrical signals from the two “pickups” is proportional to the peripheral displacement of salient features on the two wheels, and hence to the twist angle of the torsion bar and thus to the torque. These features are chosen to be sensible by any of a variety of noncontacting magnetic, optical, or capacitive techniques. With more elaborate pickups, the relative angular position of the two wheels appears as the amplitude of a *single* electrical signal, thus providing for the measurement of torque even on a stationary shaft (e.g., [13–15]). In still other constructions, a shaft-mounted variable displacement transformer or a related type of electric device is used to provide speed independent output signals proportional to ϕ .

FIGURE 24.3 Four techniques in present use for measuring transmitted torque. (a) Torsional strain in the shaft alters the electrical resistance for four strain gages (two not seen) connected in a Wheatstone bridge circuit. In the embodiment shown, electrical connections are made to the bridge through slip rings and brushes. (b) Twist of the torsion section causes angular displacement of the surface features on the toothed wheels. This creates a phase difference in the signals from the two pickups. (c) The permeabilities of the two grooved regions of the shaft change oppositely with torsional stress. This is sensed as a difference in the output voltages of the two sense windings. (d) Torsional stress causes the initially circumferential magnetizations in the ring (solid arrows) to tilt (dashed arrows). These helical magnetizations cause magnetic poles to appear at the domain wall and ring ends. The resulting magnetic field is sensed by the field sensor.

Stress

In addition to elastic strain, the stresses by which torque is transmitted are manifested by changes in the magnetic properties of ferromagnetic shaft materials. This “magnetoelastic interaction” [8] provides an inherently noncontacting basis for measuring torque. Two types of magnetoelastic (sometimes called magnetostrictive) torque transducers are in present use: Type 1 derive output signals from torque-induced variations in magnetic circuit permeances; Type 2 create a magnetic field in response to torque. Type 1 transducers typically employ “branch,” “cross,” or “solenoidal” constructions [9]. In branch and cross designs, torque is detected as an imbalance in the permeabilities along orthogonal 45° helical paths (the principal stress directions) on the shaft surface or on the surface of an *ad hoc* material attached to the shaft. In solenoidal constructions torque is detected by differences in the *axial* permeabilities of two adjacent surface regions, preendowed with symmetrical magnetic “easy” axes (typically along the 45° principal stress directions). While branch and cross type sensors are readily miniaturized [10], local variations in magnetic properties of typical shaft surfaces limit their accuracy. Solenoidal designs, illustrated in Figure 24.3(c), avoid this pitfall by effectively averaging these variations. Type 2 transducers are generally constructed with a ring of magnetoelastically active material rigidly attached to the shaft. The ring is magnetized during manufacture of the transducer, usually with each axial half polarized in an

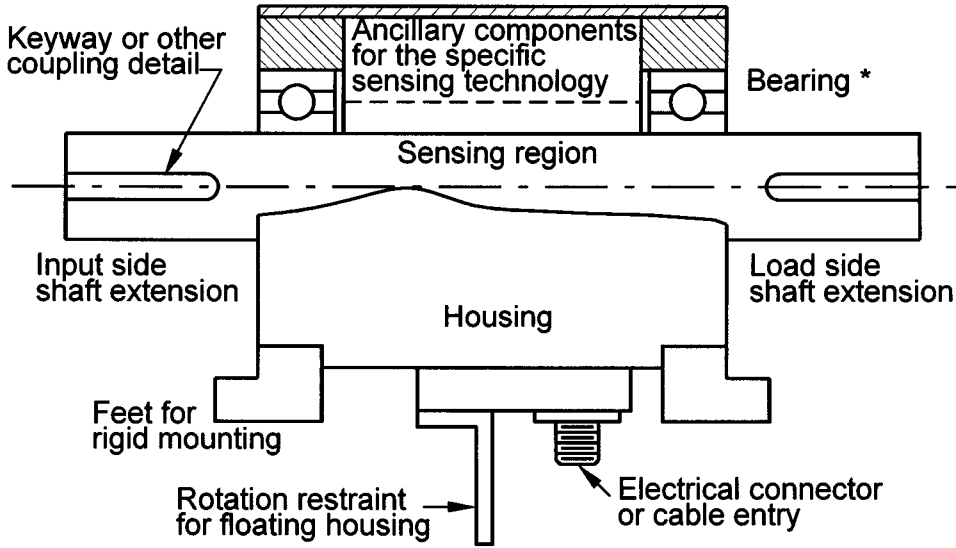

FIGURE 24.4 Modular torque transducer showing generic features and alternative arrangements for free floating or rigid mounting. Bearings* are used only on rotational models. Shaft extensions have keyways or other features to facilitate torque coupling.

opposite circumferential direction as indicated by the solid arrows in Figure 24.3(d) [11]. When torque is applied, the magnetizations tilt into helical directions (dashed arrows), causing magnetic poles to develop at the central domain wall and (of opposite polarity) at the ring end faces. Torque is determined from the output signal of one or more magnetic field sensors (e.g., Hall effect, magnetoresistive, or flux gate devices) mounted so as to sense the intensity and polarity of the magnetic field that arises in the space near the ring.

24.4 Torque Transducer Construction, Operation, and Application

Although a torque sensing region can be created directly on a desired shaft, it is more usual to install a preassembled *modular* torque transducer into the driveline. Transducers of this type are available with capacities from 0.001 N·m to 200,000 N·m. Operating principle descriptions and detailed installation and operating instructions can be found in the catalogs and literature of the various manufactures [12–20]. Tradenames often identify specific type of transducers; for example, *Torquemeters* [13] refers to a family of noncontact strain gage models; *Torkducer*[®] [18] identifies a line of Type 1 magnetoelastic transducers; *Torqstar*[™] [12] identifies a line of Type 2 magnetoelastic transducers; *Torquetronic* [16] is a class of transducers using wrap-around twist angle sensors; and *TorXimitor*[™] [20] identifies optoelectronic based, noncontact, strain gage transducers. Many of these devices show generic similarities transcending their specific sensing technology as well as their range. Figure 24.4 illustrates many of these common features.

Mechanical Considerations

Maximum operating speeds vary widely; upper limits depend on the size, operating principle, type of bearings, lubrication, and dynamic balance of the rotating assembly. Ball bearings, lubricated by grease, oil, or oil mist, are typical. Parasitic torques associated with bearing lubricants and seals limit the accuracy of low-end torque measurements. (Minute capacity units have no bearings [15]). Forced lubrication can

allow operation up to 80,000 rpm [16]. High-speed operation requires careful consideration of the effects of centrifugal stresses on the sensed quantity as well as of critical (vibration inducing) speed ranges. Torsional oscillations associated with resonances of the shaft elasticity (characterized by its spring constant) with the rotational inertia of coupled masses can corrupt the measurement, damage the transducer by dynamic excursions above its rated overload torque, and *even be physically dangerous*.

Housings either *float* on the shaft bearings or are *rigidly mounted*. Free floating housings are restrained from rotating by such “soft” means as a cable, spring, or compliant bracket, or by an eccentric external feature simply resting against a fixed surface. In free floating installations, the axes of the driving and driven shafts must be carefully aligned. Torsionally rigid “flexible” couplings at each shaft end are used to accommodate small angular and/or radial misalignments. Alternatively, the use of dual flexible couplings at one end will allow direct coupling of the other end. Rigidly mounted housings are equipped with mounting feet or lugs similar to those found on the frame of electric motors. Free-floating models are sometimes rigidly mounted using adapter plates fastened to the housing. Rigid mountings are preferred when it is difficult or impractical to align the driving and driven shafts, as for example when driving or driven machines are changed often. Rigidly mounted housings *require* the use of dual flexible couplings at *both* shaft ends.

Modular transducers designed for zero or limited rotation applications have no need for bearings. To ensure that *all* of the torque applied at the ends is sensed, it is important in such “reaction”-type torque transducers to limit attachment of the housing to the shaft to only one side of the sensing region. Whether rotating or stationary, the external shaft ends generally include such torque coupling details as flats, keyways, splines, tapers, flanges, male/female squares drives, etc.

Electrical Considerations

By their very nature, transducers require some electrical input power or *excitation*. The “raw” output signal of the actual sensing device also generally requires “conditioning” into a level and format appropriate for display on a digital or analog meter or to meet the input requirements of data acquisition equipment. Excitation and signal conditioning are supplied by electronic circuits designed to match the characteristics of the specific sensing technology. For example, strain gage bridges are typically powered with 10 V to 20 V (dc or ac) and have outputs in the range of 1.5 mV to 3.0 mV per volt of excitation at the rated load. Raising these millivolt signals to more usable levels requires amplifiers having gains of 100 or more. With ac excitation, oscillators, demodulators (or rectifiers) are also needed. Circuit elements of these types are normal when inductive elements are used either as a necessary part of the sensor or simply to implement noncontact constructions.

Strain gages, differential transformers, and related sensing technologies require that electrical components be mounted *on* the torqued member. Bringing electrical power to and output signals from these components on rotating shafts require special methods. The most direct and common approach is to use conductive means wherein brushes (typically of silver graphite) bear against (silver) slip rings. Useful life is extended by providing means to lift the brushes off the rotating rings when measurements are not being made. Several “noncontacting” methods are also used. For example, power can be supplied via inductive coupling between stationary and rotating transformer windings [12–15], by the illumination of shaft mounted photovoltaic cells [20], or even by batteries strapped to the shaft [21] (limited by centrifugal force to relatively low speeds). Output signals are coupled off the shaft through rotary transformers, by frequency-modulated (infrared) LEDs [19, 20], or by radio-frequency (FM) telemetry [21]. Where shaft rotation is limited to no more than a few full rotations, as in steering gear, valve actuators or oscillating mechanisms, hard wiring both power and signal circuits is often suitable. Flexible cabling minimizes incidental torques and makes for a long and reliable service life. All such wiring considerations are avoided when noncontact technologies or constructions are used.

Costs and Options

Prices of torque transducers reflect the wide range of available capacities, performance ratings, types, styles, optional features, and accessories. In general, prices of any one type increase with increasing capacity. Reaction types cost about half of similarly rated rotating units. A typical foot-mounted, 565 N·m capacity, strain gage transducer with either slip rings or rotary transformers and integral speed sensor, specified nonlinearity and hysteresis each within $\pm 0.1\%$, costs about \$4000 (1997). Compatible instrumentation providing transducer excitation, conditioning, and analog output with digital display of torque and speed costs about \$2000. A comparable magnetoelastic transducer with $\pm 0.5\%$ accuracy costs about \$1300. High-capacity transducers for extreme speed service with appropriate lubrication options can cost more than \$50,000. Type 2 magnetoelastic transducers, mass produced for automotive power steering applications, cost approximately \$10.

24.5 Apparatus for Power Measurement

Rotating machinery exists in specific types without limit and can operate at power levels from fractions of a watt to some tens of megawatts, a range spanning more than 10^8 . Apparatus for power measurement exists in a similarly wide range of types and sizes. Mechanical power flows from a *driver* to a *load*. This power can be determined *directly* by application of Equation 24.7, simply by measuring, in addition to ω , the output torque of the driver or the input torque to the load, whichever is the device under test (DUT). When the DUT is a driver, measurements are usually required over its full service range of speed and torque. The test apparatus therefore must act as a controllable load and be able to *absorb* the delivered power. Similarly, when the DUT is a pump or fan or other type of load, or one whose function is simply to alter speed and torque (e.g., a gear box), the test apparatus must include a *driver* capable of supplying power over the DUT's full rated range of torque and speed. Mechanical power can also be determined *indirectly* by conversion into (or from) another form of energy (e.g., heat or electricity) and measuring the relevant calorimetric or electrical quantities. In view of the wide range of readily available methods and apparatus for accurately measuring both torque and speed, indirect methods need only be considered when special circumstances make direct methods difficult.

Dynamometer is the special name given to the power-measuring apparatus that includes absorbing or/and driving means and wherein torque is determined by the reaction forces on a stationary part (the *stator*). An effective dynamometer is conveniently assembled by mounting the DUT in such a manner as to allow measurement of the reaction torque on its frame. Figure 24.5 shows a device designed to facilitate such measurements. Commercial models (Torque Table® [12]) rated to support DUTs weighing 222 N to 4900 N are available with torque capacities from 1.3 N·m to 226 N·m. "Torque tubes" [4] or other DUT mounting arrangements are also used. Other than for possible rotational/elastic resonances, these systems have no speed limitations. More generally, and especially for large machinery, dynamometers include a specialized driving or absorbing machine. Such dynamometers are classified according to their function as *absorbing* or *driving* (sometimes *motoring*). A *universal dynamometer* can function as either a driver or an absorber.

Absorption Dynamometers

Absorption dynamometers, often called *brakes* because their operation depends on the creation of a controllable *drag* torque, convert mechanical work into heat. A drag torque, as distinguished from an active torque, can act only to restrain and not to initiate rotational motion. Temperature rise within a dynamometer is controlled by carrying away the heat energy, usually by transfer to a moving fluid, typically air or water. Drag torque is created by inherently dissipative processes such as: friction between rubbing surfaces, shear or turbulence of viscous liquids, the flow of electric current, or magnetic hysteresis. Gaspard Riche de Prony (1755–1839), in 1821 [22], invented a highly useful form of a friction brake to meet the needs for testing the steam engines that were then becoming prevalent. Brakes of this

FIGURE 24.5 Support system for measuring the reaction torque of a rotating machine. The axis of the machine must be accurately set on the “center of rotation.” The holes and keyway in the table facilitate machine mounting and alignment. Holes in the front upright provide for attaching a lever arm from which calibrating weights may be hung [4, 11].

FIGURE 24.6 A classical prony brake. This brake embodies the defining features of all absorbing dynamometers: conversion of mechanical work into heat and determination of power from measured values of reaction torque and rotational velocity.

type are often used for instructional purposes, for they embody the general principles and major operating considerations for all types of absorption dynamometers. Figure 24.6 shows the basic form and constructional features of a *prony brake*. The power that would normally be delivered by the shaft of the driving engine to the driven load is (for measurement purposes) converted instead into heat via the work done by the frictional forces between the friction blocks and the flywheel rim. Adjusting the tightness of the

clamping bolts varies the frictional drag torque as required. Heat is removed from the inside surface of the rim by arrangements (not shown) utilizing either a continuous flow or evaporation of water. There is no need to know the magnitude of the frictional forces nor even the radius of the flywheel (facts recognized by Prony), because, while the drag torque tends to rotate the clamped-on apparatus, it is held stationary by the equal but opposite reaction torque Fr . F at the end of the torque arm of radius r (a fixed dimension of the apparatus) is monitored by a scale or load cell. The power is found from Equations 24.1 and 24.7 as $P = Fr\omega = Fr2\pi N/60$ where N is in rpm.

Uneven retarding forces associated with fluctuating coefficients of friction generally make rubbing friction a poor way to generate drag torque. Nevertheless, because they can be easily constructed, *ad hoc* variations of prony brakes, often using only bare ropes or wooden cleats connected by ropes or straps, find use in the laboratory or wherever undemanding or infrequent power measurements are to be made. More sophisticated prony brake constructions are used in standalone dynamometers with self-contained cooling water tanks in sizes up to 746 kW (1000 Hp) for operation up to 3600 rpm with torques to 5400 N·m [23]. Available in stationary and mobile models, they find use in testing large electric motors as well as engines and transmissions on agricultural vehicles. Prony brakes allow full drag torque to be imposed down to zero speed.

William Froude (1810–1879) [24] invented a *water brake* (1877) that does not depend on rubbing friction. Drag torque within a *Froude brake* is developed between the rotor and the stator by the momentum imparted by the rotor to water contained within the brake casing. Rotor rotation forces the water to circulate between cup-like pockets cast into facing surfaces of both rotor and stator. The rotor is supported in the stator by bearings that also fix its axial position. Labyrinth-type seals prevent water leakage while minimizing frictional drag and wear. The stator casing is supported in the dynamometer frame in cradle fashion by *trunnion* bearings. The torque that prevents rotation of the stator is measured by reaction forces in much the same manner as with the prony brake. Drag torque is adjusted by a valve, controlling either the back pressure in the water outlet piping [25] or the inlet flow rate [26] or sometimes (to allow very rapid torque changes) with two valves controlling both [27]. In any case, the absorbed energy is carried away by the continuous water flow. Other types of cradle-mounted water brakes, while externally similar, have substantially different internal constructions and depend on other principles for developing the drag torque (e.g., smooth rotors develop viscous drag by shearing and turbulence). Nevertheless, all *hydraulic dynamometers* purposefully function as *inefficient* centrifugal pumps. Regardless of internal design and valve settings, maximum drag torque is low at low speeds (zero at standstill) but can rise rapidly, typically varying with the square of rotational speed. The irreducible presence of some water, as well as windage, places a speed-dependent lower limit on the *controllable* drag torque. In any one design, wear and vibration caused by cavitation place upper limits on the speed and power level. Hydraulic dynamometers are available in a wide range of capacities between 300 kW and 25,000 kW, with some portable units having capacities as low as 75 kW [26]. The largest ever built [27], absorbing up to about 75,000 kW (100,000 Hp), has been used to test propulsion systems for nuclear submarines. Maximum speeds match the operating speeds of the prime movers that they are built to test and therefore generally decrease with increasing capacity. High-speed gas turbine and aerospace engine test equipment can operate as high as 30,000 rpm [25].

In 1855, Jean B. L. Foucault (1819–1868) [22] demonstrated the conversion of mechanical work into heat by rotating a copper disk between the poles of an electromagnet. This simple means of developing drag torque, based on *eddy currents*, has, since circa 1935, been widely exploited in dynamometers. [Figure 24.7](#) shows the essential features of this type of brake. Rotation of a toothed or spoked steel rotor through a spatially uniform magnetic field, created by direct current through coils in the stator, induces locally circulating (eddy) currents in electrically conductive (copper) portions of the stator. Electromagnetic forces between the rotor, which is magnetized by the uniform field, and the field arising from the eddy currents, create the drag torque. This torque, and hence the mechanical input power, are controlled by adjusting the *excitation* current in the stator coils. Electric input power is less than 1% of the rated capacity. The dynamometer is effectively an internally short-circuited generator because the power associated with the resistive losses from the generated eddy currents is dissipated *within* the machine.

FIGURE 24.7 Cross-section (left) and front view (right) of an eddy current dynamometer. G is a gear wheel and S is a speed sensor. Hoses carrying cooling water and cable carrying electric power to the stator are not shown.

Being heated by the flow of these currents, the stator must be cooled, sometimes (in smaller capacity machines) by air supplied by blowers [23], but more often by the continuous flow of water [25, 27, 28]. In *dry gap* eddy current brakes (the type shown in Figure 24.7), water flow is limited to passages within the stator. Larger machines are often of the *water in gap* type, wherein water also circulates around the rotor [28]. Water in contact with the moving rotor effectively acts as in a water brake, adding a nonelectromagnetic component to the total drag torque, thereby placing a lower limit to the controllable torque. Windage limits the minimum value of controllable torque in dry gap types. Since drag torque is developed by the motion of the rotor, it is zero at standstill for any value of excitation current. Initially rising rapidly, approximately linearly, with speed, torque eventually approaches a current limited saturation value. As in other cradled machines, the torque required to prevent rotation of the stator is measured by the reaction force acting at a fixed known distance from the rotation axis. Standard model eddy current brakes have capacities from less than 1 kW [23, 27] to more than 2000 kW [27, 28], with maximum speeds from 12,000 rpm in the smaller capacity units to 3600 rpm in the largest units. Special units with capacities of 3000 Hp (2238 kW) at speeds to 25,000 rpm have been built [28].

Hysteresis brakes [29] develop drag torque via magnetic attractive/repulsive forces between the magnetic poles established in a reticulated stator structure by a current through the field coil, and those created in a “drag cup” rotor by the stator field gradients. Rotation of the special steel rotor, through the spatial field pattern established by the stator, results in a cyclical reversal of the polarity of its local magnetizations. The energy associated with these reversals (proportional to the area of the hysteresis loop of the rotor material) is converted into heat within the drag cup. Temperature rise is controlled by forced air cooling from a blower or compressed air source. As with eddy current brakes, the drag torque of these devices is controlled by the excitation current. In contrast with eddy current brakes, rated drag torque is available down to zero speed. (Eddy current effects typically add only 1% to the drag torque for each 1000 rpm). As a result of their smooth surfaced rotating parts, hysteresis brakes exhibit low parasitic torques and hence cover a dynamic range as high as 200 to 1. Standard models are available having continuous power capacities up to 6 kW (12 kW with two brakes in tandem cooled by two blowers). Intermittent capacities per unit (for 5 min or less) are 7 kW. Some low-capacity units are convection cooled; the smallest has a continuous rating of just 7 W (35 W for 5 min). Maximum speeds range from 30,000 rpm for the smallest to 10,000 rpm for the largest units. Torque is measured by a strain gage bridge on a moment arm supporting the machine stator.

Driving and Universal Dynamometers

Electric generators, both ac and dc, offer another means for developing a controllable drag torque and they are readily adapted for dynamometer service by cradle mounting their stator structures. Moreover, electric machines of these types can also operate in a motoring mode wherein they can deliver controllable *active* torque. When configured to operate selectively in either driving or absorbing modes, the machine serves as a universal dynamometer. With dc machines in the absorbing mode, the generated power is typically dissipated in a convection-cooled resistor bank. Air cooling the machine with blowers is usually adequate, since *most* of the mechanical power input is dissipated externally. Nevertheless, *all* of the mechanical input power is accounted for by the product of the reaction torque and the rotational speed. In the motoring mode, torque and speed are controlled by adjustment of both field and armature currents. Modern ac machines utilize regenerative input power converters to allow braking power to be returned to the utility power line. In the motoring mode, speed is controlled by high-power, solid-state, adjustable frequency inverters. Internal construction is that of a simple three-phase induction motor, having neither brushes, slip rings, nor commutators. The absence of rotor windings allows for higher speed operation than dc machines. Universal dynamometers are “four-quadrant” machines, a term denoting their ability to produce torque in the same or opposite direction as their rotational velocity. This unique ability allows the effective drag torque to be reduced to zero at any speed. Universal dynamometers [25, 28] are available in a relatively limited range of capacities (56 to 450 kW), with commensurate torque (110 to 1900 N·m) and speed (4500 to 13,500 rpm) ranges, reflecting their principal application in automotive engine development. Special dynamometers for testing transmissions and other vehicular drive train components insert the DUT between a diesel engine or electric motor prime mover and a hydraulic or eddy current brake [30].

Measurement Accuracy

Accuracy of power measurement (see discussion in [4]) is generally limited by the torque measurement ($\pm 0.25\%$ to $\pm 1\%$) since rotational speed can be measured with almost any desired accuracy. Torque errors can arise from the application of extraneous (i.e., not indicated) torques from hose and cable connections, from windage of external parts, and from miscalibration of the load cell. Undetected friction in the trunnion bearings of cradled dynamometers can compromise the torque measurement accuracy. Ideally, well-lubricated antifriction bearings make no significant contribution to the restraining torque. In practice, however, the unchanging contact region of the balls or other rolling elements on the bearing races makes them prone to brinelling (a form of denting) from forces arising from vibration, unsupported weight of attached devices, or even inadvertently during the alignment of connected machinery. The problem can be alleviated by periodic rotation of the (primarily outer) bearing races. In some bearing-in-bearing constructions, the central races are continuously rotated at low speeds by an electric motor while still others avoid the problem by supporting the stator on hydrostatic oil lift bearings [28].

Costs

The wide range of torque, speed, and power levels, together with the variation in sophistication of associated instrumentation, is reflected in the very wide range of dynamometer prices. Suspension systems of the type illustrated in Figure 24.5 (for which the user must supply the rotating machine) cost \$4000 to \$6000, increasing with capacity [12]. A 100 Hp (74.6 kW) *portable* water brake equipped with a strain gage load cell and a digital readout instrument for torque, speed, and power costs \$4500, or \$8950 with more sophisticated data acquisition equipment [26]. Stationary (and some *transportable* [23]) hydraulic dynamometers cost from \$113/kW in the smaller sizes [25], down to \$35/kW for the very largest [27]. Transportation, installation, and instrumentation can add significantly to these costs. Eddy current dynamometers cost from as little as \$57/kW to nearly \$700/kW, depending on the rated capacity, type of control system, and instrumentation [24, 25, 28]. Hysteresis brakes with integral speed sensors cost

from \$3300 to \$14,000 according to capacity [29]. Compatible controllers, from manual to fully programmable for PC test control and data acquisition via an IEEE-488 interface, vary in price from \$500 to \$4200. The flexibility and high performance of ac universal dynamometers is reflected in their comparatively high prices of \$670 to \$2200/kW [25, 28].

Robots in industrial settings perform repetitive tasks, such as machine loading, parts assembly, painting, and welding. Only in rare instances can these autonomous manipulators modify their actions based on sensory information. Although, thus far, a vast majority of research work in the area of robot sensing has concentrated on computer vision, contact sensing is an equally important feature for robots and has received some attention as well. Without tactile-perception capability, a robot cannot be expected to effectively grasp objects. In this context, robotic tactile sensing is the focus of this chapter.

25.1 Sensing Classification

Robotic sensing can be classified as either of the noncontact or contact type [1]. *Noncontact sensing* involves interaction between the robot and its environment by some physical phenomenon, such as acoustic or electromagnetic waves, that interact without contact. The most important types of robotic sensors of the noncontact type are vision and proximity sensors. *Contact sensing*, on the other hand, implies measurement of the general interaction that takes place when the robot's end effector is brought into contact with an object. Contact sensing is further classified into force and tactile sensing.

Force sensing is defined as the measurement of the global mechanical effects of contact, while *tactile sensing* implies the detection of a wide range of local parameters affected by contact. Most significant among those contact-based effects are contact stresses, slippage, heat transfer, and hardness.

The properties of a grasped object that can be derived from tactile sensing can be classified into geometric and dynamometric types [2]. Among the geometric properties are presence, location in relation to the end-effector, shape and dimensions, and surface conditions [3–7]. Among the dynamometric parameters associated with grasping are: force distribution, slippage, elasticity and hardness, and friction [8–12].

Tactile sensing requires sophisticated transducers; yet the availability of these transducers alone is not a sufficient condition for successful tactile sensing. It is also necessary to accurately control the modalities through which the tactile sensor interacts with the explored objects (including contact forces, as well as end-effector position and orientation) [13–15]. This leads to active tactile sensing, which requires a high degree of complexity in the acquisition and processing of the tactile data [16].

FIGURE 25.1 An object indenting a compliant layer, where an array of force-sensing elements is placed at a distance d from the surface.

25.2 Mechanical Effects of Contact

Tactile sensing normally involves a rigid object indenting the compliant cover layer of a tactile sensor array [17], [Figure 25.1](#). The indentation of a compliant layer due to contact can be analyzed from two conceptually different points of view [1]. The first one is the measurement of the actual contact stresses (force distribution) in the layer, which is usually relevant to controlling manipulation tasks. The second one is the deflection profile of the layer, which is usually important for recognizing geometrical object features. Depending on the approach adopted, different processing and control algorithms must be utilized.

There exists a definite relationship between the local shape of a contacting body and a set of subsurface strains (or displacements); however, this relationship is quite complex. Thus, it requires the use of the Theory of Elasticity and Contact Mechanics to model sensor–object interaction [18], and the use of Finite Element Analysis (FEA) as a practical tool for obtaining a more representative model of the sensor [19].

In general, the study of tactile sensors comprises two steps: (1) the *forward analysis*, related to the acquisition of data from the sensor (changes on the stress or strains, induced by the indentation of an object on the compliant surface of the transducer); and, (2) the *inverse problem*, normally related to the recovery of force distribution or, in some cases, the recovery of the indenter’s shape.

Simplified Theory for Tactile Sensing

For simplicity, the general two-dimensional tactile problem is reduced herein to a one-dimensional one. [Figure 25.2](#) shows a one-dimensional transducer that consists of a compliant, homogeneous, isotropic, and linear layer subjected to a normal stress $q_v(x)$ created by the indentation of an object.

For modeling purposes, it is assumed that the compliant layer is an elastic half-space. This simplification yields closed-form equations for the analysis and avoids the formation of a more complex problem, in which the effect of the boundary conditions at x_{\min} and x_{\max} must be taken into account. It has been proven that the modeling of the sensor by an elastic half-space represents a reasonable approximation to the real case [18]. Under these conditions, it can be shown that the normal strain, at a depth $y = d$, due to the normal stress $q_v(y)$ is given by [20]:

FIGURE 25.2 Ideal one-dimensional transducer subjected to a normal stress.

$$\epsilon_z(x) = \int_{-\infty}^{\infty} q_v(x-x_0)h_z(x_0,d) dx_0 \quad (25.1)$$

where ϵ_z is the strain at x and $z = d$ due to the normal stress on the surface, and

$$h_z(x) = -\frac{2d(1+\nu)[d^2(1-\nu)-vx^2]}{\pi rE(x^2+d^2)^2} \quad (25.2)$$

E and ν are, respectively, the modulus of elasticity and the Poisson's coefficient of the compliant layer. In obtaining Equation 25.2, it is assumed that the analysis is performed under *planar strain* conditions. It should be noted that a similar analysis can be performed for tangential contact stresses or strains.

The normal displacement at the surface, w , is given by:

$$w(x) = \int_{-\infty}^{\infty} q_v(x-x_0)k(x_0) dx_0 \quad (25.3)$$

where

$$k(x) = \frac{-2(1-\nu^2)}{\pi E} \log \left| \frac{x}{x_a} \right| \quad (25.4)$$

The singularity at $x = 0$ is expected due to the singularity of stress at that point. Note that, $k(x)$ is the deformation of the surface when a singular load of 1 N is applied at $x = 0$. The constant x_a should be chosen such that at $x = x_a$, the deformation is zero. In this case, zero deformation should occur at $x \rightarrow \infty$ (note that it has been assumed that the sensor is modeled by an elastic half space), namely $x_a \rightarrow \infty$. This problem is associated with the two-dimensional deformation of an elastic half-space. To eliminate this difficulty, the boundary conditions of the transducer must be taken into account (i.e., a finite transducer must be analyzed), which requires, in general, the use of FEA.

FIGURE 25.3 One-dimensional transducer with discrete sensing elements located at $z = d$.

Since measurements of strain (or stress) are usually done by a discrete number of sensing elements, Equation 25.2 must be discretized (Figure 25.3). Correspondingly, the force distribution must be reconstructed at discrete positions as shown in Figure 25.3. Let Δx_q be the distance between points, where the force distribution must be reconstructed from strain (or stress) measurements carried out by strain (or stress) sensing elements uniformly distributed at intervals Δx_p , at $z = d$. Also assume, even though it is not necessary, that $\Delta x_q = \Delta x_p = \Delta x$ and that the forces are applied at positions immediately above the sensor elements. One can now define the strain (stress)-sample vector, ζ , whose components are given by $\zeta_i = \epsilon_x(x_i)$, $i = 1, 2, \dots, n$, and the force distribution vector, F , whose components are given by $f_j = q_v(x_j)$, $j = 1, 2, \dots, n$. Then, the discrete form of Equation 25.1 is given by:

$$\zeta = \mathbf{T}F \quad (25.5)$$

where the elements of the matrix \mathbf{T} are given by $T_{ij} = k_v(x_i - x_j)$, $i = 1, 2, \dots, n$ and $j = 1, 2, \dots, n$ [23]. A similar relation to Equation 25.5 can be obtained discretizing Equation 25.3. In the general case, where $\Delta x_q \neq \Delta x_p$, \mathbf{T} is not square. Furthermore, in the general case, the vector F comprises both vertical and tangential components.

Equations 25.1 and 25.3 represent the regular *forward problem*, while Equation 25.5 represents the discretized version of the forward problem. The *inverse problem*, in most cases, consists of recovering the applied force profile from the measurements of strain, stress, or deflection. (Note that the surface displacement can also be used to recover the indenter's shape.)

In [20], it was shown that the inverse problem is ill-posed because the operators h and k , of Equations 25.1 and 25.3, respectively, are ill-conditioned. Consequently, the inverse problem is susceptible to noise. To solve this problem, regularization techniques must be utilized [20].

It has been proven that, in order to avoid aliasing in determining the continuous strain (stress) at a depth d using a discretized transducer, the elements have to be separated by one tenth of the compliant layer's thickness. However, good results were obtained, without much aliasing, by separating the sensing elements by a distance equal to the sensor's depth [18].

Requirements for Tactile Sensors

In 1980, Harmon conducted a survey to determine general specifications for tactile sensors [21]. Those specifications have been used subsequently as guidelines by many tactile sensor designers:

FIGURE 25.4 General configuration of a resistive transducer.

1. Spatial resolution of 1 to 2 mm
2. Array sizes of 5×10 to 10×20 points
3. Sensitivity of 0.5×10^{-2} to 1×10^{-2} N for each force-sensing element (tactel)
4. Dynamic range of 1000:1
5. Stable behavior and with no hysteresis
6. Sampling rate of 100 Hz to 1 kHz
7. Monotonic response, though not necessarily linear
8. Compliant interface, rugged and inexpensive

While properties (5), (7), and (8) above should apply to any practical sensor, the others are merely suggestions, particularly with respect to the number of array elements and spatial resolution.

Developments on tactile sensing following [21] have identified additional desirable qualities; namely, reliability, modularity, speed, and the availability of multisensor support [16].

25.3 Technologies for Tactile Sensing

The technologies associated with tactile sensing are quite diverse: extensive surveys of the state-of-the-art of robotic-tactile-transduction technologies have been presented in [2, 3, 16, 17]. Some of these technologies will be briefly discussed.

Resistive

The transduction method that has received the most attention in tactile sensor design is concerned with the change in resistance of a conductive material under applied pressure. A basic configuration of a resistive transducer is shown in Figure 25.4. Each resistor, whose value changes with the magnitude of the force, represents a resistive cell of the transducer. Different materials have been utilized to manufacture the basic cell.

Conductive elastomers were among the first resistive materials used for the development of tactile sensors. They are insulating, natural or silicone-based rubbers made conductive by adding particles of conductive or semiconductive materials (e.g., silver or carbon). The changes in resistivity of the elastomers

under pressure are produced basically by two different physical mechanisms. In the first approach, the change in resistivity of the elastomer under pressure is associated with deformation that alters the particle density within it. Two typical designs of this kind are given in [22, 23]. In the second approach, while the bulk resistance of the elastomer changes slightly when it is compressed, the design allows the increase of the area of contact between the elastomer and an electrode, and correspondingly a change in the contact resistance. A typical design of this kind is given in [24]. In [25], a newer tactile sensor is reported with both three-axis force sensing and slippage sensing functions. In the former case, the pressure sensing function is achieved utilizing arrays of pressure transducers that measure a change in contact resistance between a specially treated polyimide film and a resistive substrate.

Piezoresistive elements have also been used in several tactile sensors. This technology is specifically attractive at present because, with micromachining, the piezoresistive elements can be integrated together with the signal-processing circuits in a single chip [26]. A 32×32 -element silicon pressure sensor array incorporating CMOS processing circuits for the detection of a high-resolution pressure distribution was reported in [8]. The sensor array consists of an x–y-matrix-organized array of pressure cells with a cell spacing of $250 \mu\text{m}$. CMOS processing circuits are formed around the array on the same chip. Fabrication of the sensor array was carried out using a 3 mm CMOS process combined with silicon micromachining techniques. The associated diaphragm size is $50 \mu\text{m} \times 50 \mu\text{m}$. The overall sensor-array chip size is $10 \text{ mm} \times 10 \text{ mm}$.

In Figure 25.4, a circuit topology, to scan a 3×3 array of piezoresistive elements, is shown. The basic idea was originally proposed in [24] and adapted on several occasions by different researchers. Using this method, the changes in resistance are converted into voltages at the output. With the connections as shown in Figure 25.4, the resistance R_{21} can be determined from:

$$V_o = \frac{R_f}{R_{21}} V_{cc} \quad (25.6)$$

where V_o is the output voltage, V_{cc} is the bias voltage, and R_f is the feedback resistance of the output amplifier stage.

One problem with the configuration shown in Figure 25.4 is the difficulty in detecting small changes in resistance due to the internal resistance of the multiplexer as well changes in the voltage of power source, which have a great influence at the output. Other methods utilized to scan resistive transducer arrays are summarized in [3].

When piezoresistors and circuits are fabricated on the same silicon substrate, the sensor array can be equipped with a complex switching circuit, next to the sensing elements, that allows a better resolution in the measurements [9].

Capacitive

Tactile sensors within this category are concerned with measuring capacitance, which varies under applied load. The capacitance of a parallel-plate capacitor depends on the separation of the plates and their areas. A sensor using an elastomeric separator between the plates provides compliance such that the capacitance will vary according to the applied normal load, Figure 25.5(a).

Figure 25.5(b) shows the basic configuration of a capacitive tactile sensor. The intersections of rows and columns of conductor strips form capacitors. Each individual capacitance can be determined by measuring the corresponding output voltage at the selected row and column. To reduce cross-talk and electromagnetic interference, the rows and columns that are not connected are grounded. Figure 25.5(c) shows an equivalent circuit when the sensor is configured to measure the capacitance formed at the intersection of row i and row j , C_{ij} , R_d is the input resistance of the detector and C_d represents the effects of the stray capacitances, including the detector-amplifier input capacitance, the stray capacitance due

FIGURE 25.5 (a) Basic cell of a capacitor tactile sensor. (b) Typical configuration of a capacitive tactile sensor. (c) Equivalent circuit for the measurement of the capacitance C_{ij} .

to the unselected rows and columns, and the capacitance contributed by the cable that connects the transducer to the detector. Since the stray capacitance due to the unselected rows and columns changes with the applied forces, the stray capacitance due to the cable is designed to be predominant [18].

The magnitude of voltage at the input of the detector, $|V_d|$ is given by:

$$|V_d| = \frac{C_{ij} R_d \omega}{\sqrt{1 + [\omega R_d (C_{ij} + C_d)]^2}} |V_s| \quad (25.7)$$

Assuming that $C_d \gg C_{ij}$ and ω is sufficiently large,

$$|V_d| \cong \frac{C_{ij}}{C_d} |V_s| \quad (25.8)$$

When a load is applied to the transducer, the capacitor is deformed as shown in Figure 25.5(a). For modeling purposes, it is assumed that the plate capacitor is only under compression. When no load is applied, the capacitance due to the element in the i th row and the j th column, C_{ij}^0 , is given by:

$$C_{ij}^0 = \epsilon \frac{wl}{h_0} \quad (25.9)$$

where ϵ is the permittivity of the dielectric, w and l are the width and the length of the plate capacitor, respectively, and h_0 is the distance between plates when no load is applied. The voltage at the input of the detector for this particular case is indicated by V_{d0} ; then from Equation 25.8, one obtains:

$$|V_{d0}| \cong \frac{C_{ij}^0}{C_d} |V_s| \quad (25.10)$$

When a load is applied, the capacitor is under compression and the capacitance is given by:

$$C_{ij} = \epsilon \frac{wl}{h_0 - \Delta h} \quad (25.11)$$

The strain in this case is given by:

$$\zeta_z \cong \frac{\Delta h}{h_0} \quad (25.12)$$

where Δh is the displacement of the top metal plate and $\Delta h \ll h_0$. The strain can be measured by:

$$\frac{|V_d| - |V_{d0}|}{|V_d|} = \frac{\frac{C_{ij}}{C_d} - \frac{C_{ij}^0}{C_d}}{\frac{C_{ij}}{C_d}} = 1 - \frac{C_{ij}^0}{C_{ij}} = 1 - \frac{h_0 - \Delta h}{h_0} = \frac{\Delta h}{h_0} = \frac{\Delta h}{h_0} \cong \zeta_z \quad (25.13)$$

Consequently, the strain at each tactel can be determined by measuring the magnitudes of V_d and V_{d0} for each element.

Note that the presence of a tangential force would offset the plates tangentially and change the effective area of the capacitor plates. An ideal capacitive pressure sensor can quantify basic aspects of touch by sensing normal forces, and can detect slippage by measuring tangential forces. However, distinguishing between the two forces at the output of a single sensing element is a difficult task and requires a more complex transducer than the one presented in Figure 25.5(a) [27].

Micromachined, silicon-based capacitive devices are especially attractive due to their potential for high accuracy and low drift. A sensor with 1024 elements and a spatial resolution of 0.5 mm was reported in [28]. Several possible structures for implementing capacitive high-density tactile transducers in silicon have been reported in [29]. A cylindrical finger-shaped transducer was reported in [18].

The advantages of capacitive transducers include: wide dynamic range, linear response, and robustness. Their major disadvantages are susceptibility to noise, sensitivity to temperature, and the fact that capacitance decreases with physical size, ultimately limiting the spatial resolution. Research is progressing toward the development of electronic processing circuits for the measurement of small capacitances using charge amplifiers [30], and the development of new capacitive structures [29].

Piezoelectric

A material is called piezoelectric, if, when subjected to a stress or deformation, it produces electricity. Longitudinal piezoelectric effect occurs when the electricity is produced in the same direction of the stress, Figure 25.6. In Figure 25.6(a), a normal stress σ ($= F/A$) is applied along the Direction 3 and the charges are generated on the surfaces perpendicular to Direction 3. A transversal piezoelectric effect occurs when the electricity is produced in the direction perpendicular to the stress.

The voltage V generated across the electrodes by the stress σ is given by:

$$V = d_{33} \frac{h}{\epsilon} \sigma \quad (25.14)$$

where d_{33} = Piezoelectric constant associated with the longitudinal piezoelectric effect

ϵ = Permittivity

h = Thickness of the piezoelectric material

FIGURE 25.6 (a) Basic cell of a piezoelectric transducer. (b) Charge amplifier utilized for the measurement of the applied force.

Since piezoelectric materials are insulators, the transducer shown in Figure 25.6(a), can be considered as a capacitor, from an electrical point of view. Consequently,

$$V = \frac{Q}{C} = \frac{Q}{\epsilon A} h \quad (25.15)$$

where Q = Charge induced by the stress σ
 C = Capacitance of the parallel capacitor
 A = Area of each electrode

A comparison of Equations 25.14 and 25.15 leads to:

$$Q = d_{33} A \sigma \quad (25.16)$$

It is concluded that the force applied to the photoelastic material can be determined by finding the charge Q . Charge amplifiers are usually utilized for determining Q . The basic configuration of a charge amplifier is shown in Figure 25.6(b). The charge generated in the transducer is transferred to the capacitor C_f and the output voltage, V_o is given by:

$$V_o = -\frac{Q}{C_f} \quad (25.17)$$

The circuit must periodically discharge the feedback capacitor C_f to avoid saturation of the amplifier by stray charges generated by the offset voltages and currents of the operational amplifier. This is achieved by a switch as shown in Figure 25.6(b) or by a resistor parallel to C_f .

The piezoelectric material most widely used in the implementation of tactile transducers is PVF2. It shows the largest piezoelectric effect of any known material. Its flexibility, small size, sensitivity, and large electrical output offer many advantages for sensor applications in general, and tactile sensors in particular. Examples of tactile sensors implemented with this technology can be found in [1, 31].

The major advantages of the piezoelectric technology are its wide dynamic range and durability. Unfortunately, the response of available materials does not extend down to dc and therefore steady loads cannot be measured directly. Also, the PVF2 material produces a charge output that is prone to electrical interference and is temperature dependent.

FIGURE 25.7 Current-to-voltage converter.

The possibility of measuring transient phenomenon using piezoelectric material has recently encouraged some researchers to use the piezoelectric effect for detecting vibrations that indicate incipient slip, occurrence of contact, local change in skin curvature, and estimating friction and hardness of the object [7, 10, 11]. If the piezoelectric transducer shown in Figure 25.6(a) is connected to an FET-input operational amplifier configured as a current-to-voltage converter as shown in Figure 25.7, the output voltage is given by:

$$V_o = \frac{dQ}{dt} R_f = AR_f d_{33} \frac{d\sigma}{dt} \quad (25.18)$$

where R_f is the feedback resistor. Correspondingly, the circuit configuration provides the mean to measure of changes in the contact stress. A detailed explanation of the behavior of this sensor can be found in [7].

Optical

Recent developments in fiber optic technology and solid-state cameras have led to numerous novel tactile sensor designs [32, 33]. Some of these designs employ flexible membranes incorporating a reflecting surface, Figure 25.8. Light is introduced into the sensor via a fiber optic cable. A wide cone of light propagates out of the fiber, reflects back from the membrane, and is collected by a second fiber. When an external force is applied onto the elastomer, it shortens the distance between the reflective side of the

FIGURE 25.8 (a) Reflective transducer. (b) Light-intensity as a function of the distance h .

FIGURE 25.9 Tactile transducer based on the principle of internal reflection.

membrane and the fibers, h . Consequently, the light gathered by the receiving fiber changes as a function of h , Figure 25.8(b). To recover univocally the distance from the light intensity, a monotonic function is needed. This can be achieved by designing the transducer such it operates for $h > h_{\min}$, where h_{\min} is indicated in Figure 25.8(b). (The region $h > h_{\min}$ is preferred to the $h < h_{\min}$ for dynamic range reasons.)

Another optical effect that can be used is that of frustrated total internal reflection [5, 34]. With this technique, an elastic rubber membrane covers, without touching, a glass plate (waveguide); light entering the side edge of the glass is totally reflected by the top and bottom surfaces and propagates along it, Figure 25.9.

The condition for total internal reflection occurs when:

$$n_2 \sin \alpha \leq n_1 \quad (25.19)$$

where n_1 = Index of refraction of the medium surrounding the waveguide (in this case air, $n_1 \cong 1$)

n_2 = Index of refraction of the waveguide

α = Angle of incidence at the interface glass-air

Objects in contact with the elastic membrane deform it and induce contact between the bottom part of the membrane and the top surface of the waveguide, disrupting the total internal reflection. Consequently, the light in the waveguide is scattered at the contact location. Light that escapes through the bottom surface of the waveguide can be detected by an array of photodiodes, a solid-state sensor, or, alternatively, transported away from the transducer by fibers [3]. The detected imaged is stored in a computer for further analysis. A rubber membrane with a flat surface yields a high-resolution binary (contact or noncontact) image [5]. If the rubber sheet is molded with a textured surface (Figure 25.9), then an output proportional to the area of contact is obtained and, consequently, the applied forces can be detected [3]. Shear forces can also be detected using special designs [35]. Sensors based on frustrated internal reflection can be molded into a finger shape [5] and are capable of forming very high-resolution tactile images. Such sensors are commercially available. An improved miniaturized version of a similar sensor was proposed in [34].

Other types of optical transducers use “occluder” devices. One of the few commercially available tactile sensors uses this kind of transducer [36]. In one of the two available designs, the transducer’s surface is made of a compliant material, which has on its underside a grid of elongated pins. When force is applied to the compliant surface, the pins on the underside undergo a mechanical motion normal to the surface,

FIGURE 25.10 Principle of operation of an occluder transducer.

FIGURE 25.11 A four-layer tactile transducer.

blocking the light path of a photoemitter–detector pair. The amount of movement determines the amount of light reaching the photoreceiver. Correspondingly, the more force applied, the less amount of light is collected by the photoreceiver, [Figure 25.10](#). The major problems with this specific device are associated with creep, hysteresis, and temperature variation. This scheme also requires individual calibration of each photoemitter–photodetector pair.

Fibers have also been used directly as transducers in the design of tactile sensors. Their use is based on two properties of fiber optic cables: (1) if a fiber is subjected to a significant amount of bending, then the angle of incidence at the fiber wall can be reduced sufficiently for light to leave the core [37]; and (2) if two fibers pass close to one another and both have roughened surfaces, then light can pass between the fibers. Light coupling between adjacent fibers is a function of their separation [3].

An example of an optical fiber tactile sensor, whose sensing mechanism is based on the increase of light attenuation due to the microbend in the optical fibers, is shown in [Figure 25.11](#) [37]. The transducer consists of a four-layer, two-dimensional fiber optic array constructed by using two layers of optical fibers as a corrugation structure, through which microbends are induced in two orthogonal layers of active fibers. Each active fiber uses an LED as the emitter and a PIN photodiode as a detector. When an object is forced into contact with the transducer, a light distribution is detected at each detector. This light distribution is related to the applied force and the shape of the object. Using complex algorithms and active sensing (moving the object in relation to the transducer), the object position, orientation, size, and contour information can be retrieved [37]. However, the recovery of the applied force profiles was not reported in [37].

Photoelastic

An emerging technology in optical tactile sensing is the development of photoelastic transducers. When a light ray propagates into an optically anisotropic medium, it splits into two rays that are linearly polarized at right angles to each other and propagate at different velocities. This splitting of a ray into two rays that have mutually perpendicular polarizations results from a physical property of crystalline material that is called *optical birefringence* or simply *birefringence*. The direction in which light propagates with the higher velocity is called the *fast axis*; and the one in which it propagates more slowly is called the *slow axis*. Some optically isotropic materials — such as glass, celluloid, bakelite, and transparent plastics in general — become birefringent when they are subjected to a stress field. The birefringent effect lasts only during the application of loads. Thus, this phenomenon is called *temporary* or *artificial birefringence* or, more commonly, the *photoelastic phenomenon*.

Figure 25.12(a) shows a photoelastic transducer proposed in [38]. It consists of a fully supported two-layer beam with a mirrored surface sandwiched in between. Normal line forces are applied to the top surface of the beam at discrete tactels, separated by equal distances, s , along the beam. The upper compliant layer is for the protection of the mirror, while the lower one is the photoelastic layer.

Circularly polarized monochromatic light, incident along the z -axis, illuminates the bottom surface of the transducer. The light propagates parallel to the z -axis, passes through the photoelastic layer, and then reflects back from the mirror. If no force is applied to the transducer, the returning light is circularly polarized because unstressed photoelastic material is isotropic. If force is applied, stresses are induced in the photoelastic layer, making the material birefringent. This introduces a certain phase difference between the components of the electric field associated with the light-wave propagation. The two directions of polarization are in the plane perpendicular to the direction of propagation (in this case, the x - y plane). As a consequence of this effect, the output light is elliptically polarized, creating a phase difference distribution, p , between the input light and the output light at each point in the x - y plane. The phase difference distribution carries the information of the force distribution applied to the transducer.

A *polariscope* is a practical method to observe the spatial variation on light intensity (fringes) due to the effect of induced phase difference distribution. Polariscopes can be either linear or circular, depending on the required polarization of the light. They can also be characterized as a reflective or a transparent type, depending on whether the photoelastic transducer reflect or transmits the light.

A circular, reflective polariscope, shown in Figure 25.12(b), is utilized to illuminate the transducer shown in Figure 25.12(a). The input light is linearly polarized and is directed toward the photoelastic transducer by a beam splitter. Before reaching the transducer, the light is circularly polarized by a quarter-wave plate. The output light is elliptically polarized when a force is applied. This light is directed toward a detector passing through the quarter-wave plate, the beam splitter, and an analyzer. Finally, it is detected by a camera linked to a frame grabber connected to a PC, for further data processing. The light that illuminates the camera consists of a set of fringes from where the force distribution applied to the transducer must be recovered. A technique for the recovery of the forces from the fringes is described in [38]. A model of the transducer using FEA is reported in [39].

One of the earlier applications of photoelasticity to tactile sensing dates back to the development phase of the Utah/MIT dexterous hand [40]. The researchers proposed the use of the photoelastic phenomenon as a transduction method for the recovery of the force profile applied to the fingers of the hand. They limited their application to the development of a single-touch transducer, although they claimed that an array of such devices could be implemented. However, the construction of a large array of their devices would be difficult. To overcome this difficulty, another research group proposed a different transducer [41]. Although an analytical model was developed for the sensor, a systematic method for recovering the two-dimensional force profile from the light intensity distribution was not reported. Thus, the sensor was used mainly for the study of the forward analysis, namely, observing the light intensity distribution for different touching objects brought into contact with the sensor. This sensor could eventually be used for determining some simple geometric properties of a touching object.

(a)

(b)

FIGURE 25.12 (a) Photoelastic transducer. (b) Circular reflective polariscope.

A tactile sensor reported in [42] is capable of detecting slippage. The output light intensity (the fringe pattern) is captured by a camera interfaced to a PC. When an object moves across the surface of the transducer, the light intensity distribution changes. A direct analysis of the fringes is used to detect movement of the grasped object; a special technique was reported to optimize the comparison process for detecting differences between two fringe patterns occurring due to the slippage of the object in contact with the sensor [42]. It is important to note that such an analysis of the fringes does not require the recovery of the applied force profile.

Photoelasticity offers several attractive properties for the development of tactile sensors: good linearity, compatibility with vision-base sensing technologies, and high spatial resolution associated with the latter, that could lead to the development of high-resolution tactile imagers needed for object recognition and fine manipulation. Also, photoelastic sensors are compatible with fiber optic technology that allows remote location of electronic processing devices and avoidance of interference problems.

Other technologies for tactile sensing include acoustic, magnetic, and microcavity vacuum sensors [43, 44].

26.1 Pressure Measurement

Kevin H.-L. Chau

Basic Definitions

Pressure is defined as the normal force per unit area exerted by a fluid (liquid or gas) on any surface. The surface can be either a solid boundary in contact with the fluid or, for purposes of analysis, an imaginary plane drawn through the fluid. Only the component of the force normal to the surface needs to be considered for the determination of pressure. Tangential forces that give rise to shear and fluid motion will not be a relevant subject of discussion here. In the limit that the surface area approaches zero, the ratio of the differential normal force to the differential area represents the pressure at a point on the surface. Furthermore, if there is no shear in the fluid, the pressure at any point can be shown to be independent of the orientation of the imaginary surface under consideration. Finally, it should be noted that pressure is not defined as a vector quantity and is therefore nondirectional.

Three types of pressure measurements are commonly performed:

Absolute pressure is the same as the pressure defined above. It represents the pressure difference between the point of measurement and a perfect vacuum where pressure is zero.

Gage pressure is the pressure difference between the point of measurement and the ambient. In reality, the ambient (atmospheric) pressure can vary, but only the pressure difference is of interest in gage pressure measurements.

TABLE 26.1 Pressure Unit Conversion Table

Units	kPa	psi	in H ₂ O	cm H ₂ O	in. Hg	mm Hg	mbar
kPa	1.000	0.1450	4.015	10.20	0.2593	7.501	10.00
psi	6.895	1.000	27.68	70.31	2.036	51.72	68.95
in. H ₂ O	0.2491	3.613×10^{-2}	1.000	2.540	7.355×10^{-2}	1.868	2.491
cm H ₂ O	0.09806	1.422×10^{-2}	0.3937	1.000	2.896×10^{-2}	0.7355	0.9806
in. Hg	3.386	0.4912	13.60	34.53	1.000	25.40	33.86
mm Hg	0.1333	1.934×10^{-2}	0.5353	1.360	3.937×10^{-2}	1.000	1.333
mbar	0.1000	0.01450	0.04015	1.020	0.02953	0.7501	1.000

Key:

- (1) kPa = kilopascal;
- (2) psi = pound force per square inch;
- (3) in. H₂O = inch of water at 4°C;
- (4) cm H₂O = centimeter of water at 4°C;
- (5) in. Hg = inch of mercury at 0°C;
- (6) mm Hg = millimeter of mercury at 0°C;
- (7) mbar = millibar.

Differential pressure is the pressure difference between two points, one of which is chosen to be the reference. In reality, both pressures can vary, but only the pressure difference is of interest here.

Units of Pressure and Conversion

The SI unit of pressure is the *pascal* (Pa), which is defined as the newton per square meter ($\text{N}\cdot\text{m}^{-2}$); 1 Pa is a very small unit of pressure. Hence, decimal multiples of the pascal (e.g., kilopascals [kPa] and megapascals [MPa]) are often used for expressing higher pressures. In weather reports, the hectopascal (1 hPa = 100 Pa) has been adopted by many countries to replace the millibar (1 bar = 10^5 Pa; hence, 1 millibar = 10^{-3} bar = 1 hPa) as the unit for atmospheric pressure. In the United States, pressure is commonly expressed in pound force per square inch (psi), which is about 6.90 kPa. In addition, the absolute, gage, and differential pressures are further specified as psia, psig, and psid, respectively. However, no such distinction is made in any pressure units other than the psi. There is another class of units e.g., millimeter of mercury at 0°C (mm Hg, also known as the *torr*) or inch of water at 4°C (in H₂O), which expresses pressure in terms of the height of a static liquid column. The actual pressure p referred to is one that will be developed at the base of the liquid column due to its weight, which is given by Equation 26.1.

$$p = \rho g h \quad (26.1)$$

where ρ is the density of the liquid, g is the acceleration due to gravity, and h is the height of the liquid column. A conversion table for the most popular pressure units is provided in [Table 26.1](#).

Sensing Principles

Sensing Elements

Since pressure is defined as the force per unit area, the most direct way of measuring pressure is to isolate an area on an elastic mechanical element for the force to act on. The deformation of the sensing element produces displacements and strains that can be precisely sensed to give a calibrated measurement of the pressure. This forms the basis for essentially all commercially available pressure sensors today. Specifically, the basic requirements for a pressure-sensing element are a means to isolate two fluidic pressures (one to be measured and the other one as the reference) and an elastic portion to convert the pressure difference into a deformation of the sensing element. Many types of pressure-sensing elements are currently in use. These can be grouped as diaphragms, capsules, bellows, and tubes, as illustrated in [Figure 26.1](#). Diaphragms

FIGURE 26.1 Pressure-sensing elements: (a) flat diaphragm; (b) corrugated diaphragm; (c) capsule; (d) bellows; (e) straight tube; (f) C-shaped Bourdon tube; (g) twisted Bourdon tube; (h) helical Bourdon tube; (i) spiral Bourdon tube.

are by far the most widely used of all sensing elements. A special form of tube, known as the *Bourdon tube*, is curved or twisted along its length and has an oval cross-section. The tube is sealed at one end and tends to unwind or straighten when it is subjected to a pressure applied to the inside. In general, Bourdon tubes are designed for measuring high pressures, while capsules and bellows are usually for measuring low pressures. A detailed description of these sensing elements can be found in [1].

Detection Methods

A detection means is required to convert the deformation of the sensing element into a pressure readout. In the simplest approach, the displacements of a sensing element can be amplified mechanically by lever and flexure linkages to drive a pointer over a graduated scale, for example, in the moving pointer barometers. Some of the earliest pressure sensors employed a Bourdon tube to drive the wiper arm over a potentiometric resistance element. In *linear-variable differential-transformer* (LVDT) pressure sensors, the displacement of a Bourdon tube or capsule is used to move a magnetic core inside a coil assembly to vary its inductance. In *piezoelectric* pressure sensors, the strains associated with the deformation of a sensing element are converted into an electrical charge output by a piezoelectric crystal. Piezoelectric pressure sensors are useful for measuring high-pressure transient events, for example, explosive pressures. In *vibrating-wire* pressure sensors, a metal wire (typically tungsten) is stretched between a fixed anchor and the center of a diaphragm. The wire is located near a permanent magnet and is set into vibration at its resonant frequency by an ac current excitation. A pressure-induced displacement of the diaphragm changes the tension and therefore the resonant frequency of the wire, which is measured by the readout electronics. A detailed description of these and other types of detection methods can be found in [1].

Capacitive Pressure Sensors.

Many highly accurate (better than 0.1%) pressure sensors in use today have been developed using the capacitive detection approach. Capacitive pressure sensors can be designed to cover an extremely wide pressure range. Both high-pressure sensors with full-scale pressures above 10^7 Pa (a few thousand psi) and vacuum sensors (commonly referred to as capacitive *manometers*) usable for pressure measurements below 10^{-3} Pa (10^{-5} torr) are commercially available. The principle of *capacitive pressure sensors* is illustrated in Figure 26.2. A metal or silicon diaphragm serves as the pressure-sensing element and constitutes one electrode of a capacitor. The other electrode, which is stationary, is typically formed by a deposited metal layer on a ceramic or glass substrate. An applied pressure deflects the diaphragm, which in turn changes the gap spacing and the capacitance [2]. In the differential capacitor design, the sensing diaphragm is located in between two stationary electrodes. An applied pressure will cause one capacitance to increase and the other one to decrease, thus resulting in twice the signal while canceling many undesirable common mode effects. Figure 26.3 shows a practical design of a differential capacitive sensing cell that uses two isolating diaphragms and an oil fill to transmit the differential pressure to the sensing diaphragm. The isolating diaphragms are made of special metal alloys that enable them to handle corrosive fluids. The oil is chosen to set a predictable dielectric constant for the capacitor gaps while providing adequate damping to reduce shock and vibration effects. Figure 26.4 shows a rugged capacitive pressure sensor for industrial applications based on the capacitive sensing cell shown in Figure 26.3. The capacitor electrodes are connected to the readout electronics housing at the top. In general, with today's sophisticated electronics and special considerations to minimize stray capacitances (that can degrade the accuracy of measurements), a capacitance change of 10 aF (10^{-18} F) provided by a diaphragm deflection of only a fraction of a nanometer is resolvable.

Piezoresistive Pressure Sensors.

Piezoresistive sensors (also known as *strain-gage* sensors) are the most common type of pressure sensor in use today. *Piezoresistive effect* refers to a change in the electric resistance of a material when stresses or strains are applied. Piezoresistive materials can be used to realize strain gages that, when incorporated into diaphragms, are well suited for sensing the induced strains as the diaphragm is deflected by an applied pressure. The sensitivity of a strain gage is expressed by its *gage factor*, which is defined as the fractional change in resistance, $\Delta R/R$, per unit strain:

$$\text{Gage factor} = \left(\frac{\Delta R}{R} \right) / \epsilon \quad (26.2)$$

where strain ϵ is defined as $\Delta L/L$, or the extension per unit length. It is essential to distinguish between two different cases in which: (1) the strain is parallel to the direction of the current flow (along which

FIGURE 26.2 Operating principle of capacitive pressure sensors. (a) Single capacitor design; and (b) differential capacitor design.

the resistance change is to be monitored); and (2) the strain is perpendicular to the direction of the current flow. The gage factors associated with these two cases are known as the *longitudinal gage factor* and the *transverse gage factor*, respectively. The two gage factors are generally different in magnitude and often opposite in sign. Typical longitudinal gage factors are ~ 2 for many useful metals, 10 to 35 for polycrystalline silicon (polysilicon), and 50 to 150 for single-crystalline silicon [3–5]. Because of its large piezoresistive effect, silicon has become the most commonly used material for strain gages. There are several ways to incorporate strain gages into pressure-sensing diaphragms. For example, strain gages can be directly bonded onto a metal diaphragm. However, hysteresis and creep of the bonding agent are potential issues. Alternatively, the strain gage material can be deposited as a thin film on the diaphragm. The adhesion results from strong molecular forces that will not creep, and no additional bonding agent is required. Today, the majority of piezoresistive pressure sensors are realized by integrating the strain gages into the silicon diaphragm using integrated circuit fabrication technology. This important class of silicon pressure sensors will be discussed in detail in the next section.

Silicon Micromachined Pressure Sensors

Silicon micromachined pressure sensors refer to a class of pressure sensors that employ integrated circuit batch processing techniques to realize a thinned-out diaphragm sensing element on a silicon chip. Strain gages made of silicon diffused resistors are typically integrated on the diaphragm to convert the pressure-induced diaphragm deflection into an electric resistance change. Over the past 20 years, silicon micro-machined pressure sensors have gradually replaced their mechanical counterparts and have captured over

FIGURE 26.3 A differential capacitive sensing cell that is equipped with isolating diaphragms and silicone oil transfer fluid suitable for measuring pressure in corrosive media. (Courtesy of Rosemount, Inc.)

80% of the pressure sensor market. There are several unique advantages that silicon offers. Silicon is an ideal mechanical material that does not display any hysteresis or yield and is elastic up to the fracture limit. It is stronger than steel in yield strength and comparable in Young's modulus [6]. As mentioned in the previous section, the piezoresistive effect in single-crystalline silicon is almost 2 orders of magnitude larger than that of metal strain gages. Silicon has been widely used in integrated circuit manufacturing for which reliable batch fabrication technology and high-precision dimension control techniques have been well developed. A typical silicon wafer yields hundreds of identical pressure sensor chips at very low cost. Further, the necessary signal conditioning circuitry can be integrated on the same sensor chip no more than a few millimeters in size [7]. All these are key factors that contributed to the success of silicon micromachined pressure sensors.

Figure 26.5 shows a typical construction of a silicon piezoresistive pressure sensor. An array of square or rectangular diaphragms is "micromachined" out of a (100) oriented single-crystalline silicon wafer by selectively removing material from the back. An anisotropic silicon etchant (e.g., potassium hydroxide) is typically employed; it etches fastest on (100) surfaces and much slower on (111) surfaces. The result is a pit formed on the backside of the wafer bounded by (111) surfaces and a thinned-out diaphragm section on the front at every sensor site. The diaphragm thickness is controlled by a timed etch or by using suitable etch-stop techniques [6, 8]. To realize strain gages, *p*-type dopant, typically boron, is diffused into the front of the *n*-type silicon diaphragm at stress-sensitive locations to form resistors that are electrically isolated from the diaphragm and from each other by reverse biased *p-n* junctions. The strain gages, the diaphragm, and the rest of the supporting sensor chip all belong to the same single-crystalline silicon. The result is a superb mechanical structure that is free from creep, hysteresis, and thermal expansion coefficient mismatches. However, the sensor die must still be mounted to a sensor housing, which typically has mechanical properties different from that of silicon. It is crucial to ensure

FIGURE 26.4 A rugged capacitive pressure sensor product for industrial applications. It incorporates the sensing cell shown in Figure 26.3. Readout electronics are contained in the housing at the top. (Courtesy of Rosemount, Inc.)

a high degree of stress isolation between the sensor housing and the sensing diaphragm that may otherwise lead to long-term mechanical drifts and undesirable temperature behavior. A common practice is to bond a glass wafer or a second silicon wafer to the back of the sensor wafer to reinforce the overall composite sensor die. This way, the interface stresses generated by the die mount will also be sufficiently remote from the sensing diaphragm and will not seriously affect its stress characteristics. For gage or differential pressure sensing, holes must be provided through the carrier wafer prior to bonding that are aligned to the etch pits of the sensor wafer leading to the back of the sensing diaphragms. No through holes are necessary for absolute pressure sensing. The wafer-to-wafer bonding is performed in a vacuum to achieve a sealed reference vacuum inside the etch pit [6, 9]. Today's silicon pressure sensors are available in a large variety of plastic, ceramic, metal can, and stainless steel packages (some examples are shown in Figure 26.6). Many are suited for printed circuit board mounting. Others have isolating diaphragms and transfer fluids for handling corrosive media. They can be readily designed for a wide range of industrial, medical, automotive, aerospace, and military applications.

Silicon Piezoresistive Pressure Sensor Limitations

Despite the relatively large piezoresistive effects in silicon strain gages, the full-scale resistance change is typically only 1% to 2% of the resistance of the strain gage (which yields an unamplified voltage output of 10 mV/V to 20 mV/V). To achieve an overall accuracy of 0.1% of full scale, for example, the combined effects of mechanical and electrical repeatability, hysteresis, linearity, and stability must be controlled or compensated to within a few parts per million (ppm) of the gage resistance. Furthermore, silicon strain gages are also very temperature sensitive and require careful compensations. There are two primary sources of temperature drifts: (1) the temperature coefficient of resistance of the strain gages (from 0.06%/°C to 0.24%/°C); and (2) the temperature coefficient of the gage factors (from -0.06%/°C to

FIGURE 26.5 A cut-away view showing the typical construction of a silicon piezoresistive pressure sensor.

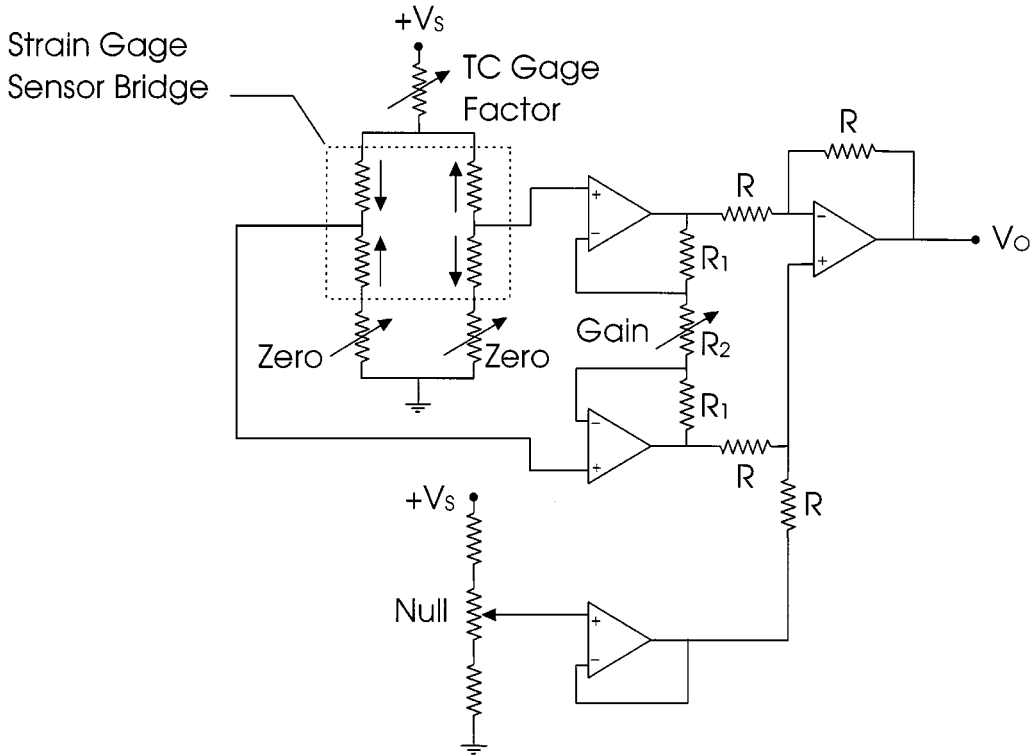

FIGURE 26.7 A signal-conditioning circuit for silicon piezoresistive pressure sensor.

$-0.24\%/^{\circ}\text{C}$), which will cause a decrease in pressure sensitivity as the temperature rises. Figure 26.7 shows a circuit configuration that can be used to achieve offset (resulting from gage resistance mismatch) and temperature compensations as well as providing signal amplification to give a high-level output. Four strain gages that are closely matched in both their resistances and temperature coefficients of resistance are employed to form the four active arms of a Wheatstone bridge. Their resistor geometry on the sensing diaphragm is aligned with the principal strain directions so that two strain gages will produce a resistance increase and the other two a resistance decrease on a given diaphragm deflection. These two pairs of strain gages are configured in the Wheatstone bridge such that an applied pressure will produce a bridge resistance imbalance while the temperature coefficient of resistance will only cause a common mode resistance change in all four gages, keeping the bridge balanced. As for the temperature coefficient of the gage factor, because it is always negative, it is possible (e.g., with the voltage divider circuit in Figure 26.7) to utilize the positive temperature coefficient of the bridge resistance to increase the bridge supply voltage, compensating for the loss in pressure sensitivity as temperature rises. Another major limitation in silicon pressure sensors is the nonlinearity in the pressure response that usually arises from the slight nonlinear behavior in the diaphragm mechanical and the silicon piezoresistive characteristics. The nonlinearity in the pressure response can be compensated by using analog circuit components. However, for the most accurate silicon pressure sensors, digital compensation using a microprocessor with correction coefficients stored in memory is often employed to compensate for all the predictable temperature and nonlinear characteristics. The best silicon pressure sensors today can achieve an accuracy of 0.08% of full scale and a long-term stability of 0.1% of full scale per year. Typical compensated temperature range is from -40°C to 85°C , with the errors of compensation on span and offset both around 1% of full scale. Commercial products are currently available for full-scale pressure ranges from 10 kPa to 70 MPa (1.5 psi to 10,000 psi). The 1998 prices are U.S.\$5 to \$20 for the most basic uncompensated sensors; \$10 to \$50 for the compensated (with additional laser trimmed resistors either integrated on-chip or on a ceramic substrate)

26.2 Vacuum Measurement

*Ron Goehner, Emil Drubetsky, Howard M. Brady,
and William H. Bayles, Jr.*

Background and History of Vacuum Gages

To make measurements in the vacuum region, one must possess a knowledge of the expected pressure range required by the processes taking place in the vacuum chamber as well as the accuracy and/or repeatability of the measurement required for the process. Typical vacuum systems require that many orders of magnitude of pressures must be measured. In many applications, the pressure range may be 8 orders of magnitude, or from atmospheric (1.01×10^5 Pa, 760 torr) to 1×10^{-3} Pa (7.5×10^{-6} torr).

For semiconductor lithography, high-energy physics experiments and surface chemistry, ultimate vacuum of 7.5×10^{-9} torr and much lower are required (a range of 11 orders of magnitude below atmospheric pressure). One gage will not give reasonable measurements over such large pressure ranges. Over the past 50 years, vacuum measuring instruments (commonly called gages) have been developed that used transducers (or sensors) which can be classified as either direct reading (usually mechanical) or indirect reading [1] (usually electronic). [Figure 26.8](#) shows vacuum gages typically in current use. When a force on a surface is used to measure pressure, the gages are mechanical and are called *direct reading* gages, whereas when any property of the gas that changes with density is measured by electronic means, they are called *indirect reading* gages. [Figure 26.9](#) shows the range of operating pressure for various types of vacuum gages.

Direct Reading Gages

A subdivision of direct reading gages can be made by dividing them into those that utilize a liquid wall and those that utilize a solid wall. The force exerted on a surface from the pressure of thermally agitated molecules and atoms is used to measure the pressure.

Liquid Wall Gages

The two common gages that use a liquid wall are the manometer and the McLeod gage. The liquid column *manometer* is the simplest type of vacuum gage. It consists of a straight or U-shaped glass tube

FIGURE 26.8 Classification of pressure gages. (From D.M. Hoffman, B. Singh, and J.H. Thomas, III (eds.), *The Handbook of Vacuum Science and Technology*, Orlando, FL: Academic Press, 1998. With permission.)

evacuated and sealed at one end and filled partly with mercury or a low vapor pressure liquid such as diffusion pump oil (See [Figure 26.10](#)). In the straight tube manometer, as the space above the mercury is evacuated, the length of the mercury column decreases. In the case of the U-tube, as the free end is evacuated, the two columns approach equal height. The pressure at the open end is measured by the difference in height of the liquid columns. If the liquid is mercury, the pressure is directly measured in mm of Hg (torr). The manometer is limited to pressures equal to or greater than ~1 torr (133 Pa). If

FIGURE 26.9 Pressure ranges for various gages. (From D.M. Hoffman, B. Singh, and J.H. Thomas, III (eds.), *The Handbook of Vacuum Science and Technology*, Orlando, FL: Academic Press, 1998. With permission.)

the liquid is a low density oil, the U-tube is capable of measuring a pressure as low as ~0.1 torr. This is an absolute, direct reading gage but the use of mercury or low density oils that will in time contaminate the vacuum system preclude its use as a permanent vacuum gage.

Due to the pressure limitation of the manometer, the McLeod gage [2, 3] was developed to significantly extend the range of vacuum measurement (see Figure 26.11). This device is essentially a mercury manometer in which a volume of gas is compressed before measurement. This can be used as a primary standard device when a liquid nitrogen trap is used on the vacuum system. Figure 26.11 shows gas at 10⁻⁶ torr and

FIGURE 26.10 Mercury manometers. (From W.H. Bayles, Jr., Fundamentals of Vacuum Measurement, Calibration and Certification, Industrial Heating, October 1992. With permission.)

a compression ratio of 10^{+7} . In this example, the difference of the columns will be 10 mm. Extreme care must be taken not to break the glass and expose the surroundings to the mercury. The McLeod Gage is an inexpensive standard but should only be used by skilled and careful technicians. The gage will give a false low reading unless precautions are taken to ensure that any condensible vapors present are removed by liquid nitrogen trapping.

FIGURE 26.11 McLeod gage. (From D.M. Hoffman, B. Singh, and J.H. Thomas, III (eds.), *The Handbook of Vacuum Science and Technology*, Orlando, FL: Academic Press, 1998. With permission.)

Solid Wall Gages

There are two major mechanical solid wall gage types: capsule and diaphragm.

Bourdon Gages.

The capsule-type gages depend on the deformation of the capsule with changing pressure and the resultant deflection of an indicator. Pressure gages using this principle measure pressures above atmospheric to several thousand psi and are commonly used on compressed gas systems. This type of gage is also used at pressures below atmospheric, but the sensitivity is low. The Bourdon gage (Figure 26.12), is used as a moderate vacuum gage. In this case, the capsule is in the form of a thin-walled tube bent in a circle, with the open end attached to the vacuum system with a mechanism and a pointer attached to the other end. The atmospheric pressure deforms the tube; a linear indication of the pressure is given that is independent of the nature of the gas. Certain manufacturers supply capsule gages capable of measuring pressures as low as 1 torr. These gages are rugged, inexpensive, and simple to use and can be made of materials inert to corrosive vapors. Since changing atmospheric pressure causes inaccuracies in the readings, compensated versions of the capsule and Bourdon gage have been developed that improve the accuracy [4].

FIGURE 26.12 Bourdon gage. (From Varian Associates, Basic Vacuum Practice, Varian Associates, Inc., Lexington, MA, 1992. With permission.)

Diaphragm Gages.

If compensated capsule or diaphragm mechanisms are combined with sensitive and stable electronic measuring circuits, performance is improved. One such gage is the capacitance diaphragm gage (also referred to as the capacitance manometer).

The capacitance diaphragm gage is shown in Figure 26.13. A flexible diaphragm forms one plate of a capacitor and a fixed probe the other. The flexible diaphragm deforms due to even slight changes in pressure, resulting in a change in the capacitance. The capacitance is converted to a pressure reading. The sensitivity, repeatability, and simplicity of this gage enables this type of direct reading gage to be a standard from 10^{-6} torr to atmospheric pressure, provided multiple heads designed for each pressure range are used. A single head can have a dynamic range of 4 or 5 orders of magnitude [5].

The strain gage type of diaphragm gage is shown in Figure 26.13. In this case, deformation of the diaphragm causes a proportional output from the attached strain gage. Sensitivities and dynamic range tend to be less than those of the capacitance diaphragm gage, but the price of the strain gage type diaphragm gage is usually lower.

Both of these gages are prone to errors caused by small temperature changes due to the inherent high sensitivity of this gage type. Temperature-controlled heads or correction tables built into the electronics have been used to minimize this problem. Other sources of error in all solid wall gages are hysteresis and metal fatigue.

Indirect Reading Gages

Indirect reading gages measure some property of the gas that changes with the density of the gas and usually produces an electric output. Electronic devices amplify and compensate this output to provide a pressure reading.

Thermal Conductivity Gages

Thermal conductivity gages utilize the property of gases in which reduced thermal conductivity corresponds to decreasing density (pressure). The thermal conductivity decreases from a nearly constant value above ~ 1 torr to essentially 0 at pressures below 10^{-2} torr. The gage controllers are designed to work with a specific sensor tube, and substitutions are limited to those that are truly functionally identical. Heat transfer at various pressures is related to the Knudsen number, as is shown in Figure 26.14 for various heat transfer regimes. The Knudsen number can then be related to pressure through the geometry of the sensor, providing a relationship of heat transfer to pressure for a particular design thermal conductivity gage.

CAPACITANCE DIAPHRAGM GAUGE

STRAIN GAUGE DIAPHRAGM GAUGE

FIGURE 26.13 Diaphragm gage. (From W.H. Bayles, Jr., *Fundamentals of Vacuum Measurement, Calibration and Certification*, Industrial Heating, October 1992. With permission.)

Pirani Gages.

The Pirani gage is perhaps the oldest indirect gage that is still used today. In operation, a sensing filament carrying current and producing heat is surrounded by the gas to be measured. As the pressure changes, the thermal conductivity changes, thus varying the temperature of the sensing filament. The temperature change causes a change in the resistance of the sensing filament. The sensing filament is usually one leg of a Wheatstone bridge. The bridge can be operated so that the voltage is varied to keep the bridge balanced; that is, the resistance of the sensing filament is kept constant.

This method is called the constant temperature method and is deemed the fastest, most sensitive, and most accurate. To reduce the effect of changing ambient temperature, an identical filament sealed off at very low pressure is placed in the leg adjacent to the sensing filament as a balancing resistor. Because of its high thermal resistance coefficient, the filament material is usually a thin tungsten wire. It has been demonstrated that a 10 W light bulb works quite well [6]. (see [Figure 26.15](#).)

A properly designed, compensated Pirani gage with sensitive circuitry is capable of measuring to 10^{-4} torr. However, the thermal conductivity of gases varies with the gas being measured, causing a variation in gage response. These variations can be as large as a factor of 5 at low pressures and as high as 10 at high pressures (see [Figure 26.16](#)). Correction for these variations can be made on the calibration curves supplied by the manufacturer if the composition of the gas is known. Operation in the presence of high partial pressures of organic molecules such as oils is not recommended.

FIGURE 26.14 Heat transfer regimes in a thermal conductivity gage.

FIGURE 26.15 Pirani gage.

Thermistor Gages.

In the thermistor gage, a thermistor is used as one leg of a bridge circuit. The inverse resistive characteristics of the thermistor element unbalances the bridge as the pressure changes, causing a corresponding change in current. Sensitive electronics measure the current and are calibrated in pressure units. The

FIGURE 26.16 Calibration curves for the Pirani gage. (Reprinted with permission from Leybold-Herqeus GmbH, Köhn, Germany.)

thermistor gage measures approximately the same pressure range as the thermocouple. The exact calibration depends on the gas measured. In a well-designed bridge circuit, the plot of current vs. pressure is practically linear in the range 10^{-3} to 1 torr [7]. Modern thermistor gages use constant-temperature techniques.

Thermocouple Gages.

Another example of an indirect reading thermal conductivity gage is the thermocouple gage. This is a relatively inexpensive device with proven reliability and a wide range of applications. In the thermocouple gage, a filament of resistance alloy is heated by the passage of a constant current (see Figure 26.17). A thermocouple is welded to the midpoint of the filament or preferably to a conduction bridge at the center of the heated filament. This provides a means of directly measuring the temperature. With a constant current through the filament, the temperature increases as the pressure decreases as there are fewer molecules surrounding the filament to carry the heat away. The thermocouple output voltage increases as a result of the increased temperature and varies inversely with the pressure. The thermocouple gage can also be operated in the constant-temperature mode.

Gas composition effects apply to all thermal conductivity gages. The calibration curves for a typical thermocouple gage are shown in Figure 26.18. The thermocouple gage can be optimized for operation in various pressure ranges. Operation of the thermocouple gage in high partial pressures of organic molecules such as oils should be avoided. One manufacturer pre-oxidizes the thermocouple sensor for stability in “dirty” environments and for greater interchangeability in clean environments.

Convection Gages.

Below 1 torr a significant change in thermal conductivity occurs as the pressure changes. Thus, the thermal conductivity gage is normally limited to 1 torr.

At pressures above 1 torr, there is, in most gages, a small contribution to heat transfer caused by convection. Manufacturers have developed gages that utilize this convection effect to extend the usable

FIGURE 26.17 Thermocouple gage. (Reprinted with permission of Televac Division, The Fredericks Co., Huntingdon Valley, PA.)

range to atmospheric pressure and slightly above [8–12]. Orientation of a convection gage is critical because this convection heat transfer is highly dependent on the orientation of the elements within the gage.

The Convectron™ uses the basic structure of the Pirani with special features to enhance convection cooling in the high-pressure region [13]. To utilize the gage above 1 torr (133 Pa), the sensor tube must be mounted with its major axis in a horizontal position. If the only area of interest is below 1 torr, the tube can be mounted in any position. As mentioned above, the gage controller is designed to be used with a specific model sensor tube; because extensive use is made of calibration curves and look-up tables stored in the controller, no substitution is recommended.

The Televac convection gage uses the basic structure of the thermocouple gage except that two thermocouples are used [14]. As in any thermocouple gage, the convection gage measures the pressure by determining the heat loss from a fine wire maintained at constant temperature. The response of the sensor depends on the gas type. A pair of thermocouples is mounted a fixed distance from each other (see Figure 26.19). The one mounted lower is heated to a constant temperature by a variable current power supply. Power is pulsed to this lower thermocouple and the temperature is measured between heating pulses. The second (upper) thermocouple measures convection effects and also compensates for ambient temperature. At pressures below ~2 torr (270 Pa) the temperature in the upper thermocouple is negligible. The gage tube operates as a typical thermocouple in the constant-temperature mode. Above 2 torr, convective heat transfer causes heating of the upper thermocouple. The voltage output is subtracted from that of the lower thermocouple, thus requiring more current to maintain the wire temperature. Consequently, the range of pressure that can be measured (via current change) is extended to atmospheric pressure (see Figure 26.20). Orientation of the sensor is with the axis vertical.

The use of convection gages with process control electronics allows for automatic pump-down with the assurance that the system will neither open under vacuum nor be subject to over-pressure during backfill to atmospheric pressure. These gages, with their controllers, are relatively inexpensive. In oil-free systems, they afford long life and reproducible results.

Hot Cathode Ionization Gages

Hot cathode ionization gage designs consist of triode gages, Bayard-Alpert gages, and others.

Triode Hot Cathode Ionization Gages.

For over 80 years, the triode electron tube has been used as an indirect way to measure vacuum [15, 16]. A typical triode connection is as an amplifier, as is shown in Figure 26.21. A brief description of its operation is given here, but more rigorous treatment of triode performance is given in [17–20]. However, if the triode is connected as in Figure 26.22 so that the grid is positive and the plate is negative with respect to the filament, then the ion current collected by the plate for the same electron current to the grid is greatly increased [21].

Today, the triode gage is used in this higher sensitivity mode. Many investigators have shown that a linear change in molecular density (pressure) results in a linear change in ion current [15, 21, 22]. This linearity allows a sensitivity factor S to be defined such that:

$$I_i = S \times I_e \times P \quad (26.3)$$

where I_i = Ion current (A)

I_e = Electron current (A)

P = Pressure

S = Sensitivity (in units of reciprocal pressure)

FIGURE 26.23 Bayard–Alpert hot cathode ionization gage.

Additional details are found in [23–25]. In nearly all cases, except at relatively high pressures, the triode gage has been replaced by the Bayard–Alpert gage.

Bayard–Alpert Hot Cathode Ionization Gages.

It became apparent that the pressure barrier observed at 10^{-8} torr was caused by a failure in measurement rather than pumping [26, 27]. A solution to this problem was proposed by Bayard and Alpert [28] that is now the most widely used gage for general UHV measurement.

The Bayard–Alpert gage is similar to a triode gage but has been redesigned so that only a small quantity of the internally generated X-rays strike the collector. The primary features of the Bayard–Alpert gage and its associated circuit are shown in Figures 26.23 and 26.24. The cathode has been replaced by a thin collector located at the center of the grid, and the cathode filament is now outside and several millimeters away from the grid. The Bayard–Alpert design utilizes the same controller as the triode gage, with

FIGURE 26.24 Bayard–Alpert gage configuration.

corrections for sensitivity differences between the gage designs. When a hot filament gage is exposed to high pressures, burn-out of the tungsten filaments often occurs. To prevent this, platinum metals were coated with refractory oxides to allow the gage to withstand sudden exposure to atmosphere with the filament hot [29, 30]. Typical materials include either thoria or yttria coatings on iridium. Bayard–Alpert and triode gages of identical structure and dimensions but with different filaments (i.e., tungsten vs. thoria iridium) were observed to have different sensitivities, with the tungsten filament versions being 20% to 40% more sensitive than the iridium of the same construction.

The lowest pressure that can be measured is limited by low energy X-rays striking the ion collector and emitting electrons. Several methods to reduce this X-ray limit were developed. Gage designs with very small diameter collectors have been made that extend the high vacuum range down to 10^{-12} torr, but accuracy was lost at the high pressures [31, 32].

The modulated gage was designed by Redhead [33] with an extra electrode near the ion collector. In this configuration, the X-ray current could be subtracted by measuring the ion current at two modulator potentials, thus increasing the range to 5×10^{-12} . Other gages use suppressor electrodes in front of the ion collector [34, 35].

The extractor gage (Figure 26.25) is the most widely used UHV hot cathode gage for those who need to measure 10^{-12} torr [36]. In this gage, the ions are extracted out of the ionizing volume and deflected or focused onto a small collector. More recent designs have been developed [37, 38]. The use of a channel electron multiplier [39] has reduced the low pressure limit to 10^{-15} torr.

The Bayard–Alpert gage suffers from some problems, however. The ion current is geometry dependent. Investigators have reported on the sensitivity variations, inaccuracy, and instability of Bayard–Alpert gages with widely differing results [40–46, 49, 50, 56]. Investigators have developed ways to reduce or eliminate some of these problems [47, 48].

Cold Cathode Ionization Gages

To measure pressures below 10^{-3} torr, Penning [51] developed the cold cathode discharge gage. Below 10^{-3} torr, the mean free path is so high that little ionization takes place. The probability of ionization was increased by placing a magnetic field parallel to the paths of ions and electrons to force these particles into helical trajectory.

This gage consists of two parallel cathodes and an anode, which is placed midway between them (see Figure 26.26). The anode is a circular or rectangular loop of metal wire whose plane is parallel to that of the cathodes. A few kilovolts potential difference is maintained between the anode and the cathodes.

FIGURE 26.27 Double inverted magnetron. (Reprinted with permission from Televac Division, The Fredericks Co., Huntingdon Valley, PA.)

Furthermore, a magnetic field is applied between the cathodes by a permanent magnet usually external to the gage body. Electrons emitted from either of the two cathodes must travel in helical paths due to the magnetic field eventually reaching the anode, which carries a high positive charge. During the travel along this long path, many electrons collide with the molecules of the gas, thus creating positive ions that travel more directly to the cathodes. The ionization current thus produced is read out on a sensitive current meter as pressure.

This is a rugged gage used for industrial applications such as in leak detectors, vacuum furnaces, electron beam welders, and other industrial processes. The Penning gage is rugged, simple, and inexpensive. Its range is typically 10^{-3} torr to 10^{-6} torr, and some instability and lack of accuracy has been observed [52]. The magnetron design [53] and the inverted magnetron design [54] extended the low pressure range to 10^{-12} Torr [55] or better. These improvements produced a better gage but instability, hysteresis, and starting problems remain [57, 58]. Magnetrons currently in use are simpler and do not use an auxiliary cathode.

More recently, a double inverted magnetron was introduced [59]. This gage has greater sensitivity (amp/torr) than the other types (see [Figure 26.27](#)). It has been operated successfully at $\sim 1 \times 10^{-11}$ torr. The gage consists of two axially magnetized, annular-shaped magnets (1) placed around a cylinder (2) so that the north pole of one magnet faces the north pole of the other one. A nonmagnetic spacer (3) is placed between the two magnets and thin shims (4) are used to focus the magnetic fields. This gage has been operated to date at 10^{-11} torr, and stays ignited and reignites quickly when power is restored at this pressure. Essentially instantaneous reignition has been demonstrated by use of radioactive triggering [60].

Resonance Gages

One example of a resonance-type vacuum gage is the quartz friction vacuum gage [61]. A quartz oscillator can be built to measure pressure by a shift in resonance frequency caused by static pressure of the surrounding gas or by the increased power required to maintain a constant amplitude. Its range is from near atmospheric pressure to about 0.1 torr. A second method is to measure the resonant electrical impedance of a tuning fork oscillator. Test results for this device show an accuracy within $\pm 10\%$ for pressure from 10^{-3} torr to 10^3 torr. There is little commercial use to date for these devices.

Molecular Drag (Spinning Rotor) Gages

Meyer [62] and Maxwell [63] introduced the idea of measuring pressure by means of the molecular drag of rotating devices in 1875. The rotors of these devices were tethered to a wire or thin filament. The gage was further enhanced by Holmes [64], who introduced the concept of the magnetic rotor suspension, leading to the spinning rotor gage. Nearly 10 years later, Beams et al. [65] disclosed the use of a magnetically levitated, rotating steel ball to measure pressure at high vacuum. Fremerey [66] reported on the historical development of this gage.

The molecular drag gage (MDG), often referred to as the spinning rotor gage, received wider acceptance after its commercial introduction in 1982 [67]. It is claimed to be more stable than other gages at lower pressures [68].

The principle of operation of the modern MDG is based on the fact that the rate of change of the angular velocity of a freely spinning ball is proportional to the gas pressure and inversely proportional to the mean molecular velocity. When the driving force is removed, the angular velocity is determined by measuring the ac voltage induced in the pickup coils by the magnetic moment of the ball (see Figure 26.28).

In current practice, a small rotor (steel ball bearing) about 4.5 mm in diameter is magnetically levitated and spun up to about 400 Hz by induction. The ball, enclosed in a thimble connected to the vacuum system, is allowed to coast by turning off the inductive drive. Then, the time of a revolution of the ball is measured by timing the signal induced in a set of pickup coils by the rotational component of the ball's magnetic moment. Gas molecules will exert a drag on the ball, slowing it at a rate set by the pressure P , its molecular mass m , temperature T , and the coefficient of momentum transfer σ , between the gas and the ball. A perfectly smooth ball would have a value of unity. There is also a pressure-independent residual drag (RD) caused by eddy current losses in the ball and surrounding structure. There will also be temperature effects that will cause the ball diameter and moment of inertia to change.

The pressure in the region of molecular flow is given by:

$$P = \frac{\pi \rho a \bar{c}}{10 \sigma_{\text{eff}}} \left(\frac{-\omega' - \text{RD} - 2 \alpha T'}{\omega} \right) \quad (26.4)$$

Note: Some sources include the term $\frac{(8kT')}{(\pi m)}$

- where ρ = Density of the rotor
- a = Radius of the rotor
- ω'/ω = Fractional rate of slowing of the rotor
- \bar{c} = Mean gas molecular velocity
- α = Linear coefficient of expansion of the ball
- T' = Rate of change of the ball's temperature

All of the terms in the first part of the equation can be readily determined except for the accommodation coefficient σ , which depends on the surface of the ball and the molecular adhesion between the gas and the surface of the ball. The accommodation coefficient σ must be determined by calibration of the MDG against a known pressure standard or, if repeatability is more important than the highest accuracy, by assuming a value of 1 for σ . Measurements of σ on many balls over several years have been repeatedly performed by Dittman et al. [68]. The values obtained ranged from 0.97 to 1.06 for 68 visually smooth balls, so using a value of 1 for σ would not introduce a large error and would allow the MDG to be considered a primary standard (Fremerey [66]).

The controller [68] contains the electronics to power and regulate the suspension and drive, detect and amplify the signal from the pickup coils, and then time the rotation of the ball. It also contains a data processor that stores the calibration data and computes the pressure.

FIGURE 26.28 Molecular drag gage (spinning rotor).

The MDG is perhaps the best available transfer standard for the pressure range of 10^{-2} torr to 10^{-7} torr (1 Pa to 10^{-5} Pa) because it is designed for laboratory use in controlled, relatively vibration-free environments [69, 70].

Partial Pressure Measurements and Mass Spectrometers

The theory and practical applications of partial pressure measurements and mass spectrometers are discussed in detail in the literature [76]; however, an overview is presented herein [78].

A simple device for measuring the partial pressure of nitrogen as well as the total pressure in a vacuum system is the residual nitrogen analyzer (RNA). Operating in high vacuum, it is used to detect leaks in a vacuum system. It is effective because various gases are pumped at different rates and nitrogen is readily pumped, leaving a much lower percentage than is present at atmospheric pressure. Thus, the presence of a significant percentage of nitrogen at high vacuum indicates an air leak. The RNA consists of a cold cathode gage with an optical filter and a photomultiplier tube. Since ionization in the cold cathode tube produces light and the color is determined by the gases present, the RNA filters out all except for that corresponding to nitrogen and is calibrated to give the partial pressure of nitrogen.

A more complex device to measure the partial pressure of many gases in a vacuum chamber is the mass spectrometer-type residual gas analyzer (RGA). This device comes in many forms and several sizes. The quadrupole mass spectrometer is shown in Figure 26.29. The sensing head consists of an ion source, a quadrupole mass filter, and a Faraday cup collector. The quadrupole mass filter consists of two pairs of parallel rods having equal and opposite RF and dc voltages. For each combination of voltages, only ions of a specific mass will pass through the filter. The mass filter is tuned to pass only ions of a specific mass-to-charge ratio at a given time. As the tuning is changed to represent increasing mass numbers, a display such as Figure 26.30 is produced, showing the relative intensity of the signal vs. the mass number. This display can then be compared electronically with similar displays for known gases to determine the composition of the gases in the vacuum chamber. The head can operate only at high vacuum. However,

by maintaining the head at high vacuum and using a sampling technique, the partial pressures of gases at higher pressures can be determined.

Calibration of mass spectrometers can be accomplished by equating the integral (the total area under all the peaks, taking into account the scale factors) to the overall pressure as measured by another gage (cold cathode, BA, or MDG). Once calibrated, the mass spectrometer can be used as a sensitive monitor of system pressure. It is also important when monitoring system pressure to know what gases are present. Most gages have vastly different sensitivities to different gas species.

Additional references on the details of the MDG and other types of gages available and on calibration are found in the literature [69–73, 75, 76]. The material in this chapter was summarized from an article on the fundamentals of vacuum measurement, calibration, and certification [77] from the authors' contribution to *The Handbook of Vacuum Technology* [76] and from other referenced sources.

26.3 Ultrasound Measurement

Peder C. Pedersen

Applications of Ultrasound

Medical

Ultrasound has a broad range of applications in medicine, where it is referred to as *medical ultrasound*. It is widely used in obstetrics to follow the development of the fetus during pregnancy, in cardiology where images can display the dynamics of blood flow and the motion of tissue structures (referred to as real-time imaging), and for locating tumors and cysts. 3-D imaging, surgical applications, imaging from within arteries (intravascular ultrasound), and contrast imaging are among the newer developments.

Industrial

In industry, ultrasound is utilized for examining critical structures, such as pipes and aircraft fuselages, for cracks and fatigue. Manufactured parts can likewise be examined for voids, flaws, and inclusions. Ultrasound has also widespread use in process control. The applications are collectively called *Non-Destructive Testing* (NDT) or *Non-Destructive Evaluation* (NDE). In addition, *acoustic microscopy* refers to microscopic examinations of internal structures that cannot be studied with a light microscope, such as an integrated circuit or biological tissue.

Underwater

Ultrasound is likewise an important tool for locating structures in the ocean, such as wrecks, mines, submarines, or schools of fish; the term SONAR (SOund Navigation And Ranging) is applied to these applications.

There are many other usages of ultrasound that lie outside the scope of this handbook: ultrasound welding, ultrasound cleaning, ultrasound hyperthermia, and ultrasound destruction of kidney stones (lithotripsy).

Definition of Basic Ultrasound Parameters

Ultrasound refers to acoustic waves of frequencies higher than 20,000 cycles per second (20 kHz), equal to the assumed upper limit for sound frequencies detectable by the human ear. As acoustic waves fundamentally are mechanical vibrations, a medium (e.g., water, air, or steel) is required for the waves to travel, or propagate, in. Hence, acoustic waves cannot exist in vacuum, such as outer space. If a single frequency sound wave is produced, also termed a *continuous wave* (CW), the fundamental relationship between frequency, f , in Hz, the sound speed of the medium, c_0 , in m s^{-1} , and the wavelength, λ , in meters, is given as:

$$\lambda = \frac{c_0}{f} \quad (26.5)$$

The wavelength λ describes the length, in the direction of propagation, of one period of the sound wave. The wavelength determines, or influences, the behavior of many acoustic functions: The sound field emitted from an acoustic radiator (e.g., a transducer or loudspeaker) is determined by the radiator's size measured in wavelengths; the ability to differentiate between closely spaced reflectors is a function of the separation measured in wavelengths. Even when a sound pulse, rather than a CW sound, is transmitted, the wavelength concept is still useful, as the pulse typically contains a dominant frequency.

The vibrational activity on the surface of the sound source transfers the acoustic energy into the medium. If one were able to observe a very small volume, referred to as a *particle*, of the medium during transmission of sound energy, one would see the particle moving back and forth around a fixed position. Associated with the particle motion is an acoustic pressure, which refers to the pressure variation around the mean pressure (which is typically the atmospheric pressure). This allows the introduction of two important — and closely related — acoustic quantities: the *particle velocity*, $\vec{u}(\vec{r}, t)$, and the *acoustic pressure*, $p(\vec{r}, t)$. In this notation, the arrow above a symbol in bold indicates a vector. The symbol \vec{r} represents the position vector, which simply defines a specific location in space. Thus, both particle velocity and pressure are functions of three spatial variables, x , y , and z , and the time variable, t .

To characterize a medium acoustically, the most important parameter is the *specific acoustic impedance*, z . For a lossless medium, z is given as follows:

$$z = \rho_0 c_0 \quad (26.6)$$

In Equation 26.6, ρ_0 is the density of the medium, measured in kg m^{-3} . When a medium absorbs acoustic energy (which all media do to a greater or smaller extent), the expression for acoustic impedance also contains a small imaginary term; this will be ignored in the discussions presented in this chapter. The acoustic impedance relates the particle velocity to the acoustic pressure:

$$z = \frac{p(\vec{r}, t)}{u(\vec{r}, t)} \quad (26.7)$$

Note that the relationship in Equation 26.7 uses the scalar value of the particle velocity (a scalar is a quantity, such as temperature, that does not have a direction associated with it). Equation 26.7 is exact for plane wave fields and a very good approximation for arbitrary acoustic fields. In a plane wave, all points in a plane normal to (i.e., which forms a 90° angle with respect to) the direction of propagation have the same pressure and particle velocity.

The acoustic impedances on either side of an interface (boundary between different media) determine the acoustic pressure reflected from the interface. Let a plane wave traveling in a medium with the acoustic impedance z_1 encounter a planar, smooth interface with another medium having the acoustic impedance z_2 . Assume that the plane wave propagates directly toward the interface; this is commonly referred to as insonification under normal incidence. In this case, the pressure and the intensity reflection coefficients, R and R_I , respectively, are as follows:

$$R = \frac{p_r}{p_i} = \frac{z_2 - z_1}{z_2 + z_1} \quad (26.8)$$

$$R_I = \frac{I_r}{I_i} = \left(\frac{z_2 - z_1}{z_2 + z_1} \right)^2$$

Intensity is a measure of the mean power transmitted through unit area and is measured in watts per square meter. The corresponding pressure and intensity transmission coefficients, T and T_I , respectively, are:

$$T = \frac{p_t}{p_i} = \frac{2z_2}{z_2 + z_1} \quad (26.9)$$

$$T_I = \frac{I_t}{I_i} = \frac{4z_1z_2}{(z_2 + z_1)^2}$$

The subscripts “i,” “r,” and “t” in Equations 26.8 and 26.9 refer to incident, reflected, and transmitted, respectively. The expressions in these two equations can be considered approximately valid for nonplanar waves under near-normal incidence. However, when the incident angle (angle between direction of propagation and the normal to the surface) becomes large, the reflection and transmission coefficients can change dramatically. In addition, the reflected and transmitted signals will also change if the surface is rough to the extent that the rms (root mean square) height exceeds a few percent of the wavelength.

The wave propagation can take several forms. In fluids and gases, only *longitudinal* (or *compressional*) waves exist, meaning that the direction of wave propagation is equal to the direction of the particle velocity vector. In solids, both longitudinal and *shear* waves exist which propagate in different directions and with different sound speeds. Transverse waves can exist on strings where the particle motion is normal to the direction of propagation. (Strictly speaking, shear waves can propagate a short distance in liquids [fluids] if the viscosity is sufficiently high.)

Conceptual Description of Ultrasound Imaging and Measurements

Most ultrasound measurements are based on the generation of a short ultrasound pulse that propagates in a specified direction and is partly reflected wherever there is an abrupt change in the acoustic properties of the medium and detection of the resulting echoes (pulse-echo ultrasound). A change in properties can be due to a cyst in liver tissue, a crack in a high-pressure pipe, or reflection from layers in the sea bottom. The degree to which a pulse is reflected at an interface is determined by the change in acoustic impedance as described in Equation 26.8. An image is formed by mapping echo strength vs. travel time (proportional to distance) and beam direction, as illustrated in [Figure 26.31](#). This is referred to as *B-mode* imaging (Brightness-mode). Further signal processing can be applied to compensate for attenuation (the damping out of the pressure pulse as it propagates) of the medium or to control focusing. Signal processing can also be applied to analyze echoes for information about the structure of materials or about the surface characteristics of rough surfaces.

A block diagram of a simplified pulse-echo ultrasound measurement system is shown in [Figure 26.32](#). The pulser circuit can generate a large voltage spike for exciting the transducer in B-mode applications, or the arbitrary function source can produce a short burst for Doppler measurements, or a coded waveform, such as a linear sweep. The amplifier brings the driving voltage to a level where the transducer can generate an adequate amount of acoustic energy.

The transducer is made from a piezoelectric ceramic that has the property of producing mechanical vibrations in response to an applied voltage pulse and generating a voltage when subjected to mechanical stress. When an image is required, the transducer can be a mechanical sector probe that produces a fan-shaped image by means of a single, mechanically steered, focused transducer element. Alternatively, the transducer can be a linear array transducer (described later) that produces a rectangular image. In the case of an array transducer, the pulser/amplifier must contain a driving circuit for each element in the array, in addition to delay control. To achieve a short pulse and good sensitivity, the transducer is equipped with backing material and matching layers (to be discussed later).

The receiver block contains a low-noise amplifier with time-varying gain to correct for medium attenuation and often a circuit for logarithmic compression. In the case of array transducers, the receiver circuitry is a complex system of amplifiers, time-varying delay elements, and summing circuits. The signal processing block can be part analog and part digital. The echo signals are envelope detected and digitized; the *envelope* of a signal is a curve that follows the amplitude of the received signal. A scan converter changes the signal into a format suitable for display on a gray-scale monitor. Information about ultrasound pulser-receiver instrumentation for NDE measurements can be found in [1] and for medical imaging in [2].

Not all ultrasound measurement systems are based on the pulse-echo concept. For material characterization, *transmission measurements* are frequently used, as illustrated in [Figure 26.33](#). The main difference between the pulse-echo system and the transmission system is that two transducers are used in the transmission system; the description of the individual blocks for the pulse-echo system applies generally here also. Imaging is generally not possible, although tomographic imaging of either attenuation

FIGURE 26.31 (a) A focused transducer insonifies the irregular object from different positions out of which only three are shown. The different transducer positions can readily be obtained by the use of an array transducer (to be described later). (b) Received echoes from the front and back of the object are displayed vs. travel time. It is here assumed that the structure is only weakly reflecting and that the attenuation has only a minimal effect. (c) An image is formed, based on the echo strengths and the echo arrival times.

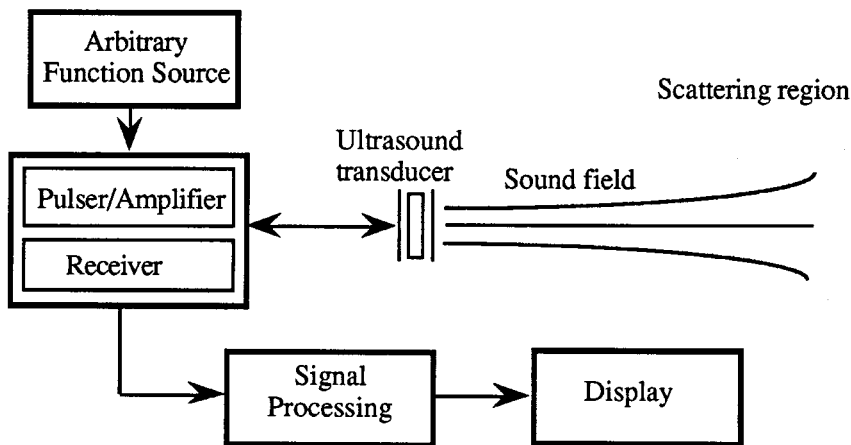

FIGURE 26.32 Simplified block diagram of a pulse-echo ultrasound system.

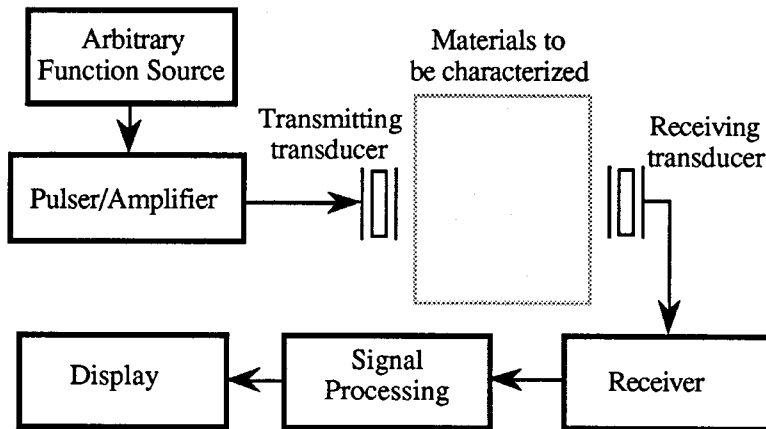

FIGURE 26.33 Simplified block diagram of ultrasound transmission system.

or velocity has been attempted. If the two transducers are moved together, voids and inclusions located in the transmission path can be detected.

Transmission measurements require, of course, that the structure or the medium of interest is accessible from opposite sides. This system allows accurate characterization of the attenuation and the sound speed of the medium from which a variety of material properties can be derived. Flow in a pipe or a channel can also be determined with a transmission system, by determining the difference between upstream and downstream propagation times.

Single-Element and Array Transducers

The device that converts electric energy into acoustic energy and vice versa is termed the *transducer* or, more specifically, the ultrasound transducer. Piezoelectric ceramics can be used for all frequencies in the ultrasound range; however, for ultrasound frequencies in the 20 kHz to 200 kHz range, magnetostrictive devices are occasionally used, which are based on materials that exhibit mechanical deformation in response to an applied magnetic field. Ultrasound transducers are commercially available for many applications over a wide range of frequencies.

Single-element transducers are used for basic measurements and material characterization, while array transducers with many individual transducer elements are used for imaging purposes. The former type costs from a few hundreds dollars and up, whereas the latter type costs in the thousands of dollars and requires extensive electronics for beam control and signal processing. A third alternative is the mechanical sector scanner where a single transducer is mechanically rotated over a specified angle. A single-element transducer consists of a piezoelectric element, a backing material that enables the transducer to respond to a fairly wide range of frequencies (but with reduced sensitivity), and a matching layer and faceplate that provide improved coupling into the medium and protect the transducer.

Although broadband transducers are very desirable, the energy conversion characteristics of the practical transducer correspond to that of a bandpass filter, i.e., the ultrasound pulse has most of its energy distributed around one frequency. This is the frequency referred to when, for example, one orders a 3.5 MHz transducer. The 6 dB bandwidth can be from 50% to 100% of the transducer frequency; the 6 dB bandwidth is the frequency range over which the transducer can produce an acoustic pressure that is at least 50% of the acoustic pressure at the most efficient frequency. The radiation characteristics of a transducer are determined by the geometry of the transducer (square, circular, plane, focused, etc.) and by the dimensions measured in wavelengths. Hence, a 10 MHz transducer tends to be smaller than a 5 MHz transducer. Focusing can also be achieved by means of an acoustic lens.

Array transducers exist in three main categories: phased arrays, linear arrays, and annular arrays. A fourth category could exist commercially in a few years: the 2-D array or a sparse 2-D array. Common for these array transducers is the fact that *during transmission*, the excitation time and excitation signal amplitude for each transducer element are controlled independently. This allows the beam to be steered in a given direction, as well as focused at a given point in space. *During reception*, an independently controlled time delay — which may be time varying — can be applied to each element before summation with the signal from other elements. The delay control permits the transducer to have maximal sensitivity to an echo from a specified range, and, moreover, to shift this point in space away from the transducer as echoes from structures further away are received. A limitation of the phased and linear arrays is that beam steering and focusing can only take place within the image plane. In the direction normal to the image plane, a fixed focus is produced by the physical shape of the array elements.

The phased array transducer consists of a fairly small number of elements, such as 16 to 32. Both beam steering and focusing are carried out, producing a pie-shaped image. The phased array is most suitable when only a narrow observation window exists, as is the case when imaging the heart from the space between the ribs. The linear array transducer has far more elements, typically between 128 and 256. It activates only a subset of all the elements for a given measurement, and produces focusing, but generally not beam steering, so that the beam direction is normal to the array surface. Consider a linear array transducer with 128 elements, labeled 1 to 128. If one assumes that the first pulse-echo measurement is made with elements 1 to 16, the next measurement with elements 2 to 17, etc., the beam will have been *linearly* translated along the long dimension of the linear array (hence the name), producing a rectangular image format. The annular array transducer consists of a series of concentric rings. As such, it cannot steer the beam, but can focus both in transmit and receive mode, just as the phased and linear arrays. Thus, the annular array transducer is not suitable for imaging unless the transducer is moved mechanically. Its specific advantage is uniform focusing.

Selection Criteria for Ultrasound Frequencies

The discussion so far has often mentioned *frequency* as an important variable, without providing any guidance as to what ultrasound frequencies should be used. There is generally no technological limitation with respect to choice of ultrasound frequency, as frequencies even in the gigahertz (GHz, 10^9 Hz) range can be produced. The higher the frequency, the better is the control over the direction and the width of the ultrasound beam, leading to improved axial and lateral resolution. However, the attenuation increases with higher frequency. For many media, the attenuation varies with the frequency squared; while for biological soft tissue, the attenuation varies nearly linearly with frequency.

Generally, the ultrasound frequency is chosen as high as possible while still allowing a satisfactory signal-to-noise ratio (SNR) of the received signal. This rule does not always hold; for example, for grain size estimation in metals and for rough surface characterization, the optimal frequency has a specific relationship to the mean grain dimension or the rms roughness.

Basic Parameters in Ultrasound Measurements

Ultrasound technology today has led to a very wide range of applications, and the following overview mentions only the basic parameters. For an in-depth review, see [3]. A discussion of applications is given at the end of the Ultrasound Theory and Applications section.

Reflection (or Transmission) Detected or Not

The most basic measurement consists of determining whether a reflected or transmitted signal is received or not. This can be used to monitor liquid level where the absence of liquid prevents ultrasound transmission from taking place, or to detect the existence of bubbles in a liquid (e.g., for dialysis purposes, where the bubbles are the reflectors) or for counting objects, such as bottles, on a conveyer belt.

Travel Time

Travel time is the elapsed time from transmission of an ultrasound pulse to the detection of a received pulse in either a pulse-echo or a transmission system. If the sound speed is known, the thickness of an object can be found from the time difference between the front surface echo and the back surface echo. Conversely, sound speed can be determined when the thickness is known. By measuring with a broadband pulse (a short pulse containing a broad range of frequencies), velocity dispersion (frequency dependence of velocity) can be found, which has applications for materials characterization. Elastic parameters can also be found from velocity measurements. Imaging applications are generally made based on the assumption of a known, constant velocity; thus, round-trip travel times from the transducer to the reflecting structures and back in a known direction gives the basis for the image formation.

Attenuation

The attenuation and its frequency dependence are important materials parameters, as they can be used to differentiate between normal and pathological biological tissue, measure porosity of ceramics, the grain size of metals, and the structure of composite materials. Attenuation can be found by means of transmission measurements by determining the signal amplitude with the test object first absent and then present; here, transmission losses must also be considered, as quantified in Equation 26.9. Attenuation can be obtained from pulse-echo measurements, by comparing the strength of echoes from the front and back surfaces of the specimen under test. Diffraction effects (described later in the *Advanced Topics in Ultrasound* section) might need to be considered. Attenuation can be considered as a bulk parameter for the medium as a whole, or it can be determined for small regions of the medium.

Reflection Coefficient

The strength of a reflection at an interface between two media is determined by the change in acoustic impedance across the interface, as shown in Equation 26.8. This allows, at least in principle, the impedance of one medium to be determined from the measured reflection coefficient and the impedance of the other medium. In fact, the term *impediography* refers to the determination of the impedance profile of a layered medium by means of this concept. In practice, the measurement is not easy to carry out, as the transducer must be aligned very accurately at normal incidence to the medium surface. By measuring the reflection coefficient vs. incident angle at a planar, smooth surface, a velocity estimate of the reflecting medium can be made; in an alternative application, reflection measurements vs. frequency permit the evaluation of rough surface parameters.

Parameters Obtained Through Signal Processing

A number of object parameters can be obtained from analysis of the received signals. Material properties can be extracted from speckle analysis (analysis of statistical fluctuations in the image) and other forms of statistical analysis. Recognition of objects with complex shapes can, in some cases, be done by extracting specific features of the received signals. Doppler processing for velocity estimation is another example of information that is only attainable by means of signal processing. By combining several “stacked” images, 3-D reconstruction is possible, from which volume estimation and rate of change of volume are possible, such as for determining the dynamics of the left ventricle of the heart.

Ultrasound Theory and Applications

Sound Velocity

The propagation speed, c_0 , is generally determined by the density and the elastic properties of the medium. For an ideal gas, c_0 may be expressed as [4]:

$$c_0 = \sqrt{\gamma P_0 / \rho_0} = \sqrt{\gamma r T_K} \quad (26.10)$$

where $\gamma = C_p/C_v$, the ratio of specific heats; for air, $\gamma = 1.402$. P_0 is the static pressure of the gas, which at 1 atm is $1.013 \times 10^5 \text{ N m}^{-2}$. ρ_0 is the specific density of the gas, equal to 1.293 kg m^{-3} for air at 1 atm and 0°C . The constant r is the ratio of the universal gas constant and the molecular weight of the gas, and T_K is the temperature in kelvin. Substituting the values for air into the first equation in Equation 26.10 gives $c_0 = 331.6 \text{ m s}^{-1}$ at 0°C . As the ratio P_0/ρ_0 is constant for varying pressure, but constant temperature, c_0 is likewise pressure independent. (For a real gas, c_0 exhibits, in fact, a small dependence on pressure.)

The temperature dependence of an ideal gas can be obtained by rewriting the second expression in Equation 26.10 as follows

$$c_0 = c_{\text{ref}} \sqrt{1 + T/273} \quad (26.11)$$

where c_{ref} is the sound speed at 0°C , and T is the temperature in $^\circ\text{C}$.

In liquids, the expression for c_0 is given as

$$c_0 = \sqrt{K_s/\rho_0} \quad (26.12)$$

where K_s is the adiabatic bulk modulus. Expressions for actual liquids as a function of temperature and pressure are not easily derived, and are often empirically determined. For pure water, the sound speed as a function of temperature and pressure can be given as:

$$c_{\text{H}_2\text{O}} = 1402.4 + 5.01T - 0.055T^2 + 0.00022T^3 + 1.6 \times 10^{-6} P_0 \quad (26.13)$$

In Equation 26.13, T is temperature in $^\circ\text{C}$, and P_0 is the static pressure in N m^{-2} ; the expression is valid for a pressure range from 1 atm to 100 atm.

Finally, for solids, the sound speed for longitudinal waves, c_L , is [5]:

$$c_L = \left(\frac{c_{11}}{\rho_0} \right)^{1/2} = \left(\frac{\lambda + 2\mu}{\rho_0} \right)^{1/2} \quad (26.14)$$

In Equation 26.14, c_{ij} is the the elastic stiffness constant, such that c_{11} refers to longitudinal stress over longitudinal strain, and $\lambda = c_{12}$ and $\mu = c_{44}$ are the Lamé elastic constants.

Wave Propagation in Homogeneous Media

In order to effectively use ultrasound for measurement purposes, it is essential to be able to describe the behavior of acoustic fields. This includes the general behavior, and maybe even a detailed understanding, of the radiated field from ultrasound transducers; the transmission, reflection, and refraction of an acoustic field at boundaries and layers; and the diffraction of of acoustic field at finite-sized reflectors.

The wave equation is a differential equation that formulates how an acoustic disturbance (acoustic pressure or particle velocity) propagates through a homogeneous medium. For an arbitrary wave field, the wave equation takes the following general form:

$$\nabla^2 p = \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} \quad (26.15)$$

where ∇^2 is the Laplacian operator. Equation 26.15 is also valid when particle velocity is substituted for pressure. If the condition of a plane wave field at a single frequency (also called a harmonic plane wave field) is imposed, the solution to Equation 26.15 is:

$$p(\vec{r}, t) = A \exp\left[j(\omega t - \vec{k} \times \vec{r})\right] + B \exp\left[j(\omega t + \vec{k} \times \vec{r})\right] \quad (26.16)$$

In Equation 26.16, $p(\vec{r}, t)$ consists of a plane wave propagating in the direction defined by the propagation vector \vec{k} and a plane wave in the direction $-\vec{k}$. As before, \vec{r} is a position vector that, in a Cartesian coordinate system, can be expressed as $\vec{r} = x\hat{x} + y\hat{y} + z\hat{z}$ where \hat{x} , \hat{y} , and \hat{z} are unit vectors. The magnitude of \vec{k} is called the wavenumber:

$$k = \omega/c_0 = 2\pi/\lambda \quad (26.17)$$

Expressing \vec{k} in the Cartesian coordinate system gives:

$$\vec{k} = k_x\hat{x} + k_y\hat{y} + k_z\hat{z} \quad (26.18)$$

When k , k_x , and k_y are specified, k_z is defined as well:

$$k_z = \sqrt{\left(\left(\omega/c_0\right)^2 - k_x^2 - k_y^2\right)} \quad (26.19)$$

Applying the expressions for \vec{r} and \vec{k} to Equation 26.16 and considering only the plane wave in the direction of $+\vec{k}$ gives

$$p(\vec{r}, t) = A \exp\left[j\left(\omega t - (k_x x + k_y y + k_z z)\right)\right] \quad (26.20)$$

From Equation 26.20, one sees that the amplitude of a plane wave is constant and equal to A , but that the phase varies with both time and space. When the direction of \vec{k} is specified, k_x , k_y , and k_z are found from projection onto the coordinate axes.

Solving Equation 26.15 under the assumption of spherical waves at a single frequency, with the source placed at the origin of the coordinate system, gives:

$$p(r, t) = \frac{A}{r} \exp\left[j(\omega t - kr)\right] + \frac{B}{r} \exp\left[j(\omega t + kr)\right] \quad (26.21)$$

The first term is a diverging spherical wave, and the second term is a converging spherical wave. The reason that the vector dot product does not appear in Equation 26.21 is that \vec{k} and \vec{r} always point in the same direction for spherical waves. While Equation 26.21 gives the complete solution, in most cases only a diverging spherical wave exists. If spherical waves are produced by a spherical source of radius a , then:

$$p(r, t) = \frac{A}{r} \exp\left[j(\omega t - kr)\right], \quad r > a \quad (26.22)$$

Acoustic Intensity and Sound Levels

The acoustic intensity, I , describes the mean power transported through a unit area normal to the direction of propagation. A general expression for I for a CW pressure function is:

$$I = \frac{1}{T} \int_0^T p(t)u(t)dt \quad (26.23)$$

In Equation 26.23, T represents one full cycle of the pressure function, and $u(t)$ is the particle velocity function. For a plane wave, the intensity is:

$$I = \frac{P^2}{2\rho_0 c_0} = \frac{1}{2}PU \quad (26.24)$$

where P and U are the magnitudes of the pressure and the particle velocity functions, respectively. The expression for I in Equation 26.24 can also be used as an approximation for nonplanar waves, such as spherical waves, as long as (kr) is large.

The intensity levels for pulse-echo measurements are often described by the SPTA (*Spatial Peak, Temporal Average*) value, which therefore refers to the mean intensity at the point in space where the intensity is the highest. Although the guidelines for exposure levels for medical imaging, set by the FDA, vary for different parts of the body, a general upper limit is 100 mW cm^{-2} . Given that the duty cycle (pulse duration/pulse interval) is typically in the order of 0.0001 for ultrasound imaging, the temporal peak intensity is much higher, and is even approaching the level where nonlinear effects can begin to be observed. Intensity levels used for NDE are application dependent, but are generally in the same range as in medical ultrasound.

Sound levels are logarithmic expressions (expressions in dB) of the pressure level or the intensity level. The term SPL stands for sound pressure level and is given as:

$$\text{SPL} = 20 \log \left(\frac{P_e}{P_{\text{ref}}} \right) \quad [\text{dB}] \quad (26.25)$$

In Equation 26.25, P_e is the effective pressure of the acoustic wave and P_{ref} is the reference effective pressure. Correspondingly, IL is the intensity level defined as:

$$\text{IL} = 10 \log \left(\frac{I}{I_{\text{ref}}} \right) \quad [\text{dB}] \quad (26.26)$$

where I_{ref} is the reference acoustic intensity.

Several reference levels are commonly used [6]. In air, $P_{\text{ref}} = 20 \text{ }\mu\text{Pa}$ and $I_{\text{ref}} = 10^{-12} \text{ W m}^{-2}$ are nearly equivalent reference levels. For water, typical pressure reference levels are $P_{\text{ref}} = 1 \text{ }\mu\text{Pa}$, $P_{\text{ref}} = 20 \text{ }\mu\text{Pa}$ or $P_{\text{ref}} = 1 \text{ }\mu\text{bar} = 0.1 \text{ Pa}$, with corresponding intensity reference levels of $I_{\text{ref}} = 6.76 \times 10^{-19} \text{ W m}^{-2}$, $I_{\text{ref}} = 2.70 \times 10^{-16} \text{ W m}^{-2}$, and $I_{\text{ref}} = 6.76 \times 10^{-9} \text{ W m}^{-2}$.

Wave Propagation Across Layers and Boundaries

The reflection and transmission coefficients for a plane wave impinging at normal incidence on the interface between two half spaces were given in Equations 26.8 and 26.9. It is also important to consider the transmission and reflection of waves at non-normal incidence and across a layer.

When a longitudinal wave impinges at a liquid–liquid interface, both the transmitted and the reflected waves are longitudinal waves, as illustrated in [Figure 26.34\(a\)](#). However, when a longitudinal wave propagating in a liquid medium encounters a liquid–solid interface under oblique incidence, both a longitudinal and a shear transmitted wave and a longitudinal reflected wave will result, as shown in [Figure 26.34\(b\)](#). The change of direction of the transmitted waves relative to the incident wave is referred to as *refraction*, which is caused by the difference in sound speed between the two media.

The magnitude and direction of the reflected and transmitted waves are determined by two simple boundary conditions: (1) the *pressure* on both sides of the boundary must be equal at all times, and (2) the *normal particle velocity* on both sides of the boundary must be equal at all times; the normal particle velocity refers to the component of the particle velocity that is normal to the boundary.

The boundary conditions lead to the following two relationships:

$$\sin \theta_i = \sin \theta_r ; \quad \frac{\sin \theta_i}{c_1} = \frac{\sin \theta_t}{c_2} \quad (26.27)$$

FIGURE 26.34 (a). An incident longitudinal wave at a liquid–liquid interface produces a reflected and a transmitted longitudinal wave. (b) An incident longitudinal wave at a liquid–solid interface produces a reflected longitudinal wave, transmitted longitudinal, and shear waves. The incident, reflected, and transmitted angles are indicated.

where c_1 and c_2 are the sound speeds of the two media, and θ_i , θ_r , and θ_t are the incident, reflected and transmitted angles, respectively. From Equation 26.27, one sees that

$$\theta_r = \theta_i; \quad \theta_t = \arcsin\left(\frac{c_2}{c_1} \sin\theta_i\right) \quad (26.28)$$

The second expression in Equation 26.28 is referred to as Snell’s law and quantifies the degree of refraction. Refraction affects the quality of ultrasound imaging because image formation is based on the assumption that the ultrasound beam travels in a straight path through all layers and inhomogeneities, and that the sound speed is constant throughout the medium. When the actual beam travels along a path that deviates to some extent from a straight path and passes through some parts of the medium faster than it does other parts, the resulting image is a distorted depiction of reality. Correcting this distortion is a very complex problem and, in the near future, one should only expect image improvement in the simplest cases.

It can be seen from Equation 26.28 that angle θ_t is not defined if the argument to the arcsin function exceeds unity. This defines a critical incident angle as follows:

$$\sin\theta_c = \frac{c_1}{c_2} \quad (26.29)$$

at or above which the reflection coefficient is 1 and the transmission coefficient is 0. A critical angle only exists when $c_1 < c_2$. The transmitted shear and longitudinal velocities each correspond to a different critical angle of incidence.

From the boundary conditions, the reflection coefficient as a function of incident angle can be determined [7]:

FIGURE 26.35 A pressure wave is incident on a layer of thickness L and with acoustic impedance $z_2 = \rho_2 c_2$.

$$R(\theta_i) = \frac{\left(\frac{z_2}{z_1}\right) - \left(\frac{\cos \theta_t}{\cos \theta_i}\right)}{\left(\frac{z_2}{z_1}\right) + \left(\frac{\cos \theta_t}{\cos \theta_i}\right)}, \text{ where } \cos \theta_t = \sqrt{1 - \left(\frac{c_2}{c_1}\right)^2 \sin^2 \theta_i} \quad (26.30)$$

The result in Equation 26.30 is referred to as the Rayleigh reflection coefficient.

The transmission of plane waves under normal incidence through a single layer is often of interest. The dimensions and the medium parameters are defined in Figure 26.35.

By applying the boundary conditions to both interfaces of the layer, both reflection and transmission coefficients are obtained [7], as given in Equations 26.31 and 26.32.

$$R = \frac{P_r}{P_i} = \frac{\left(1 - z_1/z_3\right) \cos k_2 L + j\left(z_2/z_3 - z_1/z_2\right) \sin k_2 L}{\left(1 + z_1/z_3\right) \cos k_2 L + j\left(z_2/z_3 + z_1/z_2\right) \sin k_2 L} \quad (26.31)$$

$$T = \frac{P_t}{P_i} = \frac{2}{\left(1 + z_1/z_3\right) \cos k_2 L + j\left(z_2/z_3 + z_1/z_2\right) \sin k_2 L} \quad (26.32)$$

A number of special conditions for Equation 26.31 can be considered, such as: (1) $z_1 = z_3$, which simplifies the numerator in Equation 26.31; and (2) the layer thickness is only a small fraction of a wavelength, that is, $k_2 L \ll 1$ which makes $\cos k_2 L \approx 1$ and $\sin k_2 L \approx k_2 L$. One case is of particular interest: the choice of thickness and acoustic impedance for the layer that makes $R = 0$, and therefore gives 100% energy transmission. This is fulfilled for:

$$k_2 L = \pi/2 + n\pi; \quad z_2 = \sqrt{z_1 z_3} \quad (26.33)$$

The result in Equation 26.33 states that the layer must be a quarter of a wavelength thick (plus an integer number of half wavelengths) and must have an acoustic impedance that is the geometric mean of the impedances of the media on either side. Among several applications of the *quarter wavelength impedance matching* is the impedance matching between a transducer and the medium, such as water. A drawback with a single matching layer is that it only works effectively over a narrow frequency range, while the

actual acoustic pulse contains a fairly broad spectrum of frequencies. A better matching is achieved by using more than one matching layer, and it has been shown that a matching layer that has a continuously varying acoustic impedance across the layer provides broadband impedance matching.

Attenuation: Its Origin, Measurement, and Applications

Attenuation refers to the damping of a signal, here specifically an acoustic signal, with travel time or with travel distance. Attenuation is typically expressed in dB, i.e., on a logarithmic scale. Attenuation is an important parameter to measure in many types of materials characterization, but also the parameter that sets an upper limit for the ultrasound frequency that can be used for a given measurement. In NDE, attenuation is used for grain size estimation [8, 9], for characterization of composite materials, and for determination of porosity [10]. In medical ultrasound, attenuation can be used for tissue characterization [11], such as differentiating between normal and cirrhotic liver tissue and for classification of malignancies. In flowmeters, attenuation caused by vortices can be used to measure the frequency at which they are shed; this frequency is proportional to the flow velocity.

Attenuation represents the combined effect of *absorption* and *scattering*, where absorption refers to the conversion of acoustic energy into heat due to the viscosity of the medium, and scattering refers to the spreading of acoustic energy into other directions due to inhomogeneities in the medium. The absorption can, in part, be due to *classical absorption*, which varies with frequency squared, and *relaxation absorption*, which can result in a complicated frequency dependence of absorption. Gases (except for noble gases), liquids, and biological tissue exhibit mainly relaxation absorption, whereas classical absorption is most prominent in solids, which can also have a significant amount of scattering attenuation.

In general, absorption dominates in homogeneous media (e.g., liquids, gases, fine-grained metals, polymers), whereas scattering dominates in heterogeneous media (e.g., composites, porous ceramics, large-grained materials, bone). The actual attenuation and its frequency dependence can be specified fairly unambiguously for gases and liquids, while for solids it is very dependent on the manufacturing process, which determines the microstructure of the material, such as the grain structure.

Measurement of attenuation can be carried out for at least two purposes: (1) to measure the *bulk attenuation* of a given homogeneous medium; and (2) to measure the *spatial distribution of attenuation* over a plane in an inhomogeneous medium. The former approach is most common in materials characterization, whereas the latter approach is found mainly in medical ultrasound. Bulk attenuation can be performed either with transmission measurements or with pulse-echo measurements, as illustrated in Figure 26.36(a) and (b), respectively.

For the measurement of attenuation, in dB/cm, of a medium of thickness d , by transmission measurements, define $v_1(t)$ as the received signal without medium present and $v_2(t)$ as the received signal with medium present, as shown in Figure 26.36(a). The attenuation is then determined from the ratio of the energies of the two signals, corrected for the transmission losses, as:

$$\text{Att [dB/cm]} = \frac{1}{d} 10 \log \left\{ \frac{\int_0^{\infty} [v_1(t)]^2 dt}{\int_0^{\infty} [v_2(t)]^2 dt} \right\} - 20 \log \left\{ \frac{4z_1 z_2}{(z_1 + z_2)^2} \right\} \quad (26.34)$$

Correction for transmission losses (2nd term) can be avoided by alternatively measuring the incremental attenuation due to an incremental thickness increase.

For the measurement of attenuation by *pulse-echo measurements*, the front and the back wall echoes are termed $v_f(t)$ and $v_b(t)$, respectively. Based on an *a priori* knowledge of the pulse duration, a time window ΔT is defined. The attenuation is most accurately measured when based on the energies of $v_f(t)$ and $v_b(t)$, but may alternatively be based on the amplitudes of $v_f(t)$ and $v_b(t)$, as stated in Equation 26.35.

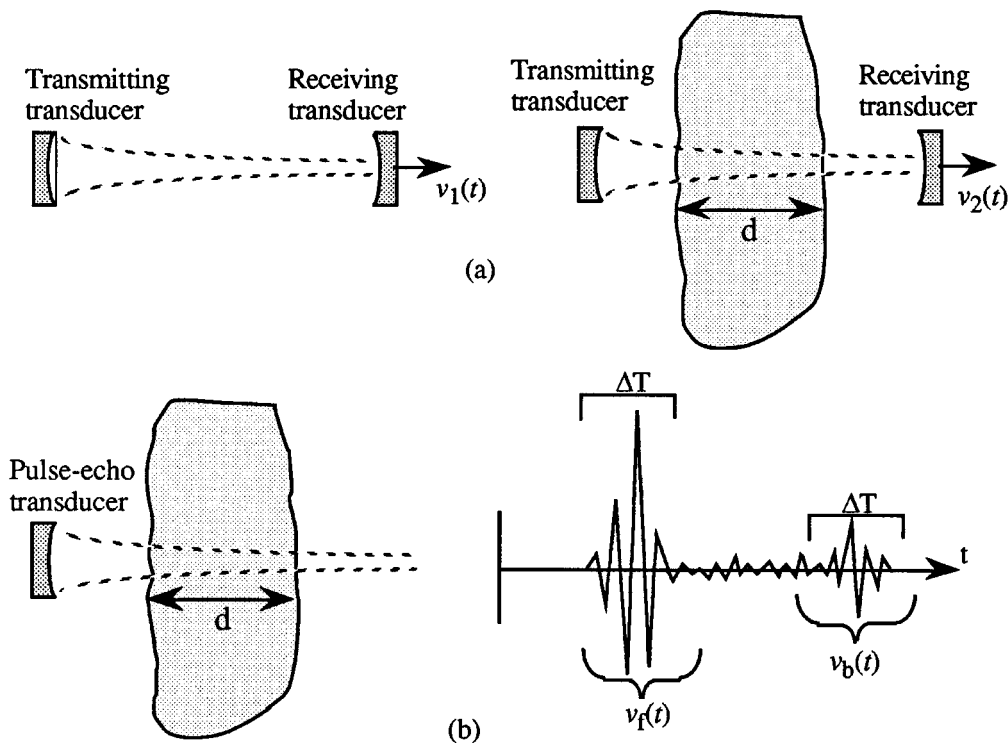

FIGURE 26.36 Measurement of bulk attenuation. (a) Measurement of attenuation by transmission measurement. (b) Measurement of attenuation by pulse-echo measurements.

$$\text{Att [dB/cm]} = \frac{1}{2d} 10 \log \left\{ \frac{\int_0^{\Delta t} [v_f(t)]^2 dt}{\int_0^{\Delta T} [v_b(t)]^2 dt} \right\} \cong \frac{1}{2d} 20 \log \left\{ \frac{\text{peak ampl., } v_f(t)}{\text{peak ampl., } v_b(t)} \right\} \quad (26.35)$$

Accurate attenuation measurements require attention to several potential pitfalls: (1) diffraction effects (even in the absence of attenuation, echoes from different ranges vary in amplitude, due to beam spreading); (2) misalignment effects (if the reflecting surface is not normal to the transducer axis, there is a reduction in detected signal amplitude, due to phase cancellation at the transducer surface); and (3) transmission losses whose magnitude it is not always easy to determine.

The spatial distribution of attenuation must be measured with pulse-echo measurements, where it is assumed that a backscatter signal of sufficient amplitude can be received from all regions of the medium. Use is made of the frequency dependence of attenuation, which has the effect that the shift in mean frequency of a given received echo relative to the mean frequency of the transmitted signal varies proportional to the total absorption. The *rate of shift* in mean frequency is thus proportional to the local attenuation.

CW Fields from Planar Piston Sources

In discussing the acoustic fields generated by acoustic radiators (transducers), a clear distinction must be made between fields due to CW excitation and due to pulse excitation. Although the overall field

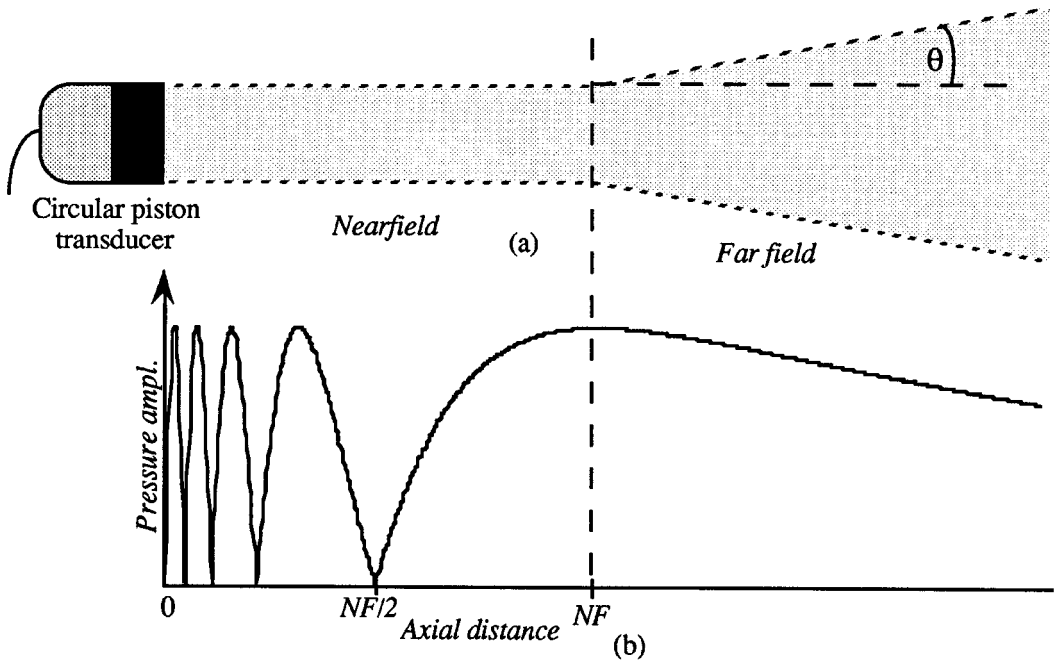

FIGURE 26.37 Pressure fields from a circular planar piston transducer operating with CW excitation. NF = Near Field. (a) Approximate field distribution in near field and far field. (b) Axial pressure in near field and far field for $(ka) = 31.4$.

patterns for these two cases are quite similar, the detailed field structure is very different. In this section, only CW fields are discussed.

When a CW excitation voltage is applied to a planar piston transducer, the resulting acoustic field can be divided into a *near field* region and a *far field* region. This division is particularly distinct when the transducer has a circular geometry. A piston transducer simply refers to a transducer with the same velocity amplitude at all points on the surface. The length of the near field, NF, is given as:

$$NF = \frac{a^2}{\lambda} \quad (26.36)$$

where a is the radius of the transducer and λ is the wavelength. As shown in [Figure 26.37\(a\)](#), the near field is approximately confined while the far field is diverging. The angle of divergence, θ , is approximately:

$$\theta = \arcsin\left(0.61 \frac{\lambda}{a}\right) \quad (26.37)$$

Additional comments to the simplified representation in [Figure 26.37\(a\)](#) are in order:

1. The actual field has no sharp boundaries, in contrast to what is shown in [Figure 26.37](#).
2. While the beam diameter is roughly constant in the near field, it is not as regular as shown; and at the same time, the near field structure is very complex.
3. The angle of divergence, θ , is only clearly established well into the far field.
4. The depiction of the far field shows only the main lobe; in addition, there are side lobes, which are directions of significant pressure amplitude, separated by *nulls* (i.e., directions with zero pressure amplitude).

In general, analytical expressions do not exist for the pressure magnitude at an arbitrary field point in the near field, and the pressure must instead be calculated by numerical techniques. However, an exact expression exists for the axial pressure amplitude, P_{ax} , valid in both near and far field [12].

$$P_{ax}(x) = 2 \rho_0 c_0 U_0 \left| \sin \left(0.5ka \left[\sqrt{x^2/a^2 + 1} - (x/a) \right] \right) \right| \quad (26.38)$$

In Equation 26.38, U_0 is the amplitude of the velocity function on the surface of the transducer. The expression is derived for a baffled planar piston transducer where the term “baffled” means that the transducer is mounted in a large rigid surface, called a baffle. Figure 26.37(b) shows the amplitude of the axial field for a planar piston transducer for which $(ka) = 31.4$. For field points located more than 3 to 4 near-field distances away from the transducer, a general expression for the pressure amplitude can be derived [12]:

$$P(r, \theta) = \frac{\rho_0 c_0}{2} U_0 ka \left(\frac{a}{r} \right) \left| \left[\frac{2J_1(ka \sin \theta)}{ka \sin \theta} \right] \right| \quad (26.39)$$

where $J_1(\cdot)$ is the Bessel function of the first order. The variable r is the length of the position vector defining the field point, and angle θ is the angle that the position vector makes with the x -axis.

Of interest in evaluating transducers in the far field is the *directivity*, D , defined as follows:

$$D(x) = \frac{I_{ax}(x) \left[\text{given source} \right]}{I_{ax}(x) \left[\text{simple source} \right]} \quad (26.40)$$

Thus, the directivity gives the factor with which the axial intensity of the given source is increased over that of a simple source (omnidirectional radiator), radiating the same total energy. For a baffled, circular planar piston transducer, the directivity in the far field can be calculated to be [12]:

$$D = \frac{(ka)^3}{ka - J_1(2ka)} \quad (26.41)$$

When $(2ka) \gg 1$, Equation 26.41 can be approximated to $D = (ka)^2$. Directivity values in the 1000s are common. For example, a 3.5 MHz transducer with 1 cm diameter radiating into water has a (ka) value of 73.3 and a directivity of 5373.

Often, focused transducers are used where the focusing is either created by the curvature of the piezoelectric element or by an acoustic lens in front of the transducer. The degree of focusing is determined by the (ka) value of the transducer.

Generation of Ultrasound: Piezoelectric and Magnetostrictive Phenomena

Ultrasound transducers today are available over a wide frequency range, in many sizes and shapes, and for a wide variety of applications. The behavior of the ultrasound transducer is determined by several parameters: the transduction material, the backing material, the matching layer(s), and the geometry and dimension of the transducer. A good overview of ultrasound transducers is available in [13].

The transduction material is most commonly a piezoelectric material, but can for some applications be a magnetostrictive material instead. These materials are inherently narrowband, meaning that they work efficiently only over a narrow frequency range. This is advantageous for CW applications such as

TABLE 26.3 List of Most Significant Piezoelectric Parameters for Common Piezoelectric Materials

Parameter	Barium titanate (BaTiO ₃)	Lead zirconate titanate, PZT-5	Lead meta-niobate, PbNb ₂ O ₆	Polyvinylidene fluoride (PVDF)
d_{33}	149 (10 ⁻¹² m/V)	374 (10 ⁻¹² m/V)	75 (10 ⁻¹² m/V)	22 (10 ⁻¹² m/V)
g_{33}	14 (10 ⁻³ Vm/N)	25 (10 ⁻³ Vm/N)	35 (10 ⁻³ Vm/N)	339 (10 ⁻³ Vm/N)
k_{33}	0.50	0.70	0.38	$k_{31} = 0.12$
k_T	0.38	0.68	0.40	0.11
Q_m	600	75	5	19

ultrasound welding and ultrasound hyperthermia, but is a problem for imaging applications, as impulse excitation will produce a long pulse with poor resolving abilities. To overcome this deficiency, a *backing material* is tightly coupled to the back side of the transducer for the purpose of damping the transducer and shortening the pulse. However, the backing material also reduces the sensitivity of the transducer. Some of this reduced sensitivity can be regained by the use of a *matching layer*, specifically selected for the medium of interest. As seen in Equation 26.33, a quarter wavelength matching layer can provide 100% efficient coupling to a medium, albeit only at one frequency. A combination of several matching layers can provide a more broadband impedance matching. The field is determined by both the geometry (planar, focused, etc.) of the transducer and by the frequency content of the velocity function of the surface of the transducer. In this section, unique aspects of the transduction material itself are described.

Piezoelectric Materials.

A piezoelectric material exhibits a mechanical strain (relative deformation) due to the presence of an electric field, and generates an electric field when subjected to a mechanical stress. A detailed review of piezoelectricity is given in [14]. Piezoelectric materials can either be: (1) natural material such as quartz; (2) man-made ceramics (e.g., barium titanate (BaTi), lead zirconate titanate (PZT), or lead meta-niobate); (3) man-made polymers (e.g., polyvinylidene fluoride (PVDF)). The piezoelectric ceramics are the most commonly used materials for ultrasound transducers. These ceramics are made piezoelectric by a so-called poling process in which the material is subjected to a strong electric field while at the same heating it to above the material's Curie temperature.

Several material constants determine the behavior of a given piezoelectric material, the most important of which are listed in Table 26.3 and defined below. An extensive list of parameter values for various piezoelectric materials is available in [15].

- d_{33} Transmission constant
- g_{33} Receiving constant
- k_{33} Piezoelectric coupling coefficient
- k_T Piezoelectric coupling coefficient for a transverse clamped material
- Q_M Mechanical Q

The transmission constant, d_{33} , gives the mechanical deformation of piezoelectric materials for frequencies well below the resonance frequency. A transducer with a large d_{33} value will therefore become an efficient transmitter. If an electric field, E_3 , is applied in the polarized direction of a piezoelectric rod or disk, the strain, S_3 , in that direction is approximately:

$$S_3 = d_{33} E_3 = d_{33} \frac{V_{\text{appl}}}{l} \quad (26.42)$$

where V_{appl} is the applied voltage and l is the thickness. The total deformation, Δl , becomes

$$\Delta l = d_{33} V_{\text{appl}} \quad (26.43)$$

The receiving constant, g_{33} , defines the sensitivity of a transducer element as a receiver when the frequency of the applied pressure is well below the resonance frequency of the transducer. If the applied stress (force/area) in the direction of polarization is T_3 , the output voltage from a rod or disk is approximately:

$$v_{\text{out}} = g_{33} T_3 l \quad (26.44)$$

The coupling coefficient describes the power conversion efficiency of a piezoelectric transducer, *operating at or near resonance*. Specifically, k_{33} is the coupling coefficient for an unclamped rod; that is, the rod is allowed to deform in the directions orthogonal to the direction of applied force or voltage. In contrast, k_T is the coupling coefficient for a *clamped* disk. Finally, Q_M gives the mechanical Q , which is a measure for how narrowband the transducer material inherently is.

Whereas expressions of the type given in Equations 26.42 to 26.44 are adequate for describing static or low-frequency behavior, the behavior near resonance where most transducers operate requires more complex models, which are beyond the scope of this chapter. The Mason model is adequate for narrowband modeling of transducers, whereas the KLM or Redwood models better describe the transducers for broadband applications [13, 15].

Magnetostrictive Materials.

The magnetostrictive phenomenon refers to a magnetically induced contraction or expansion in ferroelectric media, such as in nickel or alfenol, and was discovered by Joule in 1847. Magnetostrictive materials are generally used for ultrasound frequencies below 100 kHz, and are therefore relevant mainly for underwater applications. Eddy current losses influence the performance of magnetostrictive materials, but the losses can be reduced by constructing the magnetostrictive transducer from thin laminations.

Transducer Specifications.

Ultrasound transducers are generally specified by their diameter, center frequency, focal distance, and type of focusing (if applicable). The transducer can be designed as a contact transducer, a submersible transducer, an air transducer, etc.; in addition, the type of connector or cabling can be specified. In many cases, measurement data for the actual transducer can be supplied by the vendor in the form of a measured pressure pulse and the corresponding frequency spectrum, recorded with a hydrophone at a specific field point. Similarly, the beam profile can be measured in the form of pulse amplitude or pulse energy as a function of lateral position.

Detailed information about the acoustic field from a radiating transducer can be obtained with either the Schlieren technique or the optical interferometric technique. Such instruments are quite expensive, falling in the \$50K to \$120K range.

Display Formats for Pulse-Echo Measurements

The basic description of ultrasound imaging was presented earlier in this chapter. Based on the information presented so far in this section, more specific aspects of pulse-echo ultrasound imaging will now be described. Different display formats are used; the simplest of these is the *A-mode* display.

A-mode.

When a pulse-echo transducer has emitted a pulse in a given direction and has been switched to receive mode, an output signal from the transducer is produced based on detected echoes from different ranges, as illustrated conceptually in Figure 26.31(a). In this signal, distance to the reflecting structure has been converted into time from the start of signal. This signal is often referred to as the RF signal. Demodulating this signal (i.e., generating the envelope of the signal) produces the A-mode (amplitude mode) display, or the A-line signal. This signal can be the basis for range measurements, attenuation measurements, and measurement of reflection coefficient.

M-mode.

If the A-mode signal from a transducer in a fixed position is used to *intensity* modulate a cathode-ray tube (CRT), such as a monitor or oscilloscope, along a straight vertical line, a line of dots with brightness

according to echo strengths would appear on the screen. Moving the display electronically across the screen results in a set of straight horizontal lines. Now consider the case where the reflecting structures are moving in a direction toward or away from the transducer while pulse-echo measurements were being performed. This results in variations in the arrival time of echoes in the A-line signal, and the resulting lines across the screen are no longer straight, but curved, as determined by their velocity. Such a display is called *M-mode*, or motion mode, display. An application for this would be measurement of the diameter variation of a flexible tube, or blood vessel, due to a varying pressure inside the tube.

B-mode.

If pulse-echo measurements are repeatedly being performed, while the transducer scans the object of interest, an image of the object can be generated, as illustrated in Figure 26.31. Specifically, each A-line signal is used to intensity modulate a line on a CRT corresponding to the location of ultrasound beam, which produces an image that maps the reflectivity of the structures in the object. The resulting image is called a *B-mode* (or brightness mode) image. If the transducer is moved linearly, a rectangular image is produced, whereas a rotated transducer generates a pie-shaped, or sector image. This motion is typically done electronically or electromechanically, as described earlier under single-element and array transducers. When the scanning is done rapidly (say, 30 scans/s), the result is a real-time image.

Many forms of signal processing and image enhancement can be applied in the process of generating the B-mode image. Echoes from deeper lying structures will generally be of smaller amplitude, due to the attenuation of the overlying layers of the medium. Attenuation correction is made especially in medical imaging, so that echoes are displayed approximately with their true strength. This correction consists of a time-varying gain, called *time-gain control*, or TGC, such that the early arriving echoes experience only a low gain and later echoes from deeper lying structures experience a much higher gain. Various forms for signal compressions or nonlinear signal transfer function can selectively enhance the weaker or the stronger echoes.

C-mode.

In a C-mode display, only echoes from a specific depth will be imaged. To generate a complete image, the transducer must therefore be moved in a raster scan fashion over a plane. C-scan imaging is slow and cannot be used for real-time imaging, but has several applications in NDE for examining a given layer, or interface, in a composite structure, or the inner surface of a pipe.

Flow Measurements by Doppler Signal Processing

Flow velocity can be obtained by various ultrasonic methods (Chapter 28, Section 7), e.g., by measuring the Doppler frequency or Doppler spectrum. The Doppler frequency is the difference between the frequency (or pitch) of a moving sound source, as measured by a *stationary* observer, and the actual frequency of the sound source. The change in frequency is determined by the speed and direction of the moving source. The classical example is a moving locomotive with its whistle blowing; the pitch is increased when the train moves toward the observer, and vice versa. With respect to ultrasound measurements, only the reflecting (or scattering) gas, fluid, or structure is moving and not the the sound source, yet the Doppler phenomenon is present here as well. In order for ultrasound Doppler to function, the gas or fluid must contain scatterers that can reflect some of the ultrasound energy back to the receiver. The Doppler frequency, f_d , is given as follows:

$$f_d = \frac{2v}{c_0} \cos \theta \quad (26.45)$$

where v is the velocity of the moving scatterers, and θ is the angle between the velocity vector and the direction of the ultrasound beam. Doppler flowmeters require only access to the moving gas, fluid, or object from one side. For industrial use, when the fluids or gases often do not contain scatterers, *transmission* methods are preferred; these methods, however, are not based on the Doppler principle (Chapter 28, Section 7).

Two main categories of Doppler systems exist: the CW Doppler system and the PW (pulsed wave) Doppler system. The CW Doppler system transmits a continuous signal and does not detect the distance to the moving structure. It is therefore only applicable when there is just one moving structure or cluster of scatterers in the acoustic field. For example, a CW Doppler is appropriate for assessing the pulsatility and nature of blood flow in an arm or leg. CW Doppler systems are small and relatively inexpensive.

The PW Doppler system transmits a short burst at precise time intervals; it is therefore inherently a sampled system, and, as such, is subject to aliasing. It measures changes from one transmitted pulse to the next in the received signal from moving structures at one or several selected ranges, and is able to determine both velocity and range. Assuming that the ultrasound beam is narrow and thus very directional, the PW Doppler can create a *flow image*; that is, it can indicate the magnitude and direction of flow over an image plane. Commonly, color and color saturation are used to indicate direction and speed in a flow image, respectively. In contrast to CW Doppler systems, the PW Doppler systems require much signal processing and are therefore typically expensive and often part of a complete imaging system. When a distribution of velocities, rather than a single velocity, is encountered, as is often the case with fluid flow, a Doppler spectrum rather than a Doppler frequency is determined. An FFT (Fast Fourier Transform) routine is then used to reveal the Doppler frequencies and thus the velocity components present.

Review of Common Applications of Ultrasound and Their Instrumentation

Range Measurements, Air

Ultrasound range measurements are used in cameras, in robotics, for determining dimensions of rooms, etc. Measurement frequencies are typically around 50 kHz to 60 kHz. The measurement concept is pulse-echo, but with burst excitation rather than pulse excitation. Special electronic circuitry and a thin low-acoustic-impedance air transducer is most commonly used. Rugged solid or composite piezoelectric-based transducers, however, can also be used, sometimes up to about 500 kHz.

Thickness Measurement for Testing, Process Control, Etc.

Measurement of thickness is a widely used application of ultrasound. The measurements can be done with direct coupling between the transducer and the object of interest, or — if good surface contact is difficult to establish — with a liquid or another coupling agent between the transducer and the object. Ultrasound measurements of thickness have applications in process control, quality control, measuring build-up of ice on an aircraft wing, detecting wall thickness in pipes, as well as medical applications. The instrumentation involves a broadband transducer, pulser-receiver, and display or, alternatively, echo detecting circuitry and numerical display.

Detection of Defects, such as Flaws, Voids, and Debonds

The main ultrasound application in NDE is inspection for the localization of voids, crack, flaws, debonding, etc. [3]. Such defects can exist immediately after manufacturing, or were formed due to stresses, corrosion, etc. Various types of standard or specialized flaw detection equipment are available from ultrasound NDE vendors.

Doppler Flow Measurements

The flow velocity of a liquid or a moving surface can be determined through Doppler measurements, provided that the liquid or the surface scatters ultrasound back in the direction of the transducer, and that the angle between the flow direction and the ultrasound beam is known. Further details are given in the section about Doppler processing. CW and PW Doppler instruments are commercially available, with CW instrumentation being by far the least expensive.

Upstream/Downstream Volume Flow Measurements

When flow velocity is measured in a pipe with access to one or both sides, an ultrasound transmission technique can be used in which transducers are placed on the same or opposite sides of the pipe, with

one transducer placed further upstream than the other transducer. From the measured *difference* in travel time between the upstream direction and the downstream direction, and knowledge about the pipe geometry, the volume flow can be determined. Special clamp-on transducers and instrumentation are available. An overview of flow applications in NDE is given in [16].

Elastic Properties of Solids

Since bulk sound speed varies with the elastic stiffness of the object, as given in Equation 26.15, sound speed measurements can be used to estimate elastic properties of solids under different load conditions and during solidification processes. Such measurements can also be used for measurement of product uniformity and for quality assurance. The measurements can be performed on bulk specimens or on thin rods, using either pulse-echo or transmission instrumentation [17]. Alternatively, measurements of the material's own resonance frequencies can be performed for which commercial instruments, such as the *Grindo-sonics*, are available.

Porosity, Grain Size Estimation

Measurement of ultrasound attenuation can reveal several materials parameters. By observing the attenuation in metals as a function of frequency, the grain size and grain size distribution can be estimated. Attenuation has been used for estimating porosity in composites. In medical ultrasound, attenuation is widely used for tissue characterization, that is, for differentiating between normal and pathological tissues. Pulse-echo instrumentation interfaced with a digitizer and a computer for data analysis is required.

Acoustic Microscopy

The measurement approaches utilized in acoustic microscopy are similar to other ultrasound techniques, in that A-scan, B-scan, and C-scan formats are used. It is in the applications and the frequency ranges where acoustic microscopy differs from conventional pulse-echo techniques. Although acoustic microscopes have been made with transducer frequencies up to 1 GHz, the typical frequency range is 20 MHz to 100 MHz, giving spatial resolutions in the range from 100 μm to 25 μm . Acoustic microscopy is used for component failure analysis, electronic component packaging, and internal delaminations and dis-bonds in materials, and several types of acoustic microscopes are commercially available.

Medical Ultrasound

Medical imaging is a large and diverse application area of ultrasound, especially in obstetrics, cardiology, vascular studies, and for detecting lesions and abnormalities in organs. The display format is either B-mode, using gray scale image, or a combination of Doppler and B-mode, with flow presented in color and stationary structures in gray scale. A wide variety of instruments and scanners for medical ultrasound are available.

Selected Manufacturers of Ultrasound Products

Table 26.4 contains a representative list of ultrasound equipment and manufacturers.

Advanced Topics in Ultrasound

Overview of Diffraction

The ultrasound theory presented thus far has emphasized basic concepts, and the applications that have been discussed tacitly assume that the field from the transducer is a plane wave field. This simplifying assumption is acceptable for applications such as basic imaging and measurements based on travel time. However, the plane wave assumption introduces errors when materials parameters (e.g., attenuation, surface roughness, and object shape) are sought to be measured with ultrasound. Therefore, to use ultrasound as a quantitative tool, an understanding is needed of the structure of the radiated acoustic field from a given transducer with a given excitation, and — equally important — the ability to calculate the actual radiated field. This leads to the topic of diffraction, which is the effect that accounts for the complex structure of both radiated and scattered fields. Not surprisingly, there are direct parallels between optical diffraction and acoustic diffraction. (As a separate issue, it should be noted that the ultrasound

theory presented here assumes that the wave amplitudes [pressure, displacement] are small enough so that nonlinear effects can be disregarded.)

Diffraction is basically an edge effect. Whereas a plane wave incident on a large planar interface is reflected in a specific direction, the plane wave incident on an edge results in waves scattered in many directions. Similar considerations hold for the field produced by a transducer: The surface of the transducer produces a so-called *geometric wave* that has the shape of the transducer itself; the edge of the transducer, however, generates an *edge wave* with the shape of an expanding torus. The actual pressure field is a combination of the two wave fields. Very close to a large transducer, the geometric wave dominates, and diffraction effects might not need to be considered. Over small regions far away from the transducer, the field can be approximated by a plane wave field, and diffraction does not need to be considered. However, in many practical cases, diffraction must be considered if detailed information about the pressure field is desired, and numerical methods must be employed for the calculations.

The structure of the axial field, shown in Figure 26.37(b), is a direct result of diffraction. Numerical evaluation of the diffracted field from a transducer can be done in several ways: (1) use of the Fresnel or Fraunhofer integrals (not applicable close to the transducer) to calculate the field at a single frequency at a specified plane normal to the transducer axis; (2) calculation of the pressure function at any point of interest in space, based on a specified velocity function, $u(t)$, on the surface of the transducer, using Rayleigh integral; (3) decomposing the velocity field in the plane of the transducer into its plane wave components, using a 2-D Fourier transform technique, followed by a forward propagation of the plane waves to the plane of interest and an inverse Fourier transform to give the diffracted field; or (4) use of finite element methods to calculate the diffracted field at any point or plane of interest. In the following, methods (1) and (2) will be described.

Fresnel and Fraunhofer Diffraction.

Let the velocity function on the surface of the transducer, $u(x, y)$, be specified for a particular frequency, ω . Assume that the transducer is located in the $(x, y, 0)$ plane and that one is interested in the pressure field in the (x_0, y_0, z) plane. The Fresnel diffraction formulation [18] assumes that the paraxial approximation is fulfilled, requiring z to be at least 5 times greater than the transducer radius, in which case the *Fresnel diffraction integral* applies:

$$p(x_0, y_0, z, \omega) = \frac{A_0}{\lambda_z} \iint_S u(x, y, \omega) \exp\left[-jk \frac{x^2 + y^2}{2z}\right] \exp\left[jk \frac{x_0 x + y_0 y}{z}\right] dx dy \quad (26.46)$$

where S is the surface of the transducer and A_0 is a constant. If one defines the two first terms of the integrand as some complex spatial function, $\Gamma(x,y)$, then Equation 26.46 is a scaled Fourier transform of $\Gamma(x,y)$.

If $k(x^2 + y^2)/2z \ll 1$, or, equivalently, $z > 10 a^2/\lambda$, the second term in Equation 26.46 can be ignored, and the resulting equation is called the *Fraunhofer diffraction integral*:

$$p(x_0, y_0, z, \omega) = \frac{A_0}{\lambda z} \iint_S u(x, y, \omega) \exp\left[jk \frac{x_0 x + y_0 y}{z}\right] dx dy \quad (26.47)$$

Thus, one can only use the Fraunhofer integral for calculating the far field diffraction. From Equation 26.47, one can make the interesting observation that the far field of a transducer is a scaled version of the Fourier transform of the source.

Pressure Function at a Given Field Point, Based on Rayleigh Integral.

While the Fresnel and Fraunhofer diffraction methods are CW methods, calculation of pressure from the Rayleigh integral is fundamentally an impulse technique, and is as such better suited for analysis of pulse-echo measurements. The basis for the calculation is the *velocity potential impulse response*, $h(\vec{r}, t)$, obtained from the Rayleigh integral:

$$h(\vec{r}, t) = \frac{1}{2\pi} \iint_S \frac{\delta(t - r'/c)}{r'} dS \quad (26.48)$$

In Equation 26.48, r' is the distance from dS on the surface of the transducer to the field point, defined by the position vector \vec{r} , and $\delta(t)$ is the Dirac delta function. As can be seen, $h(\vec{r}, t)$ is the result of an impulsive velocity excitation on the surface of the transducer and is a function of both time and a spatial location. It is important to note that $h(\vec{r}, t)$ exists in analytical form for several transducer geometries, and, by extension, for annular and linear array transducers [19].

For the case of an arbitrary velocity function, $u(t)$, on the transducer surface, the corresponding velocity potential, $\phi(\vec{r}, t)$, is obtained as:

$$\phi(\vec{r}, t) = u(t) \otimes h(\vec{r}, t) \quad (26.49)$$

where \otimes refers to time domain convolution. Both particle velocity, $u(\vec{r}, t)$, and pressure, $p(\vec{r}, t)$, can be found from $\phi(\vec{r}, t)$, as follows:

$$u(\vec{r}, t) = \nabla \phi(\vec{r}, t) \quad (26.50)$$

$$p(\vec{r}, t) = -\rho_0 \frac{\partial}{\partial t} \phi(\vec{r}, t) \quad (26.51)$$

where ∇ is the gradient operator.

Thus, from the expressions above, the pressure can be calculated for any field point, \vec{r} , when $u(t)$ and the transducer geometry are defined. In this calculation, all diffraction effects are included. However, given the high frequency content in $h(\vec{r}, t)$ and in particular in the time derivative of $h(\vec{r}, t)$, care must be taken to avoid aliasing errors, as described in [19].

Received Signal in Pulse-Echo Ultrasound.

The expression in Equation 26.51 allows for quantitative evaluation of the pressure field for an arbitrary point, line, or plane. However, it does not describe the calculation of the received signal in a pulse-echo

system. Consider a small planar reflector, placed in a homogeneous medium, and referred to as dR . The reflector has the area dA . The dimensions of dR must be small with respect to the shortest wavelength in the insonifying pulse. The location and the orientation of the planar reflector is given by \vec{r} and \vec{n} , respectively, where \hat{n} is a unit normal vector to the small reflector.

The voltage from the receiving transducer in a pulse-echo system due to dR is termed $d v(\vec{r}, t)$ and can be determined when $u(t)$ is specified. The electro-acoustic transfer function for both the transmitting and the receiving transducer is assumed to be unity for all frequencies. For the case when the acoustic impedance of dR is much higher than that of the medium, $d v(\vec{r}, t)$ is given as [20]:

$$\begin{aligned} d v(\vec{r}, t) &= A_0 \rho_0 \frac{\cos[\psi(\vec{r})]}{c_0} \left[h(\vec{r}, t) \otimes h(\vec{r}, t) \otimes \frac{\partial^2}{\partial t^2} u(t) \right] dA \\ &= A_0 \cos[\psi(\vec{r})] u(t) \otimes \frac{\rho_0}{c_0} \left[\frac{\partial^2}{\partial t^2} (h(\vec{r}, t) \otimes h(\vec{r}, t)) \right] dA \end{aligned} \quad (26.52)$$

In Equation 26.52, A_0 is determined by the reflection coefficient of the reflector. The term $\cos[\psi(\vec{r})]$ is a correction term (obliquity factor) where $\psi(\vec{r})$ is the angle between \hat{n} and the propagation direction of the wave field at \vec{r} . For an extended surface, the received voltage can be found by decomposing the surface into small reflectors and calculating the total received signal as the sum of the contributions from all the small reflectors. An efficient numerical technique for this type of integration has been developed [21].

G.R.A.S. Sound and Vibration

Sound is normally defined as vibration of a solid, liquid, or gaseous medium in the frequency range of the human ear, i.e., between about 20 Hz and 20 kHz. Here, the definition is further limited and only vibrations in liquids and gaseous media are considered. In contrast to solid media, a liquid or gaseous medium cannot transmit shear forces, so sound waves are always longitudinal waves, in which the particles moves in the direction of propagation of the wave. The wave propagation in gaseous and liquid media can be described by the three variables: the pressure p , the particle velocity u , and the density ρ . The relation between these is described by the wave equation [1], and this can be derived from three basic equations: the Euler equation (this is essentially Newton's second law applied to a fluid), the Continuity equation, and the State equation. Although the wave equation in principle can be used to describe and calculate all sound waves in all situations, it will in practice often be impossible to perform the necessary calculations. In some special cases, it is possible to get analytical results directly from the wave equation and these cases are therefore of special interest. The cases most often encountered in acoustics is the *free field*, the *diffuse* (or reverberant) *field*, and the *closed coupler*. The free field is, in principle, an infinite, empty (except for the medium and the source) space, with no reflections. Here, the waves are allowed to radiate freely in all directions without reflections. In practice, the free field is implemented in an anechoic chambers, where all walls have been made nearly 100% absorptive. The diffuse field is obtained in a reverberation room where all walls have been made, in principle, 100% reflective. At the same time, the walls are made nonparallel and the result is a sound field with sound waves in all directions. The closed coupler is a small chamber, with dimensions small compared to the wavelength of the sound. A special case of this is the standing wave tube. This is a tube with a diameter smaller than the wavelength and with a sound source in one end. With a suitable loudspeaker as a source, the wave propagation in the tube can be assumed to be one-dimensional. This simplifies the mathematical description so that it is possible to calculate the sound field.

In practice, almost the only parameter measured directly in acoustics is the sound pressure, and all other parameters like sound power, particle velocity, reverberation time, directivity, etc. are derived from pressure measurements. These are performed with measurement microphones in gaseous media and

hydrophones in liquid media. The measurement microphones are all of the condenser type to ensure precision, long-term stability, and sensitivity. Hydrophones are usually made with a rubber coating over a sensitive element of piezoelectric material.

The traditional frequency range from 20 Hz to 20 kHz for acoustic measurements is selected because this is the range audible to the human ear. Sound waves exist outside this range in the form of infrasound (below 20 Hz) and ultrasound (above 20 kHz). As the basic equations (the wave equation) and measurement principles are the same for both infrasound and ultrasound, many of the principles from the frequency range from 20 Hz to 20 kHz can be extended to these ranges.

27.1 The Wave Equation

Sound wave propagation cannot take place in a vacuum, but is always associated with some kind of medium. For simplicity, assume that this medium is air, although the same equations are valid also for all gaseous and fluid media. In this medium, the concept of an air particle can be introduced. An *air particle* is a small volume of air in which the acoustical parameters like pressure, density, etc. can be considered constant. On the other hand, the air volume must be large enough to include a very large number of air molecules, so that the air volume can be considered to be a continuous medium and not a collection of molecules. The *Euler equation* for such an air particle is given by:

$$-\text{grad } p = \rho_0 \left(\frac{\partial \vec{v}}{\partial t} \right) \quad (27.1)$$

where p is the pressure, ρ_0 is the density, and v is the particle velocity. This equation can be considered as Newton's second law ($F = ma$) applied to a fluid. Here, the gradient of the pressure equals the force F acting on the air particle, the density equals the mass m , and the time differentiated particle velocity $\partial v / \partial t$ equals the acceleration.

The second equation necessary to derive the wave equation is the *continuity equation*. This simply states that if you have a small volume of air and you bring in some extra air, the density (or the mass) will increase. Mathematically, this can be formulated as:

$$\text{div } \vec{v} = -\frac{1}{\rho_0} \cdot \frac{\partial \rho}{\partial t} \quad (27.2)$$

where c is the sound velocity. The sound velocity depends on the composition of the air and the temperature. For normal air at 0°C, the velocity is 314 m s⁻¹ while at 20°C, the velocity is 340 m s⁻¹.

The third equation is the *state equation*, which relates pressure changes to changes in the density, that is, if a small volume of air is compressed, the density will increase:

$$\frac{\partial \rho}{\partial t} = \frac{1}{c^2} \times \frac{\partial p}{\partial t} \quad (27.3)$$

Now we have three equations relating the three variables: pressure, particle velocity, and density. By eliminating the particle velocity and the density, we obtain one differential equation for the sound pressure:

$$\nabla^2 p = \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} \quad (27.4)$$

This is the *wave equation* for acoustic waves in gaseous and fluid media. In principle, this allows one to calculate the sound pressure anywhere in a sound field, if some suitable boundary conditions are given. In practice, however, it is only possible to find solutions in a few simple cases.

27.2 Plane Sound Waves

In a free space, at great distance from the sound source, sound waves are approximately plane waves. This means that the wave equation only depends on one of the coordinates in the wave equation. If the direction of propagation of the wave fronts is in the x -direction, the solution to the wave equation reduces to:

$$p = A \cos\left[(\omega t - k)(x + \phi_a)\right] \quad (27.5)$$

where ω is the frequency. Similarly, the particle velocity in the free field is given by:

$$v = \frac{A}{\rho c} \cos\left[(\omega t - k)(x + \phi_a)\right] = \frac{p}{\rho c} \quad (27.6)$$

This means that in a plane wave, the particle velocity is equal to the pressure divided by the constant ρc and the pressure and particle velocity are in phase. The constant ρc is the *acoustic impedance*; and for air at 20°C, the density is 1.29 kg m⁻³ and the sound velocity is 340 m s⁻¹, giving an acoustic impedance of 438.6 kg m⁻² s⁻¹.

The plane wave transmits energy in the direction of propagation. The power transmitted per unit area is the intensity in the direction of the propagation (in many older textbooks, terms like “the intensity of the sound” were mistakenly used for the magnitude of the sound pressure). In general, the intensity is given by the product of the sound pressure and the sound velocity; thus, in the case of the plane wave, the intensity (I) can be calculated from Equations 27.5 and 27.6:

$$I = vp = \frac{p^2}{\rho c} \quad (27.7)$$

Thus, in the plane wave, the intensity transmitted by the wave can be calculated from the sound pressure and, as the sound power is the intensity per unit area, the sound power can be calculated by multiplying the intensity by the area.

27.3 Spherical Waves

Another simple solution to the wave equation can be found for the radiation from a point source into free space. The point source is an infinitely small sphere whose surface is pulsating radially. In practice, for small sound sources (i.e., where the dimensions of the sound source is small compared to the wavelength of the sound), the point source is a good approximation for the real physical source that makes the spherical wave solution of special interest.

The wave equation in Equation 27.5 is transformed into the spherical coordinates r , θ , and ψ . As the point source radiates equally in all directions, the solution depends only on the distances r from the center of the point source:

$$p = \frac{P_0}{r} \cos(\omega t - kr) \quad (27.8)$$

It can be seen that the sound pressure is inversely proportional to the distance from the sound source. The particle velocity can be divided into a near-field contribution v_n and a far-field contribution v_f :

$$v_f = \frac{P_0}{\rho c} \cos(\omega t - kr) \quad (27.9)$$

$$v_n = \frac{P_0}{\omega \rho r^2} \sin(\omega t - kr) \quad (27.10)$$

The far-field contribution in Equation 27.9 can be seen to be in-phase with the pressure in Equation 27.8 and also the particle velocity is inversely proportional to the distance r from the point source. The near-field contribution is inversely proportional to the square of the distance to the source and therefore dies away rapidly as the distance to the source increases.

As in the case of the plane wave, the intensity in the spherical wave is the product of the pressure and particle velocity. For the near-field contribution, one obtains:

$$I = v_n p = \frac{P_0}{\omega \rho r^2} \sin(\omega t - kr) \frac{P_0}{r} \cos(\omega t - kr) = 0 \quad (27.11)$$

That is, the near-field part of the particle velocity does not contribute to the radiated power as the particle velocity is 90° out of phase with the pressure.

The far-field contribution is given by:

$$I = v_f p = \frac{P_0}{\rho c} \cos(\omega t - kr) \frac{P_0}{r} \cos(\omega t - kr) = \frac{P_0^2}{r^2 \rho c} \cos^2(\omega t - kr) \quad (27.12)$$

It can be seen that the intensity decreases with the square of the distance to the source and by combining Equations 27.8 and 27.12, one obtains:

$$I = \frac{P_0^2}{r^2 \rho c} \cos^2(\omega t - kr) = \frac{P^2}{\rho c} \quad (27.13)$$

which is identical to Equation 27.7 for the plane wave. Thus, as for the plane progressive wave, the intensity in the spherical wave can be calculated from the pressure.

27.4 Acoustic Measurements

As can be seen from the wave equation, the full acoustic field can in principle be described from only pressure measurements. This means that all other acoustic parameters can be derived from pressure measurements and, in practice, pressure is often the only parameter measured. There have been a few attempts to make transducers for particle velocity measurements based on, for example, transmission of ultrasonic waves; but the absolute dominating transducers for acoustic measurements are the condenser-type microphones, [Figure 27.1](#). These have proven to be superior with respect to temperature stability, long-term stability, and insensitivity to rough handling. While measurement microphones are designed and produced to ensure well-defined and accurate measurements, a wide range of other microphones are available for other purposes. These can, for example, be for incorporation in telephones, where price is a very decisive factor, or for studio recordings, where a subjective evaluation is more important than the objective performance.

FIGURE 27.1 Measurement microphones: $\frac{1}{2}$ " and $\frac{1}{4}$ ".

FIGURE 27.2 Basic elements of a measurement microphone.

Condenser Microphones

The condenser microphone consists basically of five elements: protection grid, microphone casing, diaphragm, backplate, and insulator; see [Figure 27.2](#). The diaphragm and the backplate form the parallel plates of an air capacitor. This capacitor is polarized with a charge from an external voltage supply (externally polarized type) or by an electric charge injected directly into an insulating material on the

backplate (prepolarized type). When the sound pressure in the sound field fluctuates, the distances between the diaphragm and the backplate will change, and consequently change the capacitance of the diaphragm/backplate capacitor. As the charge on the capacitor is kept constant, the change in capacitance will generate an output voltage on the output terminal of the microphone. The acoustical performance of a microphone is determined by the physical dimensions such as diaphragm area, the distance between the diaphragm and the backplate, the stiffness and mass of the suspended diaphragm, and the internal volume of the microphone casing. These factors will determine the frequency range of the microphone, the sensitivity, and the dynamic range. The sensitivity of the microphone is described as the output voltage of the microphone for a given sound pressure excitation, and is in itself of little interest for the operation of the microphone, except for calibration purposes. However, the sensitivity of the microphone (together with the electric impedance of the cartridge) also determines the lowest sound pressure level that can be measured with the microphone. For example, with a microphone with a sensitivity of 2.5 mV Pa^{-1} , the lowest level that can be measured is around 40 dB (re. $20 \text{ }\mu\text{Pa}$), while a microphone with a sensitivity of 50 mV Pa^{-1} can measure levels down to approximately 15 dB (re. $20 \text{ }\mu\text{Pa}$).

The size of the microphone is the first parameter determining the sensitivity of the microphone. In general, the larger the diaphragm diameter, the more sensitive the microphone will be. There are, however, limits to how sensitive the microphone can be made by simply making it larger. The polarization voltage between the diaphragm and the backplate will attract the diaphragm and deflect this toward the backplate. As the size of the microphone is increased, the deflection will increase and eventually the diaphragm will be deflected so much that it will touch the backplate. To avoid this, the distance between the diaphragm and the backplate can be increased or the polarization voltage can be decreased. Both of these actions will, however, decrease the sensitivity, so that the optimum size of a practical measurement microphone for use up to 20 kHz is very close to $\frac{1}{2}$ " (12.6 mm).

As the size of the microphone is decreased, the useful frequency range of the microphone is increased. The frequency range, which can be obtained, is determined in part by the size of the microphone. At high frequencies, when the wavelength of the sound waves becomes much smaller than the diameter of the diaphragm, the diaphragm will stop behaving like a rigid piston (the diaphragm "breaks up" — this is not a destructive phenomenon). Different parts of the diaphragm will start to move with different magnitude and phase, and the frequency response of the microphone will change. To avoid this, the upper limiting frequency is placed so that the sensitivity of the microphone drops off before the diaphragm starts to break up. This gives, for a typical 0.5 in. microphone, an upper limiting frequency in the range from 20 kHz to 40 kHz, depending on the diaphragm tension. If the diaphragm is tensioned so that it becomes more stiff, the resonance frequency of the diaphragm will be higher; on the other hand, the sensitivity of the microphone will be reduced as the diaphragm deflection by a certain sound pressure level decreases.

The frequency response of the microphone is determined by the diaphragm tension, the diaphragm mass, and the acoustical damping in the airgap between the diaphragm and the backplate. This system can be represented by the mechanical analogy of a simple mass–spring–damper system as in [Figure 27.3](#). The mass in the analogy represents the mass of the diaphragm and the spring represents the tension in the diaphragm. Thus, if the diaphragm is tensioned to become stiffer, the corresponding spring will become stiffer. The damping element in the analogy represents the acoustical damping between the diaphragm and the backplate. This can be adjusted by, for example, drilling holes in the backplate. This will make it easier for the air to move away from the airgap when the diaphragm is deflected, and therefore decrease damping.

The frequency response of the simple mechanical model of the microphone is given in [Figure 27.4](#), together with the influence of the different parameters. At low frequencies (below the resonant frequency), the response of the microphone is determined by the diaphragm tension, and as described above, the sensitivity will increase if the tension is decreased. The resonant frequency is determined by the diaphragm tension and the diaphragm mass, with an increased tension giving an increased resonant frequency, and an increased mass giving a decreased resonant frequency. The response around the

FIGURE 27.3 Mechanical analogy of a microphone.

FIGURE 27.4 Influence of microphone parameters on frequency response.

resonant frequency is determined by the acoustical damping, where an increase in the damping will decrease the response.

Although the material selection and assembling techniques have changed during the last few years, the basic types of microphones remain unchanged. The basic types are the free-field microphones, the pressure microphones, and the random incidence microphones. They have been constructed with different frequency characteristics, corresponding to the different requirements.

The *pressure microphone* is meant to measure the actual sound pressure as it exists on the diaphragm. A typical application could be the measurement of the sound pressure in a closed coupler or as in Figure 27.5, the measurement of the sound pressure at a boundary. In this case, the microphone forms part of the wall and measures the sound pressure on the wall itself. The frequency response of this microphone should be flat in a frequency range as wide as possible, taking into account that the sensitivity will decrease as the frequency range is increased. The acoustical damping in the airgap between the diaphragm and the backplate is adjusted so that the frequency response is flat up to and a little beyond the resonant frequency.

The *free-field microphone* is designed to essentially measure the sound pressure as it existed before the microphone was introduced into the sound field. At higher frequencies, the presence of the microphone itself in the sound field will change the sound pressure. In general, the sound pressure around the microphone cartridge will increase due to reflections and diffraction. The free-field microphone is designed so that the frequency characteristics compensate for this pressure increase. The resulting output of the free-field microphone is a signal proportional to the sound pressure as it existed before the microphone was introduced into the sound field. The free-field microphone should always be pointed toward the sound source (0° incidence), as in Figure 27.6. In this situation, the presence of the microphone diaphragm in the sound field will result in a pressure increase in front of the diaphragm, see

FIGURE 27.5 Application of pressure microphones.

FIGURE 27.6 Application of a free-field microphone.

Figure 27.7(a), depending on the wavelength of the sound waves and the microphone diameter. For a typical $\frac{1}{2}$ " microphone, the maximum pressure increase will occur at 26.9 kHz, where the wavelength of the sound ($\lambda = 342 \text{ ms}^{-1}/26.9 \text{ kHz} \approx 12.7 \text{ mm} \approx 0.5 \text{ in.}$) coincides with the diameter of the microphone. The microphone is then designed so that the sensitivity of the microphone decreases by the same amount as the acoustical pressure increases in front of the diaphragm. This is obtained by increasing the internal acoustical damping in the microphone cartridge, to obtain a frequency response as in Figure 27.7(b). The result is an output from the microphone, Figure 27.7(c), which is proportional to the sound pressure as it existed before the microphone was introduced into the sound field. The curve in Figure 27.7(a) is also called the “free-field correction curve” for the microphone, as this is the curve that must be added to the frequency response of the microphone cartridge to obtain the acoustical characteristic of the microphone in the free field.

The free-field microphone is required in principle, to be pointed toward the sound source and that the sound waves travel in essentially one direction. In some cases, (e.g., when measuring in a reverberation room or other highly reflecting surroundings), the sound waves will not have a well-defined propagation direction, but will arrive at the microphone from all directions simultaneously. The sound waves arriving at the microphone from the front will cause a pressure increase, as described for the free-field microphone, while the waves arriving from the back of the microphone will be decrease to a certain extent due to the shadowing effects of the microphone cartridge. The combined influence of the waves coming from different directions therefore depends on the distribution of sound waves from different directions. For

FIGURE 27.7 Frequency response of free-field microphone: (a) pressure increase in front of diaphragm; (b) microphone pressure response; (c) resulting microphone output.

measurement microphones, a standard distribution has been defined, based on statistical considerations, resulting in a standardized random incidence microphone.

As mentioned previously, measurement microphones can be either of the externally polarized type or the prepolarized type. The externally polarized types are by far the most stable and accurate microphones and should be preferred for precision measurements. The prepolarized microphones are, however, preferred in some cases, in that they do not require the external polarization voltage source. This is typically the case when the microphone will be used on small hand-held devices like sound level meters, where a power supply for polarization voltage would add excessively to cost, weight, and battery consumption. Still, it should be realized that prepolarized microphones in general are much less stable to environmental changes than externally polarized microphones.

27.5 Sound Pressure Level Measurements

The human ear basically hears the sound pressure, but the sensitivity varies with the frequency. The human ear is most sensitive to sound in the frequency range from 1 kHz to 5 kHz, while the sensitivity drops at higher and lower frequencies. This has led to the development of several frequency weighting functions, which attempt to replicate the sensitivity of the human ear. Also, the response of the human ear to time-varying signals and impulses has led to the development of instruments with well-defined time weighting functions. The resulting measurement instrumentation is the *sound level meter*, as defined in for example by the IEC International Standard 651, “Sound Level Meters” [2]. The standard defines four classes of sound level meters for different accuracy’s (Table 27.1). Type 0 is the most accurate,

TABLE 27.1 IEC 651 Sound Level Meter Requirements

intended for precision laboratory measurements, while Type 1 is most widely used for general-purpose measurements, see [Figure 27.8](#). Type 2 is used where low price is of importance, while Type 3 is not used in practice because of the wide tolerances, making the results too unreliable. The output of the sound level meter is, in principle, assumed to be an approximate measure of the impression perceived by the human ear.

The sound level meter can be functionally divided into four parts: microphone and preamplifier, A-weighting filter, rms detector and display ([Figure 27.9](#)). The microphone should ensure the correct measurement of the sound pressure within the frequency range for the given class. Also, the standard gives requirements for the directionality of the microphone. The frequency response of the instrument, including the weighting filter, is given for sound waves arriving at the microphone along the reference direction. For sound waves arriving from other directions, the standard allows wider tolerances at higher frequencies, taking into account the inevitable reflections and diffraction occurring at higher frequencies.

The preamplifier converts the high-impedance output signal from the microphone to a low-impedance signal, but has in itself no or even negative voltage amplification. The signal from the preamplifier is then passed through an A-weighting filter. This is a standardized filter which, in principle, resembles the sensitivity of the human ear, so that a measurement utilizing this filter will give a result which correlates with the subjective response of an average listener. The filter, with the filter characteristic as in

FIGURE 27.8 Modern Type 1 sound level meter with built-in frequency analyzer.

FIGURE 27.9 Functional parts of a sound level meter.

FIGURE 27.10 A-weighting curve.

Figure 27.10, attenuates low and high frequencies and slightly amplifies frequencies in the mid-frequency range from 1 kHz to 5 kHz. There are a number of other weighting curves, denoted B-weighting, C-weighting and D-weighting, which may give better correlation with subjective responses in special cases, such as for very high or very low levels, or for aircraft noise.

The signal from the A-weighting filter is subsequently passed through an exponential rms detector, with a time constant of either 125 ms (“fast”) or 1 s (“slow”). These time constants simulate the behavior of the human ear when subjected to time-varying signals. Especially when the duration of the sound stimuli to the human ear becomes shorts (e.g., around 200 ms), the sound is subjectively judged as being lower compared to the same sound heard continuously. The same effect is obtained using the “fast” averaging time. This will however give a higher statistical uncertainty on the level estimate than when using the time constant “slow,” so this should be chosen if the sound signal is continuously. Other standards describe special sound level meters such as integrating sound level meters or impulse sound level meters intended for special purposes.

27.6 Frequency Analyzers

While the sound level meter gives a single reading for the sound level in the frequency range from 20 Hz to 20 kHz, it is often desirable to have more detailed information about the frequency content of the signal. Two types of frequency analyzers are commonly used in acoustic measurements: FFT analyzers and real-time filter analyzers. The *FFT analyzers*, with very high frequency resolutions, can give a wealth of frequency information and make it possible to separate closely spaced harmonics (e.g., from a gear box). In contrast to this, the *real-time filter analyzers*, Figure 27.11, uses a much broader frequency resolution, usually in 1/3-octave bands. The frequency analysis is performed by a bank of filters (nowadays mostly digital filters) with well-defined frequency and time responses. The filter responses have been internationally standardized, with the center frequencies and passbands as shown in Table 27.2. In the frequency range from 20 Hz to 20 kHz, the 1/3-octave filterbank consists of 31 filters, simultaneously measuring the input signal. The resulting 1/3-octave spectrum resembles the subjective response of the human ear.

FIGURE 27.11 Real-time frequency analyzer for acoustic measurements.

27.7 Pressure-Based Measurements

The result of sound pressure measurements will be influenced by many factors: source, source operating conditions, surroundings, measurement position, etc. Depending on the goal of the measurement, these parameters can be controlled in different manners. If the goal of the measurement is to quantify the noise exposure to an operator's ear in a noisy environment, it is important that the microphone is in the same position as the operator's ear would normally be in, and that the environment is equal to the normal operating environment. If, on the other hand, the task is to describe the sound source as a noise-emitting machine, it is important to minimize the influence of the environment on the measurement result.

If the aim is to describe the measuring object as a noise source, it is customary to state the radiated sound power for the source. This is a global parameter quantifying the total noise radiation from the source, and to a certain extent independent of the environment. The sound power can be measured in a number of different ways: in a free field, in a reverberation room, using a substitution technique, or using sound intensity technique. A free field is a sound field in which the sound is radiated freely in all directions, with no restricting walls or reflections. This is most often obtained in a semi-anechoic chamber, where all walls and ceiling have been covered by nearly 100% absorptive material, with only the floor made of reflecting material. When the sound source is placed in the semi-anechoic chamber, the emitted sound waves will radiate freely away from the source and, in the far field, the waves can be considered to be plane waves or spherical waves. Therefore, the sound intensity can be calculated from pressure measurements using Equation 27.7.

TABLE 27.2 1/3-Octave Analysis Frequencies

Nominal center frequency (Hz)	Exact center frequency (Hz)	Passband (Hz)
20	19.95	17.8–22.4

20000	19952.6	17800–22400

As real sound sources seldom radiate equally in all directions, a number of measurements around the test object are averaged. ISO Standard 3745 “Acoustics—Determination of sound power levels of noise sources—Precision method for anechoic and semi-anechoic rooms” [3] specifies an array of microphone positions on a hemisphere over the test object, as in [Figure 27.12](#), with the coordinates as in [Table 27.3](#). As all points are associated with the same area, and as the sound power is intensity times the area, the total radiated sound power can be calculated as:

$$P = A \sum I_n = \frac{2\pi r}{\rho c} \sum p_n^2 \quad (27.14)$$

where A is the area of the test hemisphere with radius r , and p_n is the pressure measured in point number n .

27.8 Sound Intensity Measurements

The calculation in Equation 27.14 of the sound power from sound pressure measurements is based on Equation 27.7. This equation, which gives the intensity based on a pressure measurement, is however only valid in a free field, in the direction of propagation. In general, in the presence of background noise or with reflections from walls, etc., it is not possible to calculate the sound intensity from a single pressure

FIGURE 27.12 Measurement points for sound power determination.

TABLE 27.3. Coordinates of Measurement Points for Hemisphere with Radius r

Measurement point no.	x/r	y/r	z/r
1	-0.99	0	0.15
2	0.5	-0.86	0.15
3	0.5	0.86	0.15
4	-0.45	0.77	0.45
5	-0.45	-0.77	0.45
6	0.89	0	0.45
7	0.33	0.57	0.75
8	-0.66	0	0.75
9	0.33	-0.57	0.75
10	0	0	1.0

measurement. In these cases, it is however possible to measure directly the sound intensity with a two-microphone intensity probe, Figure 27.13.

Sound intensity I is the product of the pressure and the particle velocity:

$$I = pv \quad (27.15)$$

While the pressure p is a scalar and independent of the direction, the particle velocity is a vector quantity and directionally dependent. When the particle velocity is stated as in Equation 27.15, it is implicit that the velocity is in a certain direction and that the resulting intensity is calculated in the same direction.

FIGURE 27.13 Two-microphone sound intensity probe.

For example, the particle velocity v in the direction of propagation, [Figure 27.14\(a\)](#), gives the intensity radiation away from the point source, while the particle velocity perpendicular to the propagation direction, [Figure 27.14\(b\)](#), is zero. The intensity calculated from Equation 27.15 will therefore be zero in the direction perpendicular to the propagation direction even though the sound pressure is the same. This means that the sound energy flows away radially from the point source and no energy is flowing tangentially.

The measurement of the sound intensity according to Equation 27.15 requires the measurement of the sound pressure and the particle velocity. With the two-microphone intensity probe, the pressure in a position in between the two microphones is calculated as the mean pressure measured by the two microphones:

$$p = \frac{p_1 + p_2}{2} \quad (27.16)$$

FIGURE 27.14 Particle velocity (a) along direction of propagation, and (b) perpendicular to direction of propagation.

The air particle velocity v , in the direction of the intensity probe, can be calculated from the pressure differences between the two microphone measurements:

$$v = \int \frac{(p_2 - p_1)}{\rho \Delta r} \partial \tau \quad (27.17)$$

where ρ is the density of the air and Δr is the distance between the microphones. The intensity I is then obtained by multiplying the pressure and the velocity:

$$I = p v = \frac{p_1 + p_2}{2} \int \frac{(p_2 - p_1)}{\rho \Delta r} \partial \tau \quad (27.18)$$

The intensity measurement technique is a powerful tool to localize acoustical noise source and to determine the sound power radiated from a sound source, even in the presence of other strong sound sources.

27.9 Near-Field Acoustic Holography Measurements

The term *acoustic holography* comes from the analogy to optical holographs. It is well known how holography, as opposed to a normal photo, enables one to reconstruct the full image of an object. This is obtained by “recording” information about both the magnitude and the phase of the light, while a normal photo only “records” the magnitude of the light. Similarly, with *acoustic holography*, both the magnitude and the phase of the sound field are measured over a plane surface. These measurements result in a complete description of the sound field where both magnitude and phase are known at all points. It is then possible to calculate acoustic quantities, including sound intensity distribution, particle velocity, sound power, radiation pattern, etc.

The basic assumption behind *near-field acoustic holography* (NAH) is that the sound field can be decomposed into two simple wave types: plane waves and evanescent waves. The *plane waves* describe the part of the sound field that is propagated away from the near field toward the far field, and the *evanescent waves* describe the complicated sound field existing in the near field. Any sound field can be described as a combination of plane waves and evanescent waves with different magnitude and directions.

FIGURE 27.15 Temporal and spatial frequency of plane wave.

The magnitude and direction of the individual waves can be described by their spatial frequencies or wave numbers. For a simple plane wave propagating in a certain direction, this can be described in terms of its temporal frequency as well as by its spatial frequency. The temporal frequency, Figure 27.15(a), is obtained by looking at the pressure changes with time at a certain point in the sound field. This gives the temporal frequency in hertz or radians per second. Similarly, the spatial frequency, Figure 27.15(b), is obtained by looking at the pressure changes at a certain time. At that instant in time, the pressure will be different in different positions in space. If one moves in a certain direction in space, one will see a certain change in the pressure, corresponding to a spatial frequency, measured with the unit cycles per meter or radians per meter. As the temporal frequency gives information about how often the pressure changes with time at a certain point, the spatial frequency gives information about how often the pressure changes with position at a certain time. In the example of Figure 27.15(b), the propagation direction of the plane wave was identical to the direction of the axis along which the spatial frequency was measured. In this case, shown again in Figure 27.16(a), the relationship between the spatial frequency k_0 (i.e., the wave number) and the temporal frequency f is given by the speed of sound c :

$$k_0 = \frac{2\pi f}{c} = \frac{\omega}{c} = \frac{2\pi}{\lambda} \quad (27.19)$$

where λ is the wavelength. If, however, the axis along which the spatial frequency is measured is not the same as the propagation direction, see the example in Figure 27.16(b), this simple relationship is not valid. In this case, although the temporal frequency is the same as in Figure 27.16(a), the spatial frequency is lower. For one particular temporal frequency, the spatial frequencies will thus give information about the propagation directions. Therefore, if the sound field is made up of several plane waves with the same temporal frequency, but with different propagation directions, this will be shown in the spatial spectrum

FIGURE 27.16 Spatial frequencies of waves propagating in different directions.

as several spatial frequency components. If, for example, the sound field is a sum of two waves, Figure 27.17, where one wave is traveling along the axis of measurement and the other at an angle of 45° relative to the first wave, the spatial spectrum will contain two spatial frequencies. One spatial frequency will be k , corresponding to a wave in the direction along the axis, and the other frequency will be $k^* \cos(45^\circ)$. Thus far, the spatial frequencies have been defined along a single axis corresponding to a one-dimensional Fourier transformation. In the NAH technique, the sound field is sampled not only along a single axis, but over a plane. Therefore, a two-dimensional Fourier transformation is used instead. This gives as a result a two-dimensional spatial frequency spectrum, but otherwise the information is the same as before: namely, information about the direction and magnitude of the simple wave types.

The sound field from a point source cannot be explained by simple plane waves such as those in Figures 27.16 and 27.17, as the amplitude decreases with the distance from the origin. The plane waves retain the same magnitude over the full plane. Thus, to describe the near-field phenomenon, one must introduce evanescent waves. In the one-dimensional Fourier spectrum, the evanescent waves can be identified as spatial frequencies higher than $k_0 = 2\pi f/c$. Similarly, in the two-dimensional spatial frequency spectrum, the evanescent waves can be identified as having spatial frequencies or wavenumbers higher than k_0 .

The individual spatial frequencies in the two-dimensional spatial frequency spectrum correspond to simple plane waves or evanescent waves in the scan plane (i.e., the measurement plane). For each of these simple wave types, it is easy to calculate the pressure in other planes, see Figure 27.18. For the plane waves, a simple phase shift of the wave is required to calculate the result in a new plane. For the evanescent waves, the changes in amplitude must be taken into account; but in principle, this is also a simple transfer function applied to the two-dimensional spatial frequency spectrum. In this way, the two-dimensional spatial frequency spectrum in a new plane can be calculated from the original data by applying simple transfer function operations. The new two-dimensional spatial frequency spectrum is then an inverse Fourier transform (in two dimensions) to get the sound field in the new plane.

FIGURE 27.17 Spatial spectrum of two waves propagating in different directions.

The overall principle of near-field acoustic holography can be simplified as in Figure 27.19. The sound field is scanned in a plane close to the measuring object. This gives an array of temporal spectra, one for each scan position. Looking at one temporal frequency at a time, one takes out the information from each of the spectra corresponding to the actual frequency of interest. This generates a new array with information about only one temporal frequency. A Fourier transform (in two dimensions) is then applied to the array to generate a two-dimensional spatial frequency spectrum. This can then be transformed to new planes using simple transfer function operations. When the two-dimensional spatial frequency spectrum in the new plane has been calculated, an inverse Fourier transform is used to obtain the new pressure distribution in the new plane. In principle, the NAH technique requires that all cross-spectra between all the scan positions are given; that is, in each of the scan positions, all the cross-spectra to all other scan positions must be determined. A simple scan of a sound field with 2540 scan positions, defining $N = 1000$ scan positions, would result in $\frac{1}{2}N(N + 1) = 500,500$ cross-spectra. Instead of measuring all these cross-spectra, the system uses a set of reference transducers to reduce the amount of cross-spectra. The number of necessary reference transducers to give a complete description of the sound field without measuring the full amount of data is determined by the complexity of the sound field. A measurement

FIGURE 27.18 Transformation of simple wave types in a spatial spectrum, from one measurement plane to another plane.

with, for example, four reference transducers and 2540 scan positions will then be reduced to $4N = 4000$ cross-spectrum measurements.

27.10 Calibration

In order to make accurate and reliable measurements, the microphone and connected instruments must be properly calibrated. The calibration of measurement microphones can be divided into two parts: a level calibration and a frequency response calibration. The *level calibration* establishes the output signal of the microphone for a given acoustic input signal at a given frequency, while the *frequency response* gives the output at other frequencies relative to the level calibration frequency. The level calibration can be performed by a number of different methods with different accuracies.

The most accurate method is the *reciprocity calibration method*. This method utilizes the fact that a condenser microphone is a reciprocal transducer; that is, it can be used as a microphone (to convert an acoustical signal to a voltage signal) and as a loudspeaker (to convert a voltage signal into an acoustical signal). By measuring the relationship between three test microphones driven as both transmitters and receivers, one obtains a set of three equations with the three microphone sensitivities as the unknowns. By solving these three equations, one obtains the sensitivity of the three microphones. The reciprocity calibration method is very accurate but rather tedious and requires well-controlled environmental conditions and is therefore seldom used in practical situations.

The comparison or substitution methods are essentially identical in that they are based on measuring the differences between the test microphone and a reference microphone with known sensitivity. In this case, the reference microphone is often calibrated at an accredited national acoustical laboratory like NIST, NPL, or PTB, whereby the traceability is ensured. In the substitution method, the acoustical output of a sound source is measured with the reference microphone. Afterward, the reference microphone is replaced with a test microphone and the output is measured again. Provided that the sound source has

FIGURE 27.19 Overall principle of NAH: (a) measurement of cross-spectra in the scan plane; (b) calculation for one temporal frequency at a time; (c) 2-D spatial Fourier transformation; (d) transformation of simple wave types; (e) inverse 2-D transformation; (f) to obtain the sound field in the new plane.

been stable, the sensitivity of the test microphone can then be calculated. The comparison method is similar to the substitution method, except that the reference microphone and the test microphone are subjected to the same sound pressure simultaneously and therefore the requirements to the sound source stability are less important.

An often-used method for microphone calibration is the *pistonphone method*. The pistonphone, [Figure 27.20](#), is a very stable sound source, which produces a well-defined sound pressure level inside a closed coupler. It works by volume displacements, [Figure 27.21](#), with a well-defined velocity, usually at 250 Hz. As the piston is moving in and out, the volume of the closed coupler is changed and this will result in pressure variations. The actual pressure level obtained in the pistonphone depends on the volume of the coupler, the volume displacement of the pistons, the barometric pressure, and—to a lesser degree—on other factors such as humidity, heat dissipation, etc. As the pistonphone is based on a relatively simple mechanical system, it is very reliable and easy to use in practice, with an accuracy around 0.1 dB. Also, the pistonphone is often used as the stable sound source for calibrations using comparisons or substitution methods.

A *sound pressure calibrator* is basically a small self-contained comparison calibration device. The test microphone is inserted into a small, closed volume and a small loudspeaker produces a single frequency signal, usually at 1 kHz. The output level of the loudspeaker is controlled in a feedback system with a signal from a reference microphone. Provided that the reference microphone and the feedback gain are

FIGURE 27.20 Pistonphone for microphone calibration.

stable, the sound level at the test microphone will be well-defined and the sensitivity can be determined. The sound level calibrators are normally not used to make accurate microphone calibrations, but rather to make field checks of the integrity of a complete measurement system.

The frequency response of a microphone is most often determined by the *electrostatic actuator method*. A conducting grid is placed close to and parallel to the microphone diaphragm. An electric field is established between the actuator and the diaphragm by applying 800 V dc to the actuator. A test signal of 50 to 150 V ac is superimposed on the dc signal, and the electrostatic forces will push and pull the

FIGURE 27.21 Principle of a pistonphone.

diaphragm, similar to a sound pressure of 1 to 10 Pa. By sweeping the test signal through the frequencies of interest, the pressure response of the test microphone can be recorded. The electrostatic actuator technique is widely used as a convenient and accurate test method, both during production and final calibration of measurement microphones.

Available instrumentation and manufacturers are given in [Tables 27.4](#) and [27.5](#).

28.1 Differential Pressure Flowmeters

Richard Thorn

Flow measurement is an everyday event. Whether you are filling up a car with petrol (gasoline) or wanting to know how much water the garden sprinkler is consuming, a flowmeter is required. Similarly, it is also difficult to think of a sector of industry in which a flowmeter of one type or another does not play a part. The world market in flowmeters was estimated to be worth \$2500 million in 1995, and is expected to grow steadily for the foreseeable future. The value of product being measured by these meters is also very large. For example, in the U.K. alone, it was estimated that in 1994 the value of crude oil produced was worth \$15 billion.

Given the size of the flowmeter market, and the value of product being measured, it is somewhat surprising that both the accuracy and capability of many flowmeters are poor in comparison to those instruments used for measurement of other common process variables such as pressure and temperature. For example, the orifice plate flowmeter, which was first used commercially in the early 1900s and has a typical accuracy of $\pm 2\%$ of reading, is still the only flowmeter approved by most countries for the fiscal measurement of natural gas. Although newer techniques such as Coriolis flowmeters have become increasingly popular in recent years, the flow measurement industry is by nature conservative and still dominated by traditional measurement techniques. For a review of recent flowmeter developments, refer to [1].

Over 40% of all liquid, gas, and steam measurements made in industry are still accomplished using common types of *differential pressure flowmeter*; that is, the orifice plate, Venturi tube, and nozzle. The operation of these flowmeters is based on the observation made by Bernoulli that if an annular restriction is placed in a pipeline, then the velocity of the fluid through the restriction is increased. The increase in velocity at the restriction causes the static pressure to decrease at this section, and a pressure difference is created across the element. The difference between the pressure upstream and pressure downstream of this obstruction is related to the rate of fluid flowing through the restriction and therefore through the pipe. A differential pressure flowmeter consists of two basic elements: an obstruction to cause a pressure drop in the flow (a *differential producer*) and a method of measuring the pressure drop across this obstruction (a *differential pressure transducer*).

One of the major advantages of the orifice plate, Venturi tube, or nozzle is that the measurement uncertainty can be predicted without the need for calibration, if it is manufactured and installed in accordance with one of the international standards covering these devices. In addition, this type of differential pressure flowmeter is simple, has no moving parts, and is therefore reliable. The main disadvantages of these devices are their limited range (typically 3:1), the permanent pressure drop they produce in the pipeline (which can result in higher pumping costs), and their sensitivity to installation effects (which can be minimized using straight lengths of pipe before and after the flowmeter). The combined advantages of this type of flowmeter are still quite hard to beat, and although it has limitations, these have been well investigated and can be compensated for in most circumstances. Unless very high accuracy is required, or unless the application makes a nonintrusive device essential, the differential flowmeter should be considered. Despite the predictions of its demise, there is little doubt that the differential pressure flowmeter will remain a common method of flow measurement for many years to come.

Important Principles of Fluid Flow in Pipes

There are a number of important principles relating to the flow of fluid in a pipe that should be understood before a differential pressure flowmeter can be used with confidence. These are the difference

between laminar and turbulent flow, the meaning of Reynolds number, and the importance of the flow's velocity profile.

Fluid motion in a pipe can be characterized as one of three types: laminar, transitional, or turbulent. In *laminar flow*, the fluid travels as parallel layers (known as streamlines) that do not mix as they move in the direction of the flow. If the flow is turbulent, the fluid does not travel in parallel layers, but moves in a haphazard manner with only the average motion of the fluid being parallel to the axis of the pipe. If the flow is *transitional*, then both types may be present at different points along the pipeline or the flow may switch between the two.

In 1883, Osborne Reynolds performed a classic set of experiments at the University of Manchester that showed that the flow characteristic can be predicted using a dimensionless number, now known as the Reynolds number. The Reynolds number Re is the ratio of the inertia forces in the flow ($\rho\bar{v}D$) to the viscous forces in the flow (η) and can be calculated using:

$$Re = \frac{\rho\bar{v}D}{\eta} \quad (28.1)$$

where ρ = Density of the fluid

\bar{v} = Mean velocity of the fluid

D = Pipe diameter

η = Dynamic viscosity of the fluid

If Re is less than 2000, viscous forces in the flow dominate and the flow will be laminar. If Re is greater than 4000, inertia forces in the flow dominate and the flow will be turbulent. If Re is between 2000 and 4000, the flow is transitional and either mode can be present. The Reynolds number is calculated using mainly properties of the fluid and does not take into account factors such as pipe roughness, bends, and valves that also affect the flow characteristic. Nevertheless, the Reynolds number is a good guide to the type of flow that can be expected in most situations.

The fluid velocity across a pipe cross-section is not constant, and depends on the type of flow present. In laminar flow, the velocity profile is parabolic since the large viscous forces present cause the fluid to move more slowly near the pipe walls. Under these conditions, the velocity at the center of the pipe is twice the average velocity across the pipe cross-section. The laminar flow profile is unaffected by the roughness of the pipe wall. In turbulent flow, inertia forces dominate, pipe wall effects are less, and the flow's velocity profile is flatter, with the velocity at the center being about 1.2 times the mean velocity. The exact flow profile in a turbulent flow depends on pipe wall roughness and Reynolds number. [Figure 28.1](#) shows the "fully developed" flow profiles for laminar and turbulent flow. These are the flow profiles that would be obtained at the end of a very long pipe, thus ensuring that any changes to the flow profile due to pipe bends and fittings are no longer present. To have confidence in the performance of a differential pressure flowmeter, both the characteristic and velocity profile of the flow passing through the flowmeter should be stable and known.

Bernoulli's Equation

The Bernoulli equation defines the relationship between fluid velocity (v), fluid pressure (p), and height (h) above some fixed point for a fluid flowing through a pipe of varying cross-section, and is the starting point for understanding the principle of the differential pressure flowmeter. For the inclined, tapered pipe shown in [Figure 28.2](#), Bernoulli's equation states that:

$$\frac{p_1}{\rho g} + \frac{v_1^2}{2g} + h_1 = \frac{p_2}{\rho g} + \frac{v_2^2}{2g} + h_2 \quad (28.2)$$

FIGURE 28.1 Velocity profiles in laminar and turbulent flow.

FIGURE 28.2 Flow through an inclined, tapered pipe.

Thus, the sum of the pressure head ($p/\rho g$), the velocity head ($v/2g$), and potential head (h) is constant along a flow streamline. The term “head” is commonly used because each of these terms has the unit of meters. Equation 28.2 assumes that the fluid is frictionless (zero viscosity) and of constant density (incompressible). Further details on the derivation and significance of Bernoulli’s equation can be found in most undergraduate fluid dynamics textbooks (e.g., [2]).

Bernoulli’s equation can be used to show how a restriction in a pipe can be used to measure flow rate. Consider the pipe section shown in Figure 28.3. Since the pipe is horizontal, $h_1 = h_2$, and Equation 28.2 reduces to:

$$\frac{P_1 - P_2}{\rho} = \frac{v_1^2 - v_2^2}{2} \quad (28.3)$$

The conservation of mass principle requires that:

FIGURE 28.3 Using a restriction in a pipe to measure fluid flow rate.

$$v_1 A_1 \rho = v_2 A_2 \rho \quad (28.4)$$

Rearranging Equation 28.4 and substituting for v_2 in Equation 28.3 gives:

$$Q = v_1 A_1 = \frac{A_2}{\sqrt{1 - \left(\frac{A_2}{A_1}\right)^2}} \sqrt{\frac{2(p_1 - p_2)}{\rho}} \quad (28.5)$$

This shows that the volumetric flow rate of fluid Q can be determined by measuring the drop in pressure ($p_1 - p_2$) across the restriction in the pipeline — the basic principle of all differential pressure flowmeters. Equation 28.5 has limitations, the main ones being that it is assumed that the fluid is incompressible (a reasonable assumption for most liquids), and that the fluid has no viscosity (resulting in a flat velocity profile). These assumptions need to be compensated for when Equation 28.5 is used for practical flow measurement.

Common Differential Pressure Flowmeters

The Orifice Plate

The orifice plate is the simplest and cheapest type of differential pressure flowmeter. It is simply a plate with a hole of specified size and position cut in it, which can then clamped between flanges in a pipeline (Figure 28.4). The increase that occurs in the velocity of a fluid as it passes through the hole in the plate results in a pressure drop being developed across the plate. After passing through this restriction, the fluid flow jet continues to contract until a minimum diameter known as the vena contracta is reached. If Equation 28.5 is used to calculate volumetric flow rate from a measurement of the pressure drop across the orifice plate, then an error would result. This is because A_2 should strictly be the area of the vena contracta, which of course is unknown. In addition, turbulence between the vena contracta and the pipe wall results in an energy loss that is not accounted for in this equation.

To overcome the problems caused by the practical application of Equation 28.5, two empirically determined correction factors are added. After some reorganization Equation 28.5 can be written as:

FIGURE 28.4 A square-edged orifice plate flowmeter.

$$Q = \frac{C}{\sqrt{1-\beta^4}} \varepsilon \frac{\pi}{4} d^2 \sqrt{\frac{2(p_1 - p_2)}{\rho}} \quad (28.6)$$

where ρ = Density of the fluid upstream of the orifice plate

d = Diameter of the hole in the orifice plate

β = Diameter ratio d/D , where D is the upstream internal pipe diameter

The two empirically determined correction factors are C the discharge coefficient, and ε the expansibility factor. C is affected by changes in the diameter ratio, Reynolds number, pipe roughness, the sharpness of the leading edge of the orifice, and the points at which the differential pressure across the plate are measured. However, for a fixed geometry, it has been shown that C is only dependent on Reynolds number and so this coefficient can be determined for a particular application. ε is used to account for the compressibility of the fluid being monitored. Both C and ε can be determined from equations and tables in a number of internationally recognized documents known as standards. These standards not only specify C and ε , but also the geometry and installation conditions for the square-edged orifice plate, Venturi tube, and nozzle, and are essentially a design guide for the use of the most commonly used types of differential pressure flowmeter. Installation recommendations are intended to ensure that fully developed turbulent flow conditions exist within the measurement section of the flowmeter. The most commonly used standard in Europe is ISO 5167-1 [3], while in the U.S., API 2530 is the most popular [4]. There are differences between some of the recommendations in these two standards (e.g., the minimum recommended length of straight pipe upstream of the flowmeter), but work is underway to resolve these.

Equation 28.6 illustrates perhaps the greatest strength of the orifice plate, which is that measurement performance can be confidently predicted without the need for calibration if the device is manufactured, installed, and operated in accordance with one of the international standards. In addition, the device is cheap to manufacture, has no moving parts, is reliable, and can be used for metering most clean gases, liquids, and steam.

FIGURE 28.5 A Venturi tube flowmeter.

The major disadvantages of the orifice plate are its limited range and sensitivity to flow disturbances. The fact that fluid flow rate is proportional to the square root of the measured differential pressure limits the range of a one plate/one differential pressure transmitter combination to about 3:1. The required diameter ratio (also known as beta ratio) of the plate depends on the maximum flow rate to be measured and the range of the differential pressure transducer available. Sizing of the orifice plate is covered in most of the books in the further reading list, and nowadays computer programs are also available to help perform this task. The flow measurement range can be increased by switching; ways in which this may be achieved are described in [5]. Equation 28.6 assumes a fully developed and stable flow profile, and so installation of the device is critical, particularly the need for sufficient straight pipework upstream of the meter. Wear of the leading edge of the orifice plate can severely alter measurement accuracy; thus, this device is normally only used with clean fluids.

Only one type of orifice plate, the square-edged concentric, is covered by the standards. However, other types exist, having been designed for specific applications. One example is the eccentric orifice plate, which is suited for use with dirty fluids. Details of these other types of orifice plate can be found in [6].

The Venturi Tube

The classical or Herschel Venturi tube is the oldest type of differential pressure flowmeter, having first been used in 1887. As Figure 28.5 shows, a restriction is introduced into the flow in a more gradual way than for the orifice plate. The resulting flow through a Venturi tube is closer to that predicted in theory by Equation 28.5 and so the discharge coefficient C is much nearer unity, being typically 0.95. In addition, the permanent pressure loss caused by the Venturi tube is lower, but the differential pressure is also lower than for an orifice plate of the same diameter ratio. The smooth design of the Venturi tube means that it is less sensitive to erosion than the orifice plate, and thus more suitable for use with dirty gases or liquids. The Venturi tube is also less sensitive to upstream disturbances, and therefore needs shorter lengths of straight pipework upstream of the meter than the equivalent orifice plate or nozzle. Like the orifice plate and nozzle, the design, installation, and use of the Venturi tube is covered by a number of international standards.

The major disadvantages of the Venturi tube flowmeter are its size and cost. It is more difficult, and therefore more expensive to manufacture than the orifice plate. Since a Venturi tube can be typically 6 diameters long, it can become cumbersome to use with larger pipe sizes, with associated maintenance of upstream and downstream pipe lengths also becoming a problem.

The Nozzle

The nozzle (Figure 28.6) combines some of the best features of the orifice plate and Venturi tube. It is compact and yet, because of its curved inlet, has a discharge coefficient close to unity. There are a number of designs of nozzle, but one of the most commonly used in Europe is the ISA-1932 nozzle, while in the U.S., the ASME long radius nozzle is more popular. Both of these nozzles are covered by international standards.

FIGURE 28.6 A nozzle flowmeter.

The smooth inlet of the nozzle means that it is more expensive to manufacture than the orifice plate as the curvature of the inlet changes with diameter ratio, although it is cheaper than the Venturi tube. The device has no sharp edges to erode and cause changes in calibration, and thus is well suited for use with dirty and abrasive fluids. The nozzle is also commonly used for high-velocity, high-temperature applications such as steam metering.

A variation of the nozzle is the sonic (or critical flow Venturi) nozzle, which has been used both as a calibration standard for testing gas meters and a transfer standard in interlaboratory comparisons [7].

Other Differential Pressure Flowmeters

There are many other types of differential pressure flowmeter, including the segmental wedge, V-cone, elbow, and Dall tube. Each of these has advantages over the orifice plate, Venturi tube, and nozzle for specific applications. For example, the segmental wedge can be used with flows having a low Reynolds number, and a Dall tube has a lower permanent pressure loss than a Venturi tube. However, none of these instruments are yet covered by international standards and, thus, calibration is needed to determine their accuracy. Further information on these, and other less-common types of differential pressure flowmeter, can be found in [8].

Performance and Applications

Table 28.1 shows the performance characteristics and main application areas of the square-edged orifice plate, Venturi tube, and nozzle flowmeters. Compared to other types of flowmeters on the market, these differential pressure flowmeters only have moderate accuracy, typically $\pm 2\%$ of reading; but of course, this can be improved if the device is calibrated after installation. Although in some circumstances these flowmeters can be used with dirty gases or liquids, usually only small amounts of a second component can be tolerated before large measurement errors occur. When calculating the cost and performance of a differential flowmeter, both the primary element and the differential pressure transducer should be taken into account. Although the orifice plate is the cheapest of the primary elements, the cost of the fitting needed to mount it in the pipeline, particularly if on-line removal is required, can be significant.

Choosing which flowmeter is best for a particular application can be very difficult. The main factors that influence this choice are the required performance, the properties of the fluid to be metered, the

TABLE 28.1 The Performance and Application Areas of Common Differential Pressure Flowmeters

	Performance					Applications				
	Typical uncalibrated accuracy	Typical range	Typical pipe diameter (mm)	Permanent pressure loss	Comparative cost	Clean gas	Dirty gas	Clean liquid	Slurry	Steam
Orifice plate	±2%	3:1	10–1000	High	Low	Yes	No	Yes	No	Yes

installation requirements, the environment in which the instrument is to be used, and, of course, cost. There are two standards that can be used to help select a flowmeter: BS 1042: Section 1.4, which is a guide to the use of the standard differential pressure flowmeters [9]; and BS 7405, which is concerned with the wider principles of flowmeter selection [10].

Because all three flowmeters have similar accuracy, one strategy for selecting the most appropriate instrument is to decide if there are any good reasons for not using the cheapest flowmeter that can be used over the widest range of pipe sizes: the orifice plate. Where permanent pressure loss is important, the Venturi tube should be considered, although the high cost of this meter can only usually be justified where large quantities of fluid are being metered. For high-temperature or high-velocity applications, the nozzle should be considered because under these conditions, it is more predictable than the orifice plate. For metering dirty fluids, either the Venturi tube or the nozzle should be considered in preference to the orifice plate, the choice between the two depending on cost and pressure loss requirements. [Table 28.2](#) lists some suppliers of differential pressure flowmeters.

Installation

Correct installation is essential for successful use of a differential pressure flowmeter because the predicted uncertainty in the flow rate/differential pressure relationship in Equation 28.6 assumes a steady flow,

TABLE 28.3 The Minimum Straight Lengths of Pipe Required between Various Fittings and an Orifice Plate or Venturi Tube (as recommended in ISO 5167-1) to Ensure That a Fully Developed Flow Profile Exists in the Measurement Section. All Lengths Are Multiples of the Pipe Diameter

Diameter Ratio β	Upstream of the flowmeter			Downstream of the flowmeter	
	Single 90° bend	Two 90° bends in the same plane	Two 90° bends in different planes	Globe valve fully open	For any of the fittings shown to the left
0.2	10	14	34	18	4
0.4	14	18	36	20	6
0.6	18	26	48	26	7
0.8	46	50	80	44	8

with a fully developed turbulent velocity profile, is passing through the flowmeter. Standards contain detailed recommendations for the minimum straight lengths of pipe required before and after the flowmeter, in order to ensure a fully developed flow profile. Straight lengths of pipe are required after the flowmeter because disturbances caused by a valve or bend can travel upstream and thus also affect the installed flowmeter. Table 28.3 gives examples of installation requirements taken from ISO 5167-1. If it is not possible to fit the recommended lengths of straight pipe before and after the flowmeter, then the flowmeter must be calibrated once it has been installed.

The other major problem one faces during installation is the presence of a rotating flow or swirl. This condition distorts the flow velocity profile in a very unpredictable way, and is obviously not desirable. Situations that create swirl, such as two 90° bends in different planes, should preferably be avoided. However, if this is not possible, then swirl can be removed by placing a flow conditioner (also known as a flow straightener) between the source of the swirl and the flowmeter. There are a wide range of flow conditioner designs, some of which can be used to both remove swirl and correct a distorted velocity profile [11]. Because they obstruct the flow, all flow conditioners produce an unrecoverable pressure loss, which in general increases with their capability (and complexity).

Differential Pressure Measurement

Apart from the differential producer, the other main element of a differential pressure flowmeter is the *transducer* needed to measure the pressure drop across the producer. The correct selection and installation of the differential pressure transducer plays an important part in determining the accuracy of the flow rate measurement.

The main factors that should be considered when choosing a differential pressure transducer for a flow measurement application are the differential pressure range to be covered, the accuracy required, the maximum pipeline pressure, and the type and temperature range of the fluid being metered.

Most modern differential pressure transducers consist of a pressure capsule in which either capacitance, strain gage, or resonant wire techniques are used to detect the movement of a diaphragm. Using these techniques, a typical accuracy of $\pm 0.1\%$ of full scale is possible. See Chapter 26, Section 1 for further details of pressure transducers. The transducer is usually part of a unit known as a transmitter, which converts differential pressure, static pressure, and ambient temperature measurements into a standardized analog or digital output signal. “Smart” transmitters use a local, dedicated microprocessor to condition signals from the individual sensors and compute volumetric or mass flow rate. These devices can be remotely configured, and a wide range of diagnostic and maintenance functions are possible using their built-in “intelligence.”

As far as installation is concerned, the transmitter should be located as close to the differential producer as possible. This helps ensure a fast dynamic response and reduces problems caused by vibration of the connecting tubes. The position of the pressure tappings is also important. If liquid flow in a horizontal pipe is being measured, then the pressure tappings should be located at the side of the pipe so that they cannot be blocked with dirt or filled with air bubbles. For horizontal gas flows, if the gas is clean, the pressure tappings should be vertical; if steam or dirty gas is being metered, then the tappings should be

located at the side of the pipe. These general guidelines show that considerable care must be taken with the installation of the differential pressure transmitter if large measurement errors are to be avoided. For further details on the installation of differential pressure transmitters, see ISO 2186 [12].

Standards

International standards that specify the design, installation, and use of the orifice plate, Venturi tube, and nozzle, and allow their accuracy to be calculated without the need for calibration, are probably the main reason for the continuing use of this type of flowmeter. Table 28.4 gives details of the most common standards related to differential pressure flowmeters. There are still inconsistencies in the various standards. For example, ISO 5167-1 states that any flow conditioner should be preceded by at least 22 diameters of straight pipe and followed by at least 20 diameters of straight pipe. This would seem to contradict one application of a flow conditioner, which is to reduce the length of straight pipe required upstream of a flowmeter.

Despite the occasional inconsistency and difference between the standards, they are the internationally accepted rules for the installation and use of the square-edged orifice plate, Venturi tube, and nozzle.

Future Developments

In spite of the vast amount of published data available on differential pressure flowmeters, continued research is needed to improve the understanding of the effect of flow conditions, and flowmeter geometry, on the uncalibrated accuracy of these devices. For example, work has been recently undertaken to derive an improved equation for the discharge coefficient of an orifice plate [13].

The metering of multiphase flow is an area of increasing importance. In addition to developing new measurement techniques, many people are investigating ways in which traditional flowmeters can be used to meter multiphase flows. A good review of the use of differential pressure flowmeters for multiphase flow measurement can be found in [14].

The development of “smart” differential pressure transmitters has overcome the limitations of differential pressure flowmeters in some applications. For example, these devices are being used to linearize and extend the range of differential pressure flowmeters.

The above developments should help to ensure the continued popularity of the differential pressure flowmeter for the foreseeable future, despite increasing competition from newer types of instrument.

Defining Terms

Differential pressure flowmeter: A flowmeter in which the pressure drop across an annular restriction placed in the pipeline is used to measure fluid flow rate. The most common types use an orifice plate, Venturi tube, or nozzle as the primary device.

Orifice plate: Primary device consisting of a thin plate in which a circular aperture has been cut.

Venturi tube: Primary device consisting of a converging inlet, cylindrical mid-section, and diverging outlet.

Nozzle: Primary device consisting of a convergent inlet connected to a cylindrical section.

Differential pressure transmitter: Secondary device that measures the differential pressure across the primary device and converts it into an electrical signal.

28.2 Variable Area Flowmeters

Adrian Melling, Herbert Köchner, and Reinhard Haak

The term *variable area flowmeters* refers to those meters in which the minimum cross-sectional area available to the flow through the meter varies with the flow rate. Meters of this type that are discussed in this section include the rotameter and the movable vane meter used in pipe flows, and the weir or flume used in open-channel flows. The measure of the flow rate is a geometrical quantity such as the height of a bob in the rotameter, the angle of the vane, or the change in height of the free surface of the liquid flowing over the weir or through the flume.

Most of the discussion here is devoted to the rotameter, firstly because the number of installed rotameters and movable vane meters is large relative to the number of weirs and flumes, and secondly because the movable vane is often used simply as a flow indicator rather than as a meter.

The following section includes basic information describing the main constructional features and applications of each type of meter. In the third section, the principles of measurement and design of rotameters and open-channel meters are described in some detail; the movable vane meter is not considered further because most design aspects are similar to those of rotameters. Then, the contribution of modern computational and experimental methods of fluid mechanics to flowmeter design is discussed, using the results of a detailed investigation of the internal flow.

Details of manufacturers of rotameters and movable vane meters, together with approximate costs of these meters, are also tabulated in [Tables 28.5 through 28.7](#).

General Description of Variable Area Flowmeters

Rotameter

The *rotameter* is a robust and simple flowmeter for gases and liquids, and holds a large share of the market for pipe diameters smaller than about 100 mm. In its basic form, the rotameter consists of a conical transparent vertical glass tube containing a “bob” ([Figure 28.7](#)), which rises in the tube with increasing flow rate until a balance is reached between gravitational, buoyancy, and drag forces on the bob. Within the range of a particular flowmeter (depending on the bob shape and density, the tube shape and the fluid density and viscosity), the flow rate is linearly proportional to the height of the bob in the tube and is determined simply by reading the level of the upper edge of the bob. The rotameter is also

TABLE 28.5 Approximate Rotameter Prices

Type	Size	Price (plastic)	Price (stainless steel, borosilicate glass)
Glass	< 1/2 in. (12.7 mm)	\$50	\$200
Plastic	1/2 in. (12.7 mm)	\$50	\$200
	1 in. (25.4 mm)	\$70	\$150
	2 in. (50.8 mm)	\$200	\$500
Metal	1/2 in. (12.7 mm)		\$500
	1 in. (25.4 mm)		\$600
	2 in. (50.8 mm)		\$700
	3 in. (76.2 mm)		\$1100
	4 in. (101.6 mm)		\$1400
Additional costs			
	Electric limit switch	\$100	
	Current transducer	\$500	
	Pneumatic	\$1200	

TABLE 28.6 Approximate Movable Vane Meter Prices

Type	Price
Plastic versions (small scale)	From \$10
Direct coupled pointer versions incl. electric flow switch: Metal, screw connections 1/2 in. (12.7 mm) to 2 in. (50.8 mm)	\$400 (brass) to \$600 (stainless steel)
Flanged versions	Add \$200 (1/2 in., 12.7 mm) to \$400 (2 in., 50.8 mm)
Magnetic coupled indicator, stainless steel	\$1200 (1/2 in., 12.7 mm) to \$2100 (8 in., 203 mm)

known as “floating element flowmeter,” although the buoyancy force on the “floating element” is not sufficient to make it float.

The bob is commonly formed of a combination of cylindrical and conical sections, but a spherical bob is often used in small diameter tubes (see [Figures 28.8](#)). More complicated bob geometries can reduce the sensitivity to viscosity of the fluid. Frequently, the bob has several shallow inclined grooves around the upper rim that induce a slow rotation (frequency about 1 Hz) of the bob, which helps to maintain a stable position of the bob. In larger rotameters where the additional friction is acceptable, the bob can be allowed to slide up and down a rod on the tube axis to prevent any sideways motion.

Various tube geometries are in use. The basic requirement for an increase in the cross-sectional area up the height of the tube leads to the conical tube. An alternative form uses three ribs arranged circumferentially around the tube to guide the bob; the flow area between the ribs increases along the tube height. For spherical bobs, a triangular tube in which the bob remains in contact with three surfaces over the whole height of the tube prevents lateral movement of the bob with minimum friction. Commonly, the tube is made of glass to facilitate the reading of the flow rate from a scale engraved on the tube. For general-purpose applications, the scale can be marked in millimeters; the flow rate is then determined by a conversion factor depending on the tube dimensions, the mass of the bob, the pressure and temperature, and the properties of the fluid. For specific application to a single fluid under controlled conditions, it is more convenient to have the flow rate directly marked on the tube.

For laboratory use, medical equipment, and other applications with small flow rates, the glass tube is almost universal. Laboratory meters are often equipped with a flow valve that allows direct flow setting and reading. For many small rotameters, integrated flow controllers are offered; these hold the pressure drop and the flow setting constant, even with changing upstream or downstream pressure.

For most rotameters, electric limit switches or analog electric signal transducers are available. For glass and plastic meters, inductive or optical switches are used that can be positioned to the desired level of

the bob. While some units just detect the bob within their active area, other switches have bistable operation, wherein the switch is toggled by the float passing the switch.

For industrial applications, the metering of corrosive fluids or fluids at high temperature or pressure leads to the use of stainless steel tubes or a wide range of other materials chosen to suit the application requirements (e.g., temperature, pressure, corrosion). Most metal rotameters use a permanent magnetic coupling between the float and the pointer of the indicator, enabling a direct analog flow reading without electric supply. Electric switches can, however, be added to the indicator, and electric and pneumatic transmitters for the flow reading are offered by most producers. Some units are equipped with options such as flow totalizers, mass flow calculation units for gas applications in conjunction with temperature and pressure sensors, or energy calculation units. Due to the frequent application of the rotameter in the chemical and petrochemical industry, electric options are often designed for use in hazardous areas.

The rotameter is characterized by:

- Simple and robust construction
- High reliability
- Low pressure drop

FIGURE 28.7 Cross-section of a rotameter. The level of the bob rises linearly with increasing flow rate.

FIGURE 28.8 Typical rotameter bob geometries.

FIGURE 28.9 Movable vane meter. The magnet (N,S) transmits the vane position to an indicator.

- Applicable to a wide variety of gases and liquids
- Flow range typically 0.04 L h^{-1} to $150 \text{ m}^3 \text{ h}^{-1}$ for water
- Flow range typically 0.5 L h^{-1} to $3000 \text{ m}^3 \text{ h}^{-1}$ for air
- 10:1 flow range for given bob-tube combination
- Uncertainty 0.4% to 4% of maximum flow
- Insensitivity to nonuniformity in the inflow (no upstream straight piping needed)
- Typical maximum temperature 400°C
- Typical maximum pressure 4 MPa (40 bar)
- Low investment cost
- Low installation cost

Movable Vane Meter

The movable vane meter is a robust device suitable for the measurement of high flow rates where only moderate requirements on the measurement accuracy are made. Dirty fluids can also be metered. It contains a flap that at zero flow is held closed by a weight or a spring (Figure 28.9). A flow forces the vane open until the dynamic force of the flow is in balance with the restoring force of the weight or the spring. The angle of the vane is thus a measure of the flow rate, which can be directly indicated by a pointer attached to the shaft of the vane on a calibrated scale. The resistance provided by the vane depends on the vane position and hence on the flow rate or Reynolds number; a recalibration is therefore necessary when the fluid is changed. An important application is the metering of the air flow in automotive engines with fuel injection.

In low-cost flow indicators, a glass or plastic window allows a direct view of the flap (Figure 28.10). Sometimes, optical or reed switches in combination with a permanent magnet attached to the flap are used as electric flow switches. All-metal units use a magnetic coupling between the vane and the pointer of the indicator, thus avoiding most of the friction and material selection problems. Many applications use the movable vane meter as a flow switch with appropriate mechanical, magnetic, inductive, or optical switches. The setting of the switch is done once for all during the installation. Since a continuous flow indication is not needed, flow reading uncertainties are not of concern.

Most aspects of design and application of rotameters can be applied to movable vane meters, although the latter are characterized by a higher uncertainty of the flow reading. General features of both types of variable area flowmeter are summarized, for example, in reference [1]. Since the basic construction of the two meter types is very similar, the unit costs also lie in the same range.

FIGURE 28.10 Flow indicator. The angle of the vane provides a measure of the flow rate.

Weir, Flume

Of the methods available for the metering of a liquid (generally water) in open-channel flow, the weir and the flume fall within the scope of this discussion on variable area flowmeters. In each case, the flow metering depends on measurement of the difference in height h of the water surface over an obstruction across the channel and the surface sufficiently far upstream. There is a wide variety of geometries in use (see reference [2]), but most of these can be described as variants of three basic types. In the sharp crested weir, also known as the thin plate weir (Figure 28.11), the sill or crest is only about 1 mm to 2 mm thick. The sheet of liquid flowing over the weir, called the nappe or vein, separates from the weir body after passing over the crest. An air-filled zone at atmospheric pressure is formed underneath the outflowing jet, and the streamlines above the weir are strongly curved. If the width of the weir is less than that of the upstream channel (Figures 28.12 and 28.13), the term “notch” is frequently used. A broad crested weir (Figure 28.14) has a sill which is long enough for straight, parallel streamlines to form above the crest. In this review, the term “weir” is applied generally to both the weir and the notch.

The resistance to flow introduced by the weir causes the water level upstream to rise. If it is assumed that the flow velocity some distance upstream of the weir is zero, then a simple measure of the upstream water level suffices to determine the discharge over a weir of known geometry. As in the case of an orifice in pipe flow, there will be a contraction of the nappe and a frictional resistance at the sides as water flows over a weir. The actual discharge is less than the theoretical discharge according to an empirically determined coefficient of discharge C_d . In the analysis of rectangular notches and weirs, it is frequently assumed that the channel width remains constant so that a contraction of the nappe occurs only in the vertical direction as the water accelerates over the obstacle. When the weir is narrower than the upstream channel, there is an additional horizontal contraction. The effect of a significant upstream velocity is accounted for empirically.

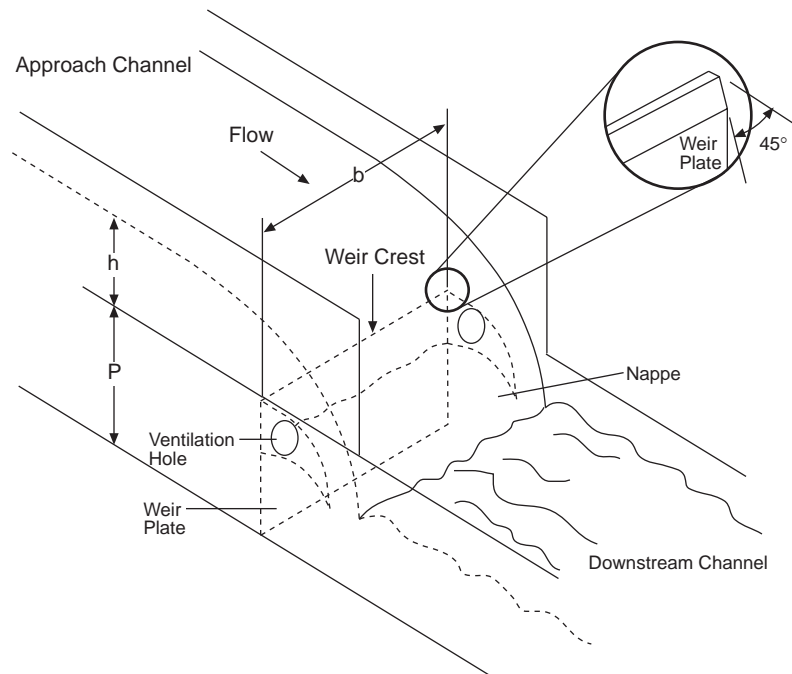

FIGURE 28.11 Full-width thin plate weir. Flow rate \dot{Q} varies with water level h above the weir crest ($\dot{Q} \sim h^{3/2}$) and with a flow-dependent discharge coefficient C_d .

As an alternative to the weir, the flume (Figure 28.15) provides a method for flow metering with relatively low pressure loss. By restricting the channel width, analogous to the Venturi tube used in pipe flow, the flow velocity in the narrow portion of the channel is increased and the water level sinks accordingly. Most of the head of water is recovered in the diffusing section of the weir. The water levels upstream and in the throat of the weir can be determined by simple floats and recorded on a chart by pens driven mechanically from the floats. For remote monitoring, the use of echo sounders is advantageous.

The weir is preferentially used in natural river beds and the flume in canalized water courses. The flume must be used in streams with sediment transport to avoid the accumulation of deposits that would occur at the approach to a weir. Weirs and flumes are characterized by

- Simple measurement of the water level
- Simple maintenance
- Reliable measurement of large flow rates at low stream velocity
- Limited measurement accuracy (at best about 2%)
- High installation costs, particularly for flumes

Recommendations for installation of weirs and flumes, for the location of the head measuring station upstream, and for determining the discharge from the measured head are given, for example, in [2] and [3] as well as in appropriate standards (e.g., [4–6]).

Measuring Principles of Variable Area Flowmeters

Rotameter

Flow Rate Analysis.

The forces acting on the bob lead to equilibrium between the weight of the bob $\rho_b g V_b$ acting downwards and the buoyancy force $\rho g V_b$ and the drag force F_d acting upwards, where V_b is the volume and ρ_b is the density of the bob, ρ is the density of the fluid, and g is the gravitational acceleration:

$$\rho_b g V_b = \rho g V_b + F_d \quad (28.7)$$

The drag force results from the flow field surrounding the bob and particularly from the wake of the bob. In flow analyses based on similarity principles, these influences are accounted for by empirical coefficient C_L or C_T in the drag law for:

$$\text{Laminar flow } F_d = C_L \mu D_b U \quad (28.8)$$

$$\text{Turbulent flow } F_d = C_T \rho D_b^2 U^2 \quad (28.9)$$

where μ = Fluid viscosity

D_b = Maximum bob diameter

U = Velocity in the annular gap around the bob at the minimum cross-section

FIGURE 28.15 Venturi flume: maximum discharge when throat depth = $2/3 \times$ total head.

The volume flow rate through the rotameter is:

$$\dot{Q} = \frac{\pi}{4} (D^2 - D_b^2) U \quad (28.10)$$

or

$$\dot{Q} = m \frac{\pi}{4} D_b^2 U \quad (28.11)$$

where m is the open area ratio, defined as:

$$m = \frac{D^2 - D_b^2}{D_b^2} \quad (28.12)$$

and D is the tube diameter at the height of the bob.

Combining Equations 28.7, 28.8, and 28.10 gives for laminar flow:

$$\dot{Q}_L = \alpha D_b^4 \frac{(\rho_b - \rho)g}{\mu} \quad (28.13)$$

where the parameter α is defined in terms of a constant $K = V_b/D_b^3$ characteristic of the shape of the bob:

$$\alpha = \frac{\pi m K}{4 C_L} \quad (28.14)$$

Using Equation 28.9 instead of Equation 28.8 yields for turbulent flow:

$$\dot{Q}_T = \beta D_b^{5/2} \sqrt{\frac{(\rho_b - \rho)g}{\rho}} \quad (28.15)$$

where

$$\beta = \frac{\pi m}{4} \sqrt{\frac{K}{C_T}} \quad (28.16)$$

With either laminar or turbulent flow through the rotameter, it is clear from Equations 28.13 and 28.15 that the flow rate is proportional to m . If the cross-sectional area of the tube is made to increase linearly with length, i.e.,

$$D = D_b (1 + h \tan \phi) \quad (28.17)$$

then since the cone angle ϕ of the tube is small, Equation 28.12 can be written as:

$$m = 2h \tan \phi \quad (28.18)$$

and the flow rate is directly proportional to the height h of the bob.

Similarity Analysis.

In early studies of floating element flowmeters, Ruppel and Umpfenbach [7] proposed the introduction of characteristic dimensionless quantities, to permit the use of experimentally determined flow coefficients in flowmeter analysis. Lutz [8] extended these ideas by showing that the transfer of flow coefficients from one flowmeter to another is possible if geometrical similarity exists. More recent works [9–12] have used these principles to produce graphical or computer-based design schemes and have proposed general guidelines for laying out practical flow metering systems.

The basic scaling parameter for flow is the Reynolds number, defined as:

$$Re = \frac{\rho U_{IN} D_b}{\mu} \quad (28.19)$$

where U_{IN} is the velocity at the rotameter inlet, and the tube diameter D is represented by its value at the inlet, equal to the bob diameter D_b . Through the Reynolds number regimes of laminar or turbulent flow, and particularly important for the rotameter flow regimes with strong or weak viscosity dependence, can be distinguished. Originating in the work [7], it has been found to be practical for rotameters to use an alternative characteristic number, the Ruppel number, defined as:

$$Ru = \frac{\mu}{\sqrt{m_b g \rho (1 - \rho/\rho_b)}} \quad (28.20)$$

where $m_b = \rho_b D_b^3$ is the mass of the bob. By combining Equations 28.15, 28.16, and 28.20, the mass flow \dot{m} through the rotameter can be written as:

$$\dot{m} = \frac{\pi}{4} \frac{m D_b \mu}{\sqrt{C_T} Ru} \quad (28.21)$$

Alternatively, from the definition:

$$\dot{m} = \rho \dot{Q} = \rho U_{IN} \frac{\pi}{4} D_b^2 \quad (28.22)$$

and Equation 28.19, the flow rate is:

$$\dot{m} = \frac{\pi}{4} D_b \mu Re \quad (28.23)$$

Equations 28.21 and 28.23 give the following relationship between the Ruppel number and the Reynolds number:

$$Ru = \frac{m}{\sqrt{C_T} Re} \quad (28.24)$$

An analysis for laminar flow leads to the relationship:

$$Ru = \sqrt{\frac{m}{C_L Re}} \quad (28.25)$$

The advantage of the Ruppel number is its independence of the flow rate. Since the Ruppel number contains only fluid properties and the mass and the density of the bob, it is a constant for a particular instrument.

At low Ruppel numbers the linear resistance law assumed in Equation 28.8 applies and α is a constant for given m , as shown in Figure 28.16. At higher Ruppel numbers, the flow is transitional or turbulent, and $\log \alpha$ decreases linearly with $\log Ru$. In Figure 28.17, curves for β against Ruppel number show a linear increase of $\log \beta$ with $\log Ru$ in the laminar region, followed by a gradual transition to horizontal curves in fully turbulent flow.

Similarity analysis of rotameters allows the easy calculation of the flow reading with changing density and viscosity of the fluid. For lower viscosities, only the density effect has to be taken into account; hence, for most gas measurements, simple conversion factors can be used. With higher viscosity, manufacturers offer either Ruppel number-related conversion factors or two-dimensional tables of conversion factors to be applied to different heights of the bob. Some manufacturers offer recalibration services, allowing the user to order new scales for instruments to be used in changed applications and environments. For large-order users, simple computer programs are available from some manufacturers for scale calculations.

Theories based on similarity considerations can predict the variation of the flow coefficient with the Ruppel number in the laminar and turbulent flow regimes but not in laminar-turbulent transitional flow. Detailed experimental and computational studies can assist the flow analysis of floating element flowmeters. An example is given in the section "Rotameter Internal Flow Analysis."

FIGURE 28.16 Rotameter flow coefficient α as a function of Ruppel number Ru and open area ratio m . For a given geometry, α is constant for low Ru (laminar flow).

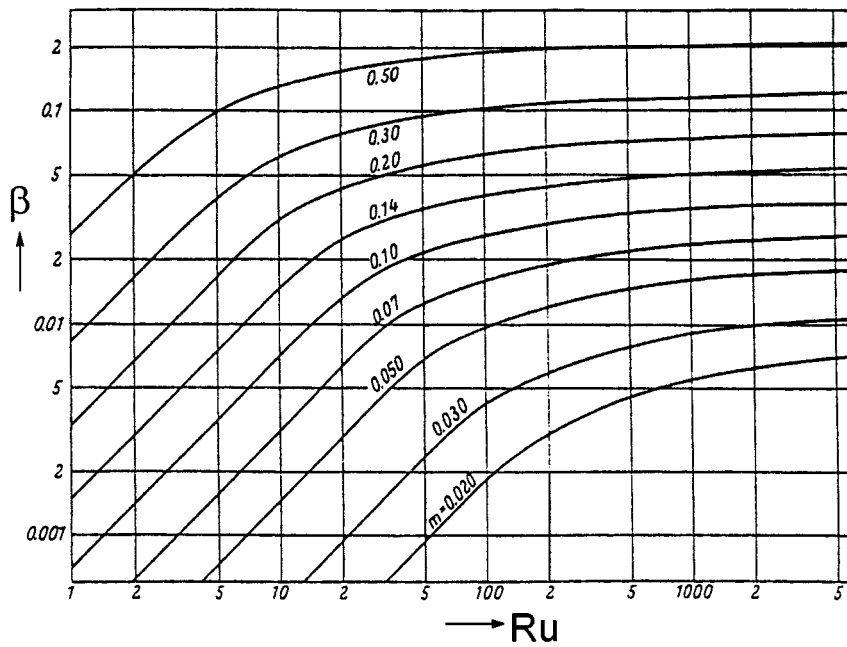

FIGURE 28.17 Rotameter flow coefficient β as a function of Ruppel number Ru and open area ratio m . For a given geometry, β is constant for high Ru (turbulent flow).

Weir, Flume

Flow Rate Analysis for Weirs.

Although the determination of the discharge across a weir or a flume generally requires the knowledge of one or more empirical coefficients, the basic equations describing the head-discharge characteristics of the various geometrical forms are readily derived from simple fluid mechanics considerations.

The discharge over a sharp crested weir of width b (Figure 28.11) when the water level over the sill is h is analyzed by considering a horizontal strip of water of thickness δy at a depth y below the water surface. Since the velocity of the water through this strip is $\sqrt{2gy}$, the discharge is:

$$\delta\dot{Q} = b\delta y\sqrt{2gy} \quad (28.26)$$

The total discharge is obtained by integration, introducing a coefficient of discharge C_d :

$$\dot{Q} = C_d \sqrt{2gb} \int_0^h \sqrt{y} dy \quad (28.27)$$

$$\dot{Q} = \frac{2}{3} C_d \sqrt{2gb} h^{3/2} \quad (28.28)$$

Empirical corrections to Equation 28.28 to account for the weir height p are given, for example, in [3], but provided h/p does not exceed 0.5, it is adequate to use Equation 28.28 with a discharge coefficient of 0.63 to achieve a flow rate tolerance of 3%.

For the rectangular notch, Equation 28.28 also applies with a discharge coefficient of 0.59 and a flow rate tolerance of 3%. Since in practice the discharge coefficient varies slightly with the head of water for both weirs and notches, it is sometimes preferred to replace Equation 28.28 by $\dot{Q} = Kbh^n$, where K and n are determined by calibration.

The triangular notch (Figure 28.13) offers the advantage that the length of the wetted edge varies with the head of water, in contrast with the rectangular notch where it is constant. Consequently, the discharge coefficient of the triangular notch is constant for all heads. Furthermore, the achievable range (ratio of maximum to minimum flow rates) is higher for the triangular geometry. If h is the height of the water surface and θ is the angle of the notch, then a horizontal strip of the notch of thickness δy at depth y has a width $2(h-y)\tan(\theta/2)$. The discharge through this strip is

$$\delta\dot{Q} = 2(h-y)\tan\frac{\theta}{2}\delta y\sqrt{2gy}C_d \quad (28.29)$$

giving a total discharge through the notch:

$$\dot{Q} = 2C_d\sqrt{2g}\tan\frac{\theta}{2}\int_0^h(h-y)\sqrt{y}dy \quad (28.30)$$

$$\dot{Q} = \frac{8}{15}C_d\sqrt{2g}\tan\frac{\theta}{2}h^{5/2} \quad (28.31)$$

The discharge coefficient is about 0.58.

Commonly used notch angles are 90° ($\tan \theta/2 = 1$, $C_d = 0.578$), 53.13° ($\tan \theta/2 = 0.5$, $C_d = 0.577$), and 28.07° ($\tan \theta/2 = 0.25$, $C_d = 0.587$). Notches with $\theta = 53.13^\circ$ and $\theta = 28.07^\circ$ deliver, respectively, one half and one quarter of the discharge of the 90° notch at the same head.

The above derivations assume that the water is discharging from a reservoir with cross-sectional area far exceeding the flow area at the weir, so that the velocity upstream is negligible. When the weir is built into a channel of cross-sectional area A , the water will have a finite velocity of approach $v_1 = \dot{Q}/A$. As a first approximation, \dot{Q} is obtained from Equation 28.28 assuming zero velocity of approach. Assuming further that v_1 is uniform over the weir, there will be an additional head $v_1^2/2g$ acting over the entire weir. Referring to Figure 28.11, the total discharge is then:

$$\dot{Q} = C_d \sqrt{2gb} \int_{v_1^2/2g}^{h+v_1^2/2g} \sqrt{y} dy \quad (28.32)$$

$$\dot{Q} = \frac{2}{3} C_d \sqrt{2gb} \left[\left(h + v_1^2/2g \right)^{3/2} - \left(v_1^2/2g \right)^{3/2} \right] \quad (28.33)$$

From Equation 28.33, a corrected value of v_1 can be determined. Further iterations converge rapidly to the final value of the discharge \dot{Q} . Equation 28.33 can be written as:

$$\dot{Q} = \frac{2}{3} C_v C_d \sqrt{2gb} h^{3/2} \quad (28.34)$$

where

$$C_v = \left(1 + \frac{v_1^2}{2gh} \right)^{3/2} - \left(\frac{v_1^2}{2gh} \right)^{3/2} \quad (28.35)$$

is the coefficient of velocity, which is frequently determined empirically.

Over a broad-crested weir (Figure 28.14), the discharge depends on the head h_1 , the width b , and the length l of the sill. There is also a dependence on the roughness of the sill surface and the viscosity. Consequently, there is a loss of head as the water flows over the sill. It is assumed that the sill is of sufficient length to allow the velocity to be uniform at a value v throughout the depth h_2 of the water at the downstream edge of the sill. Neglecting losses

$$v = \sqrt{2g(h_1 - h_2)}$$

and the discharge is:

$$\dot{Q} = C_d b h_2 v = C_d b \sqrt{2g(h_1 h_2^2 - h_2^3)} \quad (28.36)$$

From Equation 28.36, the discharge is a maximum when $(h_1 h_2^2 - h_2^3)$ reaches a maximum, i.e., when $h_2 = 2h_1/3$. This discharge is then:

$$\dot{Q} = \left(\frac{2}{3} \right)^{3/2} C_d b \sqrt{g} h_1^{3/2} \quad (28.37)$$

The stable condition of the weir lies at the maximum discharge.

Flow Rate Analysis for Flumes.

The discharge through a flume depends on the water level h , the channel width b , and velocity v at each of the stations 1 (upstream) and 2 (at the minimum cross-section) in Figure 28.15. Applying Bernoulli's equation to the inlet and the throat, neglecting all losses, one obtains:

$$\rho g H = \rho g h_1 + \frac{1}{2} \rho v_1^2 = \rho g h_2 + \frac{1}{2} \rho v_2^2 \quad (28.38)$$

where H is the total head. The analysis is then formally the same as that for the broad-crested weir, giving the same expression for the discharge as in Equation 28.37. The flow through the flume is a maximum when the depth at the throat is two thirds of the total head. Normally, a coefficient of velocity is introduced so that the discharge equation is:

$$\dot{Q} = \left(\frac{2}{3}\right)^{3/2} C_v C_d b \sqrt{g h_1^3} \quad (28.39)$$

The combined coefficient is determined empirically. In [3], a value $C_v C_d = 1.061 \pm 0.085$ is quoted.

The validity of the empirical coefficients quoted above, or of other coefficients given in the various standards for metering of open-channel flows, can only be guaranteed with a given confidence level for meter installations satisfying certain geometrical constraints. Limits on quantities such as b , h , h/b , etc. are given in [3] and the standards.

Rotameter: Internal Flow Analysis

Computation of Internal Flow.

Improvement of rotameter design could be assisted by detailed knowledge of the internal flow field, which is characterized by steep velocity gradients and regions of separated flow. Measurements of the internal flow field are complicated by the small dimensions of the gap around the bob and the strongly curved glass tube. Bückle et al. [13] successfully used laser Doppler anemometry [14] for velocity measurements in a rotameter. The working fluid was a glycerine solution with an index of refraction (1.455) close to that of glass (1.476). Problems with refraction of the laser beams at the curved tube wall were thus avoided, but the high viscosity of glycerine restricted the experiments to laminar flow at Reynolds numbers $Re = \rho U_{IN} D_b / \mu < 400$.

The application of computational fluid dynamics to the flow in a rotameter [13] involves the finite volume solution of the conservation equations for mass and momentum. For a two-dimensional laminar flow, these equations can be written in a cylindrical polar coordinate system as:

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho u)}{\partial z} + \frac{1}{r} \frac{\partial(\rho r v)}{\partial r} = 0 \quad (28.40)$$

$$\frac{\partial(\rho u)}{\partial t} + \frac{\partial}{\partial z} \left(\rho u u - 2\mu \frac{\partial u}{\partial z} \right) + \frac{1}{r} \frac{\partial}{\partial r} \left(\rho r u v - \mu r \left(\frac{\partial u}{\partial r} + \frac{\partial v}{\partial z} \right) \right) = -\frac{\partial p}{\partial z} \quad (28.41)$$

$$\frac{\partial(\rho v)}{\partial t} + \frac{\partial}{\partial z} \left(\rho u v - \mu r \left(\frac{\partial u}{\partial r} + \frac{\partial v}{\partial z} \right) \right) + \frac{1}{r} \frac{\partial}{\partial r} \left(\rho r v v - 2\mu r \frac{\partial v}{\partial r} \right) = -\frac{\partial p}{\partial r} \quad (28.42)$$

where ρ is the density, u , v and r , z are the velocity components and coordinate directions in the axial and radial directions, respectively, μ is the dynamic viscosity, and p is the pressure.

For the numerical solution, the governing equations for a generalized transport variable ϕ (i.e., u or v) are formally integrated over each control volume (CV) of the computational grid. The resulting flux balance equation can in turn be discretized as an algebraic equation for ϕ at the center P of each CV in terms of the values ϕ_{nb} at the four nearest neighbors of point P and known functions A:

$$A_{p\phi p} + \sum_{nb} A_{nb} \phi_{nb} = S_{\phi} \quad (28.43)$$

For the whole solution domain, a system of equations results that can be solved by a suitable algorithm (e.g. [15]).

For a rotameter, the symmetry of the problem allows the computational solution domain to be chosen as one half diametral plane of the rotameter. The boundary conditions are:

$$u = v = 0 \quad (28.44)$$

along the walls, and

$$\frac{\partial u}{\partial r} = v = 0 \quad (28.45)$$

along the axis of symmetry. At the input boundary, the initial profile for the u -velocity is taken from the experiment. At the outlet boundary, zero gradient is assumed for all dependent variables.

Computed Flow Field.

Representative calculations for Reynolds number 220 are shown as velocity vectors (Figure 28.18) and streamlines (Figure 28.19). Experimental and computed velocity profiles over a radius of the flowmeter tube are shown in Figure 28.20.

At $z = 45$ mm, the computations indicate a stagnation point at the bob tip, but the measurements show a low but finite axial velocity. The deviation from zero is attributable to slight unsteadiness in the position of the bob and to smearing of the steep radial velocity gradient along the measuring volume. This effect is also apparent at radii up to about 5 mm, where the computations show a notably steeper velocity gradient than the measurements. The measured and computed peak velocities agree well, although the measured peak is located at a larger radius.

In the strongly converging annulus between the bob and the tube wall ($z = 65$ mm) and in the plane $z = 88$ mm, the computations reproduce well the trend of the measured results, particularly near the flowmeter wall. Discrepancies in the region adjacent to the bob are attributable to asymmetry in measured profiles arising from the piping upstream of the rotameter tube.

Above the bob ($z = 110$ mm), there is a strong upward flow in an annular region near the tube wall and a recirculation region around the axis occupying almost half the tube cross-section. The forward velocities show a good match between computations and measurements, but there is a very marked discrepancy in the recirculation zone. At $z = 135$ mm, the recirculation zone is finished, but the wake of the bob is still very evident. Except for a discrepancy of about 10% on the axis, the results from the two methods agree remarkably well.

The effect of rotation of the bob on the flow field was considered by computations, including an equation for the azimuthal velocity component w .

$$\frac{\partial(\rho w)}{\partial t} + \frac{\partial}{\partial z} \left(\rho u w - \mu \frac{\partial w}{\partial z} \right) + \frac{1}{r} \frac{\partial}{\partial r} \left(\rho r v w - \mu r \frac{\partial w}{\partial r} \right) = -\rho \frac{v w}{r} - \mu \frac{w}{r^2} \quad (28.46)$$

Calculations for 1 Hz rotation frequency showed the highest swirl velocities close to the axis above the bob. There was no observable influence of the rotation on the u - and v -velocity components [16].

Summary

For pipe flows, variable area flowmeters are most suitable for low flow rates of gases or liquids at moderate temperatures and pressures. Favorable features include rugged construction, high reliability, low pressure drop, easy installation, and low cost. Disadvantages include measurement uncertainty of 1% or more, limited range (10:1), slow response, and restrictions on the meter orientation. A generally good price/performance ratio has led to widespread use of these meters in numerous scientific and medical instruments and in many industrial applications for flow monitoring.

Variable area flowmeters in open-channel flows have applications for flow measurements in waste water plants, waterworks, rivers and streams, irrigation, and drainage canals. Hydrological applications of weirs with adjustable sill or crest height include flow regulation, flow measurement, upstream water level control, and discharge of excess flow in streams, rivers, and canals. Ruggedness, simplicity, and low maintenance costs are favorable characteristics for field applications of these meters.

28.3 Positive Displacement Flowmeters

Zaki D. Husain and Donald J. Wass

A *positive displacement flowmeter*, commonly called a PD meter, measures the volume flow rate of a continuous flow stream by momentarily entrapping a segment of the fluid into a chamber of known volume and releasing that fluid back into the flow stream on the discharge side of the meter. By monitoring the number of entrapments for a known period of time or number of entrapments per unit time, the total volume of flow or the flow rate of the stream can be ascertained. The total volume and the flow rate can then be displayed locally or transmitted to a remote monitoring station.

The positive displacement flowmeter has been in use for many decades to measure both liquid and gas flows. A PD meter can be viewed as a hydraulic motor with high volumetric efficiency that generally absorbs a small amount of energy from the flowing fluid. The energy absorption is primarily to overcome the internal resistance of the moving parts of the meter and its accessories. This loss of energy is observed as the pressure drop across the meter. The differential pressure across the meter is the driving force for the internals of the PD meter.

Design and Construction

A positive displacement meter has three basic components: an outer housing, the internal mechanism that creates the dividing chamber through its repetitive motion, and the display or counter accessories that determines the number of entrapments of fluid in the dividing chamber and infers the flow rate and the total volume of flow through the meter.

The external housing acts as the holding chamber of the flowing fluid before and after the entrapments by the internals. For low line pressures, the housing is usually single walled while, for higher operating pressures, the housing is double walled where the inner wall is the containment wall for the entrapment chamber and the outer wall is the pressure vessel. For the double-walled housing, the entrapment chamber walls are subjected to the differential pressure across the meter while the external housing is subjected to the total line pressure. This allows fabrication of a thin-walled inner chamber that can retain its precise shape and dimensions independent of line pressure.

The measuring mechanism consists of precise metering elements that require tight tolerances on the mating parts. The metering elements consist of the containment wall of the metering chamber and the moving components of the meter that forms the entrapment volume of the flowing fluid by cyclic or repetitive motion of those elements. The most common types of positive displacement meters are the oscillating piston, nutating disk, oval gear, sliding vane, birotor, trirotor, and diaphragm designs.

The counter or output mechanism converts the motion of the internal measuring chamber of a PD meter and displays the flow rate or total flow by correlating the number of entrapments and each entrapped volume. Many positive displacement meters have a mechanical gear train that requires seals and packing glands to transmit the motion of the inner mechanism to the outside counters. This type of display requires more driving power to overcome resistance of the moving parts and the seals, which results in an additional pressure drop for the meter. Many PD meters transmit the motion of the inner mechanism to the counters through switch output utilizing electromechanical, magnetic, optical, or purely electronic techniques in counting the entrapments and displaying the flow rate and total flow volume. The latter processing techniques normally have less pressure drop than the all-mechanical or part-mechanical transmission methods. All-mechanical drive counters do not require external power and, through proper selection of gear train, can display the actual flow volume or the flow rate. Thus, meters can be installed at remote locations devoid of any external power source. Meters with mechanical display cannot easily correct for the changes in volume due to thermal expansion or contraction of the measuring chamber due to flow temperature variation and, in the case of single-walled housing, the changes in the entrapment volume due to variations of the line pressure. An electronically processed output device could monitor both the pressure and temperature of the meter and provide necessary corrections to the meter output. With constantly changing and improving electronics technology, many PD meters are now installed with solar or battery-powered electronic output for installations at remote locations with no external power source. Many electronic displays allow access to meter data from a central monitoring station via radio or satellite communication.

Some Commercially Available PD Meter Designs

Commercially available PD meters have many noticeably different working mechanisms and a few designs are unique and proprietary. Although each design and working mechanism can be noticeably different from another, all positive displacement meters have a stationary fluid retaining wall and a mechanism that momentarily entraps inlet fluid into a partitioned chamber before releasing it to the downstream side of the meter. This entrapment and release of the flowing fluid occur with such repetitive and sweeping motion that, for most practical purposes, the flow rate appears to be uniform and steady, even though, in reality, the exit flow does have some pulsation. The flow pulsation out of the meter may be more pronounced for some designs of positive displacement meters than others. These flow pulsations are more pronounced at the lower flow rates for all designs. Some designs are more suitable for either liquid or gas flows, while some designs can measure both gas and liquid. For liquid applications, PD meters

FIGURE 28.21 Sliding-vane type PD meter. (Courtesy of Daniel Industries, Inc.)

FIGURE 28.22 Trirotor type PD meter. (Courtesy of Liquid Controls LLC.)

work best for liquids with heavy viscosities. Almost all PD meters require precisely machined, high-tolerance mating parts; thus, measured fluid must be clean for longevity of the meter and to maintain the measurement precision.

Sliding-Vane Type Positive Displacement Meter

Figure 28.21 shows a working cycle of a sliding-vane type PD meter where vanes are designed to move in and out of the rotating inner mechanism. The position of each sliding vane relative to specific angular rotation of the rotor is usually maintained by a mechanical cam. In the design shown in Figure 28.21, each blade is independently retained in the slots. There are designs with even numbers of blades where diametrically opposite blades are one integral unit. High-pressure application would utilize dual wall construction.

Tri-Rotor Type PD Meter

This design has three rotating parts that entrap fluid between the rotors and an outer wall. The working cycle of this type of meter is shown Figure 28.22. In this design, for one rotation of the top mechanism, two blades rotate twice. The driving mechanism and rotation of each blade with respect to the others is maintained by a three-gear assembly where each rotating blade shaft is connected to one gear of the three-gear assembly to maintain relative rotational speed. This design is used to measure liquid flows.

Birotor PD Meter

The measuring unit of the birotor PD meter has two spiral type rotors kept in perfect timing by a set of precision gears and is used to measure liquid flows. Flow can enter the meter either perpendicular or parallel to the axis of rotation of the mating rotors, as shown in Figure 28.23. The axial design birotor is identical to the standard model in component parts and in principle; however, it utilizes a measuring unit mounted parallel, rather than perpendicular, to flow. Meter output is registered mechanically through a gear train located outside the measuring chamber or, electronically, using a pickup assembly mounted with a timing gear. Axial orientation results in compact installation, improved accuracy, and low pressure loss. The axial design is ideal for high flow rate applications.

Piston Type PD Meter

A typical design of a piston type PD meter is shown in Figure 28.24. A centrally located rotating part generates the reciprocating motion for each of the four pistons of the meter. The reciprocating motion of each of the piston is timed such that the discharge from an individual piston cylinder occurs in a cycle to generate a semicontinuous discharge from the meter. These PD meters are used for very low flow rates of liquid flows. A piston-cylinder design can withstand large differential pressures across the meter, so high viscous liquids can be measured by this type of meters and measurements are very precise. Mechanical

FIGURE 28.24 Piston-type PD meter. (Courtesy of Pierburg Instruments, Inc.)

FIGURE 28.25 Oval Gear Meter. (Courtesy of Daniel Industries, Inc.)

components of this type of meter require very precise mechanical tolerances, which increase the product cost.

Oval Gear PD Meter

The measurement of volumetric flow of an oval gear meter is obtained by separating partial volumes formed between oval gears and the measuring chamber wall, as shown in Figure 28.25. The rotation of the oval gears results from the differential pressure across the flowmeter. During one revolution of the oval gears, four partial volumes are transferred. The rotation of the gears is transmitted from the measuring chamber to the output shaft directly with mechanical seals or via a magnetic coupling. This type of meter is used to measure liquids having a wide range of viscosity.

FIGURE 28.26 Nutating-disk type PD meter. (Courtesy of DEA Engineering Company.)

FIGURE 28.27 Schematic diagram of roots meter.

Nutating-Disk Type PD Meters

A disk placed within the confines of a boundary wall at a specific orientation can induce a flow instability that can generate a wobbling or nutating motion to the disk. The operating cycle of one such design is shown in Figure 28.26. The entrapment and discharge of the fluid to and from the two chambers occur during different phases of the repetitive cycle of the nutating disk. This type of meter is used to measure liquids. The design provides economic flow measurement where accuracy is not of great importance and is often used in water meters.

Meter designs described hereafter are for gas flows. PD meters for gas flows require very tight tolerances of the moving parts to reduce leak paths and, therefore, the gas must be clean because the meters are less tolerant to solid particles.

Roots PD Meter

The roots meter design is shown in Figure 28.27. This is the most commonly used PD meter to measure gas flows. This is one of the oldest designs of a positive displacement meter. The mechanical clearance between the rotors and the housing requires precisely machined parts. Roots meters are adversely affected if inlet flow to the meter has a relatively high level of pulsation. The main disadvantage of this meter is that it introduces cyclic pulsations into the flow. This meter cannot tolerate dirt and requires filtering upstream of the meter. A roots meter in single-case design is used at near-ambient line pressures. This

FIGURE 28.28 Operation of CVM meter.

FIGURE 28.29 Operation of a diaphragm meter.

meter design is very widely used in the low-pressure transmission and distribution market of natural gas. If this meter ever seizes up at any position, the flow is completely blocked.

The CVM Meter

The CVM meter (Figure 28.28) is a proprietary design of a positive displacement meter used to measure gas flows. This meter has a set of four vanes rotating in an annular space about the center of the circular housing. A gate similar in shape to the center piece of the trirotor design (Figure 28.22) allows the vanes to pass — but not the gas. The measurement accuracy of the CVM meter is similar to the roots meter, but the amplitude of exit pulsation is lower than the roots meter for similar meter size and flow rate. This design is also not as sensitive to inlet flow fluctuations, and is widely used in the low-pressure, natural gas distribution market in Europe.

Diaphragm Meter

The diaphragm meter, also known as a bellows-type meter, is simple, relatively inexpensive, has reliable metering accuracy, and is widely used as a domestic gas meter. This design, shown in Figure 28.29, acts like a reciprocating piston meter, where the bellows act as the piston. The operation is controlled by a double slide valve. In one position, the slide valve connects the inlet to the inside of the bellow, while the outside of the bellow is open to the outlet. In the other position, the outside is connected to the inlet while the inside of the bellow is open to the outlet. This design can measure extremely low flow rates (e.g., pilot light of a gas burner).

Advantages and Disadvantages of PD Meters

High-quality, positive displacement meters will measure with high accuracy over a wide range of flow rates, and are very reliable over long periods. Unlike most flowmeters, a positive displacement meter is insensitive to inlet flow profile distortions. Thus, PD meters can be installed in close proximity to any upstream or downstream piping installations without any loss of accuracy. In general, PD meters have minimal pressure drop across the meter; hence, they can be installed in a pipeline with very low line pressures. Until the introduction of electronic correctors and flow controls on other types of meters, PD

meters were most widely used in batch loading and dispensing applications. All mechanical units can be installed in remote locations.

Positive displacement meters are generally bulky, especially in the larger sizes. Due to the tight clearance necessary between mating parts, the fluid must be clean for measurement accuracy and longevity of the meter. More accurate PD meters are quite expensive. If a PD meter ever seizes up, it would completely block the flow. Many PD meters have high inertia of the moving parts; therefore, a sudden change in the flow rate can damage the meter. PD meters are normally suitable over only limited ranges of pressure and temperature. Some designs will introduce noticeably high pulsations into the flow. Most PD meters require a good maintenance schedule and are high repair and maintenance meters. Recurring costs in maintaining a positive displacement flowmeter can be a significant factor in overall flowmeter cost.

Applications

Liquid PD meters are capable of measuring fluids with a wide range of viscosity and density. Minor changes in viscosity of the fluid have minimal influence on the accuracy of a PD meter. However, no one specific design of PD meter is capable of such a broad application range. The physical properties of the fluid, especially the fluid viscosity, must be reviewed for proper selection of a meter for the application. Many PD meter designs accurately measure flow velocities over a wide range.

Careful dimensional control is required to produce well-regulated clearances around the moving parts of the PD meter. The clearances provide a leakage path around the flow measurement mechanism, and the amount of leakage depends on the relative velocity of the moving parts, the viscosity of the fluid, and the clearances between parts. In general, the leakage flow rate follows the Poiseuille equation; that is, leakage is directly proportional to the differential pressure and inversely proportional to the absolute viscosity and the length of the leakage path.

The leakage flow, in percentage of the total flow rate, is useful information for error measurement. At low flow rates, percent leakage error can be significant; while with modest flow rates, leakage can be insignificant. However, the differential pressure across the PD meter increases exponentially with increasing flow rates. Therefore, at very high flow rates, leakage flow can again be a significant portion of the total flow. As a result, PD meters tend to dispense more fluid than is indicated by the register at the very low and very high flow rates. The amount of error due to leakage depends on the meter design and on the viscosity of the fluid.

PD meters are driven by the differential pressure across the meter. The primary losses within the meter can be attributed to the friction losses and the viscous drag of the fluid on the moving parts. At very low flow rates, the bearing losses are predominant, while at high flow rates, the viscous drags predominate. The viscous drag is directly proportional to the fluid viscosity and the relative velocity of the moving parts and inversely proportional to the clearance. Within each design, the differential pressure is limited to a predetermined value. Excessive differential pressures can damage the meter. High differential pressure can be avoided by limiting the maximum flow rate, lowering viscosity by heating the fluid, increasing clearances, or by various combinations of these techniques. In general, if the differential pressure limit can be addressed, PD meters measuring high-viscosity fluids have less measurement error over a wide flow rate range.

The viscosity of most gases is too low to cause application problems relating to viscous drag of the form discussed for liquid PD meters. Gas PD meters utilize smaller clearances than liquid PD meters; therefore, gas must be very clean. Even small particles of foreign material can damage gas PD meters. PD meters used in gas flow measurement are primarily in the low line pressure application.

Accessories

Many accessories are available for PD meters. Among the most common and useful accessories for liquid PD meters are the automatic air eliminator and the direct-coupled shut-off valve for batch loading operations. The automatic air eliminator consists of a pressure-containing case surrounding a float valve.

When gas in the liquid flow enters the chamber, the float descends by gravity and allows the float valve to open and purge the gas. An air eliminator improves the precision of flow measurement in many applications and is an absolute necessity in applications where air or gas is trapped in the flow stream. The direct-coupled shut-off valve is directly linked to the mechanical register. A predetermined fluid quantity can be entered into the register. When the dispensed amount equals the amount entered in the register, the mechanical linkage closes the valve. Two-stage shut-off valves are often used to avoid line shock in high flow rate dispensing applications. Similarly, all-electronic units can control batch operations. The all-electronic units provide great convenience in the handling of data. However, the register-driven mechanical valves have advantages in simplicity of design, field maintenance or repair, and initial cost.

Gas PD meters can be equipped with mechanical registers that correct the totals for pressure and temperature. The pressure and temperature compensation range is limited in the mechanical units but with appropriate application; the range limitation is not a problem. Electronic totalizers for gas PD meters can correct for broad ranges of temperature and pressure. Electronic accessories can provide various data storage, logging, and remote data access capabilities.

Price and Performance

In general, the accuracy of the PD meter is reflected in the sales price. However, several additional factors influence the cost. The intended application, the materials of construction, and the pressure rating have a strong influence on the cost. Although they provide excellent accuracy, small PD meters for residential water or residential natural gas service are very inexpensive. Meters produced for the general industrial market provide good accuracy at a reasonable cost, and meters manufactured for the pipeline or petrochemical markets provide excellent accuracy and are expensive.

Very inexpensive PD meters are available with plastic cases or plastic internal mechanisms. Aluminum, brass, ductile iron, or cast iron PD meters are moderately priced. Steel PD meters are relatively expensive, especially for high-pressure applications. If stainless steel or unusual materials are necessary for corrosive fluids or special service requirements, the costs are very high. PD meters are manufactured in a wide range of sizes, pressure ratings, and materials, with a multitude of flow rate ranges, and with an accuracy to match most requirements. The cost is directly related to the performance requirements.

28.4 Turbine and Vane Flowmeters

David Wadlow

This section describes a range of closed-conduit flowmeters that utilize rotating vaned transduction elements, with particular emphasis on axial turbine flowmeters. Single jet and insertion tangential turbines, also known as paddlewheel flowmeters, are described in another section. The various vaned flowmeters used for open-channel and free-field flow measurement are not included in this section.

Axial Turbine Flowmeters

The modern axial turbine flowmeter, when properly installed and calibrated, is a reliable device capable of providing the highest accuracies attainable by any currently available flow sensor for both liquid and gas volumetric flow measurement. It is the product of decades of intensive innovation and refinements to the original axial vaned flowmeter principle first credited to Woltman in 1790, and at that time applied to measuring water flow. The initial impetus for the modern development activity was largely the increasing needs of the U.S. natural gas industry in the late 1940s and 1950s for a means to accurately measure the flow in large-diameter, high-pressure, interstate natural gas lines. Today, due to the tremendous success of this principle, axial turbine flowmeters of different and often proprietary designs are used for a variety of applications where accuracy, reliability, and rangeability are required in numerous major industries besides water and natural gas, including oil, petrochemical, chemical process, cryogenics, milk and beverage, aerospace, biomedical, and others.

Figure 28.30 is a schematic longitudinal section through the axis of symmetry depicting the key components of a typical meter. As one can see, the meter is an in-line sensor comprising a single turbine rotor, concentrically mounted on a shaft within a cylindrical housing through which the flow passes. The shaft or shaft bearings are located by end supports inside suspended upstream and downstream aerodynamic structures called diffusers, stators, or simply cones. The flow thus passes through an annular region occupied by the rotor blades. The blades, which are usually flat but can be slightly twisted, are inclined at an angle to the incident flow velocity and hence experience a torque that drives the rotor. The rate of rotation, which can be up to several $\times 10^4$ rpm for smaller meters, is detected by a pickup, which is usually a magnetic type, and registration of each rotor blade passing infers the passage of a fixed volume of fluid.

General Performance Characteristics

Axial turbines perform best when measuring clean, conditioned, steady flows of gases and liquids with low kinematic viscosities (below about 10^{-5} m²s⁻¹, 10 cSt, although they are used up to 10^{-4} m²s⁻¹, 100 cSt), and are linear for subsonic, turbulent flows. Under these conditions, the inherent mechanical stability of the meter design gives rise to excellent repeatability performance. Not including the special case of water meters, which are described later, the main performance characteristics are:

- Sizes (internal diameter) range from 6 mm to 760 mm, (1/4 in. to 30 in.).
- Maximum measurement capacities range from 0.025 Am³ h⁻¹ to 25,500 Am³ h⁻¹, (0.015 ACFM to 15,000 ACFM), for gases and 0.036 m³ h⁻¹ to 13,000 m³ h⁻¹, (0.16 gpm to 57,000 gpm or 82,000 barrels per hour), for liquids, where A denotes actual.
- Typical measurement repeatability is $\pm 0.1\%$ of reading for liquids and $\pm 0.25\%$ for gases with up to $\pm 0.02\%$ for high-accuracy meters. Typical linearities (before electronic linearization) are between $\pm 0.25\%$ and $\pm 0.5\%$ of reading for liquids, and $\pm 0.5\%$ and $\pm 1.0\%$ for gases. High-accuracy meters have linearities of $\pm 0.15\%$ for liquids and $\pm 0.25\%$ for gases, usually specified over a 10:1 dynamic range below maximum rated flow. Traceability to NIST (National Institute of Standards and Technology) is frequently available, allowing one to estimate the overall absolute accuracy performance of a flowmeter under specified conditions. Under ideal conditions, absolute accuracies for optimum designs and installations can come close to the accuracy capabilities at the NIST, which are stated as $\pm 0.13\%$ for liquid flows and $\pm 0.25\%$ for air.
- Rangeability, when defined as the ratio of flow rates over which the linearity specification applies, is typically between 10:1 and 100:1.
- Operating temperature ranges span -270°C to 650°C , (-450°F to 1200°F).
- Operating pressure ranges span coarse vacuum to 414 MPa (60,000 psi).
- Pressure drop at the maximum rated flow rate ranges from around 0.3 kPa (0.05 psi) for gases to in the region of 70 kPa (10 psi) for liquids.

FIGURE 28.30 Longitudinal section of an axial turbine flowmeter depicting the key components. The flowmeter body is usually a magnetically transparent stainless steel such as 304. Common end-fittings include face flanges (depicted), various threaded fittings and tri-clover fittings. The upstream and downstream diffusers are the same in bidirectional meters, and generally supported by three or more flat plates, or sometimes tubular structures, aligned with the body, which also act as flow straighteners. The relative size of the annular flow passage at the rotor varies among different designs. Journal rotor bearings are frequently used for liquids, while ball bearings are often used for gases. Magnetic reluctance pickups (depicted) are frequently used. Others types include mechanical and modulated carrier pickups. (1) End fitting — flange shown; (2) flowmeter body; (3) rotation pickup — magnetic, reluctance type shown; (4) permanent magnet; (5) pickup cold wound on pole piece; (6) rotor blade; (7) rotor hub; (8) rotor shaft bearing — journal type shown; (9) rotor shaft; (10) diffuser support and flow straightener; (11) diffuser; (12) flow conditioning plate (dotted) — optional with some meters.

Theory

There are two approaches described in the current literature for analyzing axial turbine performance. The first approach describes the fluid driving torque in terms of momentum exchange, while the second describes it in terms of aerodynamic lift via airfoil theory. The former approach has the advantage that it readily produces analytical results describing basic operation, some of which have not appeared via airfoil analysis. The latter approach has the advantage that it allows more complete descriptions using fewer approximations. However, it is mathematically intensive and leads rapidly into computer-generated solutions. One prominent pioneer of the momentum approach is Lee [1] who, using this approach, later went on to invent one of the few, currently successful, dual rotor turbine flowmeters, while Thompson and Grey [2] provided one of the most comprehensive models currently available using the airfoil

FIGURE 28.31 Vector diagram for a flat-bladed axial turbine rotor. The difference between the ideal (subscript *i*) and actual tangential velocity vectors is the rotor slip velocity and is caused by the net effect of the rotor retarding torques. This gives rise to linearity errors and creates swirl in the exit flow. V , incident fluid velocity vector; V_E , exit fluid velocity vector; θ , exit flow swirl angle due to rotor retarding torques; β , blade pitch angle, same as angle of attack for parallel flow; ω , rotor angular velocity vector; r , rotor radius vector; F , flow-induced drag force acting on each blade surface; c , blade chord; s , blade spacing along the hub; c/s , rotor solidity factor.

approach, which for example, took into account blade interference effects. In the following, the momentum exchange approach is used to highlight the basic concepts of the axial turbine flowmeter.

In a hypothetical situation, where there are no forces acting to slow down the rotor, it will rotate at a speed that exactly maintains the fluid flow velocity vector at the blade surfaces. Figure 28.31 is a vector diagram for a flat-bladed rotor with a blade pitch angle equal to β . Assuming that the rotor blades are flat and that the velocity is everywhere uniform and parallel to the rotor axis, then referring to Figure 28.31, one obtains:

$$r\omega_i = \frac{\tan\beta}{V} \quad (28.47)$$

When one introduces the total flow rate, this becomes:

$$\frac{\omega_i}{Q} = \frac{\tan\beta}{\bar{r}A} \quad (28.48)$$

where ω_i = "Ideal" rotational speed

Q = Volumetric flow rate

A = Area of the annular flow cross-section

\bar{r} = Root-mean-square of the inner and outer blade radii, (R, a)

Eliminating the time dimension from the left-hand-side quantity reduces it to the number of rotor rotations per unit fluid volume, which is essentially the flowmeter K factor specified by most manufacturers. Hence, according to Equation 28.48, in the ideal situation, the meter response is perfectly linear and determined only by geometry. (In some flowmeter designs, the rotor blades are helically twisted to improve efficiency. This is especially true of blades with large radius ratios, (R/a). If the flow velocity profile is assumed to be flat, then the blade angle in this case can be described by $\tan\beta = \text{constant} \times r$. This is sometimes called the "ideal" helical blade.) In practice, there are instead a number of rotor

retarding torques of varying relative magnitudes. Under steady flow, the rotor assumes a speed that satisfies the following equilibrium:

$$\begin{aligned} \text{Fluid driving torque} = & \text{rotor blade surfaces fluid drag torque} + \text{rotor hub} \\ & \text{and tip clearance fluid drag torque} + \text{rotation sensor} \\ & \text{drag torque} + \text{bearing friction retarding torque} \end{aligned} \quad (28.49)$$

Referring again to Figure 28.31, the difference between the actual rotor speed, $r\omega$, and the ideal rotor speed, $r\omega_i$, is the rotor slip velocity due to the combined effect of all the rotor retarding torques as described in Equation 28.49, and as a result of which the fluid velocity vector is deflected through an exit or swirl angle, θ . Denoting the radius variable by r , and equating the total rate of change of angular momentum of the fluid passing through the rotor to the retarding torque, one obtains:

$$\int_a^R \frac{\rho Q 2\pi r^2 (r\omega_i - r\omega)}{\pi(R^2 - a^2)} dr = N_T \quad (28.50)$$

which yields:

$$\bar{r}^2 \rho Q (\omega_i - \omega) = N_T \quad (28.51)$$

where ρ is the fluid density and N_T is the total retarding torque. Combining Equations 28.47 and 28.51 and rearranging, yields:

$$\frac{\omega}{Q} = \frac{\tan\beta}{\bar{r}A} - \frac{N_T}{\bar{r}^2 \rho Q^2} \quad (28.52)$$

The trends evident in Equation 28.52 reflect the characteristic decline in meter response at very low flows and why lower friction bearings and lower drag pickups tend to be used in gas vs. liquid applications and small diameter meters. In most flowmeter designs, especially for liquids, the latter three of the four retarding torques described in Equation 28.49 are small under normal operating conditions compared with the torque due to induced drag across the blade surfaces. As shown in Figure 28.31, the force, F , due to this effect acts in a direction along the blade surface and has a magnitude given by:

$$F = \frac{\rho V^2}{2} C_D S \quad (28.53)$$

where C_D is the drag coefficient and S is the blade surface area per side. Using the expression for drag coefficient corresponding to turbulent flow, selected by Pate et al. [3] and others, this force can be estimated by:

$$F = \rho V^2 0.074 \text{Re}^{-0.2} S \quad (28.54)$$

where Re is the flow Reynolds number based on the blade chord shown as dimension c in Figure 28.31. Assuming θ is small compared with β , then after integration, the magnitude of the retarding torque due to the induced drag along the blade surfaces of a rotor with n blades is found to be:

$$N_D = n(R+a)\rho V^2 0.037 \text{Re}^{-0.2} S \sin\beta \quad (28.55)$$

Combining Equations 28.55 and 28.52, and rearranging yields:

$$\frac{\omega}{Q} = \frac{\tan\beta}{\bar{r}A} - \frac{0.036n(R+a)SA^2 \text{Re}^{-0.2} \sin\beta}{\bar{r}^2} \quad (28.56)$$

Equation 28.56 is an approximate expression for the K factor because it neglects the effects of several of the rotor retarding torques, and a number of important detailed meter design and aerodynamic factors, such as rotor solidity and flow velocity profile. Nevertheless, it reveals that linearity variations under normal, specified operating conditions are a function of certain basic geometric factors and Reynolds number. These results reflect general trends that influence design and calibration. Additionally, the marked departure from an approximate ρV^2 (actually $\rho^{0.8} V^{1.8} \mu^{-0.2}$ via Re in Equation 28.54) dependence of the fluid drag retarding torque on flow properties under turbulent flow, to other relationships under transitional and laminar flow, gives rise to major variations in the K factor vs. flow rate and media properties for low-flow Reynolds numbers. This is the key reason why axial turbine flowmeters are generally recommended for turbulent flow measurement.

Calibration, Installation, and Maintenance

Axial turbine flowmeters have a working dynamic range of at least 10:1 over which the linearity is specified. The maximum flow rate is determined by design factors related to size vs. maximum pressure drop and maximum rotor speed. The minimum of the range is determined by the linearity specification itself. Due to small, unavoidable, manufacturing variances, linearity error curves are unique to individual meters and are normally provided by the manufacturer. However, although recommended where possible, the conditions of the application cannot usually and need not necessarily duplicate those of the initial or even subsequent calibrations. This has pivotal importance in applications where actual operating conditions are extreme or the medium is expensive or difficult to handle. Figure 28.32 depicts a typically shaped calibration curve of linearity vs. flow rate expressed in terms of multiple alternative measures, various combinations of which can be found in current use. The vertical axis thus represents either the linearity error as a percentage of flow rate, a K factor expressed in terms of the number of pulses from the rotation sensor output per volume of fluid, or the deviation from 100% registration; the latter only applies to flowmeters with mechanical pickups. The horizontal axis can be expressed in terms of flow rate in volume units/time, Reynolds number (Re), or pulse frequency (from the rotation sensor for nonmechanical) divided by kinematic viscosity, (f/ν), in units of $\text{Hz}/\text{m}^2\text{s}^{-1}$, (Hz/cSt or Hz/SSU ; $10^{-6} \text{m}^2\text{s}^{-1} = 1 \text{ centistoke} = 31.0 \text{ seconds, Saybolt Universal}$), and where kinematic viscosity is the ratio of absolute viscosity (μ) to density. Calibrations are preferably expressed vs. Re or f/ν , which is proportional to Re . The hump shown in the curve is a characteristic frequently observed at lower Re and is due to velocity profile effects. K factor vs. f/ν calibration curves are specifically called universal viscosity curves (UVC) and, for most meters, are available from the manufacturer for an extra charge. A key utility of UVC is that where media type and properties differ significantly from those of the original calibration, accuracies much greater than the overall linearity error can still readily be obtained via the flowmeter UVC if the kinematic viscosity of the application is known. An alternative, advanced calibration technique [4] is to provide response in terms of Strouhal number vs. Re or Roshko number. This approach is not widely adopted, but it is particularly relevant to high-accuracy and extreme temperature applications because it further allows correct compensation for flowmeter thermal expansion errors.

The accuracy of axial turbine flowmeters is reduced by unconditioned flow, especially swirl. An installation incorporating flow conditioners along with specific upstream and downstream straight pipe lengths is generally recommended [5]. Some axial turbine flowmeters can be purchased with additional large flow straighteners that mount directly ahead of the flowmeter body or conditioning plates that are integral to the body. The manufacturer is the first source of information regarding installation. Errors due to flow velocity pulsations are another concern, particularly in certain gas installations. However, no standard technique for effectively counteracting this source of error has yet been adopted. Periodic

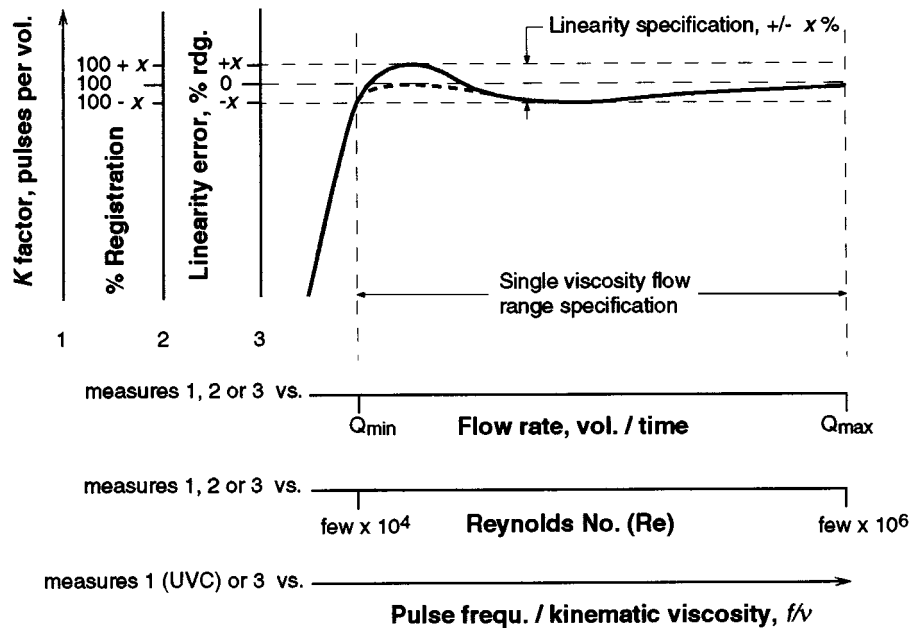

FIGURE 28.32 A typical single rotor axial turbine linearity error, or calibration, curve for a low-viscosity fluid showing the main alternative presentations in current use. Higher accuracy specifications usually correspond to a 10:1 flow range down from Q_{\max} , while extended operating ranges usually correspond to reduced accuracies. The hump in the depicted curve is a characteristic feature caused by flow velocity profile changes as Re approaches the laminar region. This feature varies in magnitude between meters. Sensitivity and repeatability performance degrade at low Re . Percent registration is only used with meters that have mechanical pickups. All other meters have a K factor. Universal viscosity curve (UVC) and Re calibrations remain in effect at different known media viscosities provided Re or f/v stays within the specified range. Re is referenced to the connecting conduit diameter and is less within the flowmeter. The Re range shown is therefore approximate and can vary by an order of magnitude, depending on the meter. Linearity error can also be expressed in terms of Strouhal number (fD/V) vs. Re (VD/ν) or Roshko number (fD^2/ν), when instead D is a flowmeter reference diameter [4]. UVC, Universal Viscosity Curve; - - -, the effect of a rotor shroud in a viscosity compensated flowmeter.

maintenance, testing, and recalibration is required because the calibration will shift over time due to wear, damage, or contamination. For certain applications, especially those involving custody transfer of oil and natural gas, national standards, international standards, and other recommendations exist that specify the minimum requirements for turbine meters with respect to these aspects [6–10].

Design and Construction

There are numerous, often proprietary, designs incorporating variations in rotors, bearings, pickups, and other components in format and materials that are tailored to different applications. Meter bodies are available with a wide range of standard end-fittings. Within application constraints, the primary objective is usually to optimize the overall mechanical stability and fit in order to achieve good repeatability performance. Design for performance, application, and manufacture considerations impacts every internal component, but most of all the rotor with respect to blade shape and pitch, blade count, balance and rigidity vs. drag, stress, and inertia, bearings with respect to precision vs. friction, speed rating and durability, and rotation pickup vs. performance and drag.

Most low-radius ratio blades are machined flat, while high-ratio blades tend to be twisted. The blade count varies from about 6 to 20 or more, depending on the pitch angle and blade radius ratio so that the required rotor solidity is achieved. Rotor solidity is a measure of the “openness” to the flow such that higher solidity rotors are more highly coupled to the flow and achieve a better dynamic range. The pitch

angle, which primarily determines the rotor speed, is typically 30° to 45° but can be lower in flowmeters designed for low-density, gas applications. Rotor assemblies are usually a close fit to the inside of the housing. In large-diameter meters, the rotor often incorporates a shroud around the outer perimeter for enhanced stability. Also, since large meters are often used for heavy petroleum products, via selection of a suitable wall clearance, the fluid drag resulting from this clearance gap is often designed to offset the tendency at high media viscosities for the meter to speed up at lower Reynolds numbers. The materials of construction range from nonmagnetic to magnetic steels to plastics.

Stainless steel ball bearings tend to be used for gas meters and low lubricity liquids such as cryogenic liquids and freon, while combination tungsten carbide or ceramic journal and thrust bearings are often considered best for many other liquid meters, depending on the medium lubricity. Fluid bearings (sometimes called “bearingless” designs) are often used in conjunction with the latter, but also sometimes with gases, for reducing the drag. They operate by various designs that use flow-induced forces to balance the rotor away from the shaft ends. Bearing lubrication is either derived from the metered medium or an internal or external system is provided. The more fragile, jeweled pivot bearings are also used in certain gas applications and small meters. Sanitary meters can incorporate flush holes in the bearing assembly to meet 3A crack and crevice standards.

The most common types of rotation sensor are magnetic, modulated carrier, and mechanical, while optical, capacitive, and electric resistance are also used. In research, a modulated nuclear radiation flux rotation sensor for use in certain nuclear reactors has also been reported [11, 12]. Mechanical pickups, which sometimes incorporate a magnetic coupling, are traditional in some applications and can have high resolution; one advantage is that they require no electric power. However, the pickup drag tends to be high. The magnetic and modulated carrier types utilize at least a coil in a pickup assembly that screws into the meter housing near the rotor. In magnetic inductance types, which are now less common, the blades or shroud carry magnetized inserts, and signals are induced in the coil by the traversing magnetic fields. In the more prevalent magnetic reluctance type, an example of which is schematically depicted in Figure 28.30, the coil is wrapped around a permanent magnet or magnet pole piece in the pickup assembly which is mounted next to a high magnetic permeability bladed rotor (or machined shroud). The latter is then typically made of a magnetic grade of stainless steel such as 416, 430, or 17-4Ph. As the rotor turns, the reluctance of the magnetic circuit varies, producing signals at the coil. In the more expensive modulated carrier types, the rotor need only be electrically conductive. The coil is part of a radio frequency (RF) oscillator circuit and the proximity of the rotor blades changes the circuit impedance, giving rise to modulation at a lower frequency that is recovered. The RF types have much lower drag, higher signal levels at low flow, and can operate at temperatures above the Curie point of typical ferromagnetic materials. They are preferred for wide dynamic range and high-temperature applications. Bidirectional flowmeters usually have two magnetic pickups to determine flow direction. This is useful, for example, in the monitoring of container filling and emptying operations often encountered in sanitary applications. Multiple magnetic pickups are also used in some designs to provide increased measurement resolution. Regarding output, various pulse amplifiers, totalizers, flow computers for gas pressure and temperature correction, along with 4–20 mA and other standard interface protocols, are available to suit particular applications. As an example of advanced transmitters, at least one manufacturer (EG&G Flow Technology, Inc.) provides a real-time, miniature, reprogrammable, “smart” transmitter that is integrated into the pickup housing along with a meter body temperature sensor, for full viscosity compensation and UVC linearization. These are for use in dedicated applications, such as airborne fuel management, where the medium viscosity–temperature relationship is known.

Certain applications have uniquely different design requirements and solutions, and two are discussed separately in the following.

Propeller Meters.

Propeller meters are used in either municipal, irrigation, or wastewater measurement. Although in some designs, propeller and turbine meters look almost identical and operate on the same axial rotor principle, this type of flowmeter is currently commercially and officially [13, 14] distinguished as a separate category

distinct from the axial turbine. Diameters up to 2440 mm (96 in.) are available. The flow rate capacity of a 1800 mm (72 in.) diameter propeller meter is up to about 25,000 m³ h⁻¹, (110,000 gpm). Typical accuracies are $\pm 2\%$ of reading. A primary requirement is ruggedness, and it is in the designs most suited to harsh environments that the formats are most distinctive. Rotor and pickup assemblies are generally flanged to the housing and removable. The rotors have large clearances, are often cantilevered into the flow, and supported via a sealed bearing without stators. The rotors are typically made of plastic or rubber and carry as few as three highly twisted, high radius ratio blades. Pickups are always mechanical and frequently have magnetic couplings.

Spirometers.

Monitoring spirometers measure the volumes of gas flows entering and leaving the lungs and can also be incorporated in ventilator circuits. Diagnostic spirometers are used to monitor the degree and nature of respiration. With these, a clinician can determine patient respiratory condition by various measures and clinical maneuvers. Low cost, light weight, speed of response, and patient safety are major considerations. Measurement capabilities include the gas volume of a single exhalation and also the peak expiratory flow for diagnostic types, measured in liters and liters per second, respectively. Various technologies are used. However, the Wright respirometer, named after the original inventor [15], today refers to a type of hand-held monitoring spirometer that utilizes a special type of tangential turbine transducer with a two-bladed rotor connected to a mechanical pickup and a dial readout for the volume. These particular spirometers are routinely used by respiratory therapists for patient weaning and ventilator checking. Other axial turbine-based flowmeters are available for ventilation measurements involving, for example, patient metabolics measurements. One axial turbine-based diagnostic spirometer made by Micro Medical, Ltd., currently claims most of the European market. This device utilizes an infrared, optical pickup and has a battery-powered microprocessor-controlled display. In these medical devices, rotors tend to be plastic with a large blade radius ratio. Flow conditioning is minimal or absent. The meters are typically accurate to \pm a few percent of reading. In the U.S., spirometers are designated as class 2 medical devices and as such certain FDA approvals are required concerning manufacture and marketing. In the EU they are class IIb medical devices under a different system, and other approvals are required.

Dual-Rotor Axial Turbines

Dual-rotor axial turbines have performance features not found in single rotor designs. In 1981, Lee et al. [16] were issued a U.S. patent for a self-correcting, self-checking dual-rotor turbine flowmeter that is currently manufactured exclusively by Equimeter, Inc. and sold as the Auto-Adjust. This is a high-accuracy flowmeter primarily intended for use on large natural gas lines where even small undetected flow measurement errors can be costly. It incorporates two closely coupled turbine rotors that rotate in the same direction. The upstream rotor is the main rotor and the second rotor, which has a much shallower blade angle, is the sensor rotor. Continuous and automatic correction of measurement errors due to varying bearing friction is achieved by calculating the flow rate based on the difference between the rotor speeds. As shown in Figure 28.31 and discussed in the theory section, the flow exit angle is due to the net rotor retarding torque. If this torque increases in the main rotor, thereby reducing its speed, the exit angle increases and the speed of the sensor rotor is then also reduced. The meter is also insensitive to inlet swirl angle because the swirl affects both rotor speeds in the same sense and the effect is then subtracted in the flow calculation. The meter also checks itself for wear and faults by monitoring the ratio of the two rotor speeds and comparing this number with the installation value [17].

A dual-rotor liquid flowmeter, invented by Ruffner et al. [18], was recently introduced by Exact Flow, LLC. It is being offered as a high-accuracy flowmeter (up to $\pm 0.1\%$ accuracy and $\pm 0.02\%$ repeatability), which has an extraordinarily wide dynamic range of 500:1 with a single-viscosity liquid. This flowmeter has had early commercial success in fuel flow measurement in large jet engine test stands where the wide dynamic range is particularly useful [19]. The meter comprises two, closely and hydraulically coupled rotors that rotate in opposite directions. Due to the exit angle generated by the first rotor, the second rotor continues to rotate to much lower flow rates compared with the first.

Two-Phase Flow Measurement Using Axial Turbines

A differential pressure producing flowmeter such as a venturimeter in series with a turbine is known to be a technically appropriate and straightforward method for measuring the volumetric and mass flow rates of some fine, solid aerosols. However, this section highlights a current research area in the application of axial rotor turbine meters to a range of industrial flow measurement problems where gas/liquid, two-phase flows are encountered. Customarily, turbine meters are not designed for and cannot measure such flows accurately. Errors of the order 10% arise in metering liquids with void fractions of around 20%. Such flows are normally measured after gas separators. Although this problem is not restricted to these industries, the current main impetuses for research are the direct measurement of crude oil in offshore multiphase production systems, the measurement of water/steam mixtures in the cooling loops of nuclear reactors, and the measurement of freon liquid–vapor flows in refrigeration and air conditioning equipment. Several techniques investigated thus far use an auxiliary sensor. This can either be a void fraction sensor or a pressure drop device such as a venturimeter or drag disk, of which the pressure drop approach appears to be technically more promising [20, 21]. Also, from a practical standpoint, gamma densitometers for measuring void fraction are additional and expensive equipment and not, for example, well adapted for use in undersea oil fields. Two techniques currently being studied do not require an auxiliary in-line sensor. The first uses the turbine meter itself as the drag body and combines the output of the turbine with that of a small differential pressure sensor connected across the inlet and outlet regions. This technique requires a homogenizer ahead of the turbine, and measurement accuracies of $\pm 3\%$ for the volumetric flow rates of both phases have recently been reported for air/water mixtures up to a void fraction of 80% [22]. The second technique is based entirely on analysis of the turbine output signal and has provided significant correlations of the signal fluctuations with void fraction. Accuracies of water volumetric flow rate measurement of $\pm 2\%$ have been reported when using air/water mixtures with void fractions of up to 25% [23].

Insertion Axial Turbine Flowmeters

These flowmeters comprise a small axial rotor mounted on a stem that is inserted radially through the conduit wall, often through a shut-off valve. They measure the flow velocity at the rotor position from which the volumetric flow rate is inferred. They are an economical solution to flow measurement problems where pipe diameters are high and accuracy requirements are moderate, and also may be technically preferred where negligible pressure drop is an advantage, as in high-speed flows. They are typically more linear than insertion tangential turbine flowmeters and compete also with magnetic and vortex shedding insertion flowmeters. They are available for the measurement of a range of liquids and gases, including steam, similar to the media range of full bore axial turbines, and have a similarly linear response. Flow Automation, Inc., is currently the leading manufacturer. The rotors, which are usually metal but can be plastic, typically have diameters of 25 mm to 51 mm (1 in. to 2 in.). They can be inserted into pipes with diameters ranging from 51 mm to 2032 mm (2 in. to 80 in.). Velocity measurement ranges cover 0.046 ms^{-1} to 91 ms^{-1} , (9 fpm to 18,000 fpm) for gases and 0.03 ms^{-1} to 30 ms^{-1} (6 fpm to 6000 fpm) for liquids. Dynamic ranges vary between 10:1 and 100:1. The maximum flow rate measurement capacity in a 1836 mm (72 in.) diameter pipe can be as high as nearly $56,500 \text{ m}^3 \text{ h}^{-1}$, (about 250,000 gpm). Since these devices are local velocity sensors, calculating the volumetric flow rate requires a knowledge of the area velocity profile and the actual flow area. Flow conditioning is therefore particularly important for accurate volumetric measurements, while radial positioning, which is a further responsibility of the user, must be according to the manufacturer's recommendation, which can either be centerline, one third of the diameter, 12% of the diameter, or determined by "profiling." Quick [24] discusses operation and installation for natural gas measurement. Although linearities or "accuracies" can be quoted up to $\pm 1\%$ of velocity, achieving the same accuracy for the volumetric flow rate, although possible, can be difficult or impractical. In this respect, a unique dual rotor design, exclusive to Onicon, Inc., and primarily used for chilled-water flow measurement in HVAC systems, requires less flow conditioning than single rotor designs. An Onicon dual rotor turbine assembly is depicted in [Figure 28.33](#). It comprises two rotors that

FIGURE 28.33 The rotor assembly of a dual rotor, insertion axial turbine flowmeter for water flow measurement. This patented design renders the flowmeter insensitive to errors due to flow swirl; an important source of potential error in single rotor axial turbine flowmeters. The rotations are sensed by two separate, electric impedance sensors. (Courtesy of Onicon Incorporated.)

rotate in opposite directions. The output is based on the average rotor speed. Any flow swirl present due to poor flow conditioning changes the speed of rotation of each rotor by the same but opposite amounts. Swirl-induced error is thus virtually absent in the averaged output. Also, flow profile sampling is improved over that of a single rotor. The devices are calibrated using a volumetric prover and the specified accuracy of $\pm 2\%$ of reading is for volumetric flow rate rather than velocity. This is the total error and includes an allowance for dimensional variations in industry standard pipes.

Angular Momentum Flowmeters

These are accurate, linear, liquid mass flowmeters that utilize vaned components and are used in aerospace applications. They are currently the instrument of choice for airborne, jet engine fuel flow measurement

for large commercial aircraft and some military aircraft for afterburner applications. They are more expensive than the equivalent turbine flowmeters for this application, but they provide mass flow rate measurements directly and are unaffected by fuel density variations. Typical accuracies lie between $\pm 0.5\%$ and $\pm 1.0\%$ over a 40:1 or greater dynamic range. Measurement ranges are available for fuel flows from about 0.01 to 6 kg s^{-1} (70 to 46,000 PPH).

The principle of operation is long established and based on imparting angular momentum to the fluid flow using a driven, flat-bladed impeller. The force required to drive the impeller at constant speed is monitored as a proportional indication of mass flow rate as this quantity varies. Some designs use an electric motor to drive the impeller. However, the current trend in design is motorless. In such a device, a constant driving speed in the region of 100 rpm to 200 rpm is provided by one or more turbine rotors driven by the flow. A variable shunt metering valve assembly adjacent to the turbine rotor mechanically opens and closes in response to flow dynamic pressure and thereby automatically maintains a constant speed of rotation provided that the flow rate is above the minimum of the range. The driven impeller carries vanes that are parallel to the flow, and resides on a common axis with the turbine rotor. A flow straightener ensures parallel flow past the impeller. There is a carefully engineered constant rate spring connection between the turbine shaft and the impeller so that the angular deflection between the two is proportional to the applied torque, and this quantity is directly proportional to the mass flow rate. Two pickup coils sense the rotations of the turbine and the vaned impeller, and only the time difference between the pulses in these two signals is measured and used to calculate the flow rate. Chiles et al. [25] provide a detailed illustration and explanation of the intricate mechanism.

Multijet Turbine Flowmeters

These are linear, volumetric flowmeters designed for liquids measurements and comprise a single, radial-vaned impeller, vertically mounted on a shaft bearing within a vertically divided flow chamber, sometimes called a distributor. The impeller is often plastic and can even be neutrally buoyant in water. There are various designs, but typically, both chambers access a series of radially distributed and angled jets. The lower chamber jets connect to the flowmeter input port and distribute the flow tangentially onto the lower region of the impeller blades, while the upper series, which is angled oppositely, allow the flow to exit. The flow pattern within the flow chamber is thus a vertical spiral and the dynamic pressure drives the impeller to track the flow. This design gives the meters good sensitivity at low flow rates. Due to the distribution principle, the meters are also insensitive to upstream flow condition. Impeller rotation pickups are always mechanical, often magnetically coupled, and frequently also connect with electric contact transmitters. They are primarily used in water measurement, including potable water measurement for domestic and business billing purposes and in conjunction with energy management systems such as hot water building or district heating, and to a much lesser extent in some chemical and pharmaceutical industries for dosing and filling systems involving solvents, refrigerants, acids and alkalis with absolute viscosities less than 4.5 mPa s , (0.045 Poise). Available sizes range from 15 mm to 50 mm. Dynamic ranges lie between 25:1 and 130:1 and flow measurement ranges cover 0.03 to $30 \text{ m}^3 \text{ h}^{-1}$, (0.13 to 130 gpm). Measurement linearities range between $\pm 1\%$ to $\pm 2\%$, with typical repeatabilities of $\pm 0.3\%$. Operating temperatures range from normal to 90°C (200°F) and maximum operating pressures are available up to 6.9 MPa (1000 psi). A number of potable water measurement systems come with sophisticated telemetry options that allow remote interrogation by radio or telephone. For potable water applications in the U.S., these meters normally comply with the applicable AWWA standard [26], while in Europe EEC, DIN, and other national standards apply.

In the author's opinion, there is also another type of vaned flowmeter that could be classified as a type of multijet turbine. This type comprises an axially mounted, vaned impeller with an upstream element that imparts a helical swirl to the flow. The transducer is typically a small, low-cost, sometimes disposable, plastic component, and is usually designed for liquids (but also to lower accuracies, gases), low-flow rate measurements (down to 50 mL min^{-1}). The dynamic range is high and accuracies range up to $\pm 0.5\%$.

Goss [27] describes one particular design in current use. Specialized applications cover the pharmaceutical, medical, and beverage industries.

Cylindrical Rotor Flowmeter

Instead of coupling to a turbulent flow using the fluid dynamic pressure or momentum flux, as in most axial and tangential turbines, a demonstrated research device due to Wadlow et al. [28] provides a linear, volumetric, low gas flow rate measurement using a single, low inertia, smooth cylindrical tangential rotor that couples to a laminar flow via surface friction. The geometry is conceptually that of a single-surfaced rotating vane. A plane Poiseuille flow is created that passes azimuthally over most of the curved rotor surface in a narrow annular passage between the rotor and a concentric housing. The rotor is motor driven via a feedback control loop connected to an error signal producing, differential pressure sensor connected across the gas ports so as to maintain the meter pressure drop equal to zero. Under this condition, the response, as indicated by motor shaft speed, is exactly linear, determined only by geometry and is independent of gas density and viscosity. The demonstration device reported has a 40 mm diameter rotor and 15 mm diameter gas ports. It measures up to a maximum of 25 Lpm bidirectionally, has a linear dynamic range greater than 100:1, is insensitive to upstream flow condition, and has a $1/e$ step response time of 42 ms, limited only by the external motor torque and combined motor and rotor inertia.

Manufacturers

There is significant and dynamic competition among the numerous manufacturers of the different types of flowmeters described in this section. In all flowmeter types, most manufacturers have exclusive patent rights concerning one or more detailed design aspects that make their products perform differently from those of the competition. Every few years, one or more major turbine flowmeter company can be identified that has changed ownership and name or formed a new partnership. Identifying the competition and selecting the manufacturer are important and sometimes time-consuming parts of the flowmeter selection and specification process. To assist with this, [Table 28.8](#) gives a few selected examples from different manufacturers, of all of the different flowmeter types described in this section. [Table 28.9](#) gives the corresponding contact information for those selected manufacturers, along with the general types offered by each.

Conclusion

However anachronistic intricate mechanical sensors might appear amid current everyday high technology, there are fundamental reasons why axial turbines are likely to experience continued support and development rather than obsolescence, especially for in-line applications requiring in the region of tenth percent volumetric accuracy. Mechanical coupling is the most direct *volume* interaction for a flowing fluid, which is why mechanical meters historically developed first and continue to be the most accurate and reliable types of flowmeter for so many different fluids. Other nonmechanical, perhaps higher technology, or newer approaches thus face high demands for accurate compensation to render such less directly volume-coupled techniques as generally accurate, or more accurate. This is because the error in each corrected factor or assumption in an indirect technique contributes to the overall error. The technology of high-accuracy flowmeters continues to be driven by applications, such as the custody transfer of valuable oil and natural gas, which demand high accuracy and reliability. There is a continuing demand for accurate and reliable water flowmeters. By reason of long proven field experience, turbine and other vane type devices have become one of a few broadly accepted techniques in many major applications such as these where the demands for flow sensors is significant or growing.

TABLE 28.8 Examples of Turbine and Vaned Flowmeters

Type	Size(s), in.	Description	Example application(s)	Manufacturer	Approx. price range
Axial	0.5	FT 4-8, with SIL smart transmitter	Helicopters — fuel	EG&G Flow Technology	\$2,500
Axial	1	6700 series, type 60	Raw milk, de-ionized water	Flow Automation	\$1,500
Axial	16	Parity series	Custody transfer oil	Fisher-Rosemount Petroleum	\$30,000–\$38,000
Axial dual rotor	12	Auto-Adjust Turbo-Meter	Custody transfer gas	Equimeter	\$42,000
Axial dual rotor	0.25–2	DR Series	Fuel — large jet engine test stands	Exact Flow	\$1,300–\$1,800
Propeller	48	FM182 (150 PSI)	Municipal water	Sparling	\$6,500
Propeller	6	FM102 (150 PSI)	Irrigation	Sparling	\$850
Special tangential	—	Wright Mark 8	Monitoring spirometer	Ferraris Medical	\$800
Axial	—	MS03/MS04 MicroPlus	Diagnostic spirometer	Micro Medical	\$600
Axial	4	WTX802	Chemical dosing for water treatment	SeaMetrics	\$450–\$550
Axial insertion	1.5–10	TX101	Municipal water, water — HVAC	SeaMetrics	\$450
Axial insertion	2+	VTS-300	High pressure steam	Flow Automation	\$2,900
Axial insertion	3+	VL-150-LP	Flare stack control	Flow Automation	\$2,500
Axial insertion dual rotor	2.5–72	F-1200	Water — HVAC	Onicon	\$900
Angular momentum	—	Model 9-217 True Mass Fuel Flowmeter	Large jet aircraft, e.g., Airbus A320, A321	Eldec	Not available
Multijet	1	1720	Domestic water	ABB Kent Messtechnik	\$170
Multijet	1.5	AMD3000	Chemical liquid filling and dosing	Aquametro AG	\$950
Multijet axial	9/32	DFS-2W	Pharmaceutical filling lines, kidney dialysis dialyte, beverage dispensers, OEM	Digiflow Systems	\$42 or less, transducer; \$235 electronics
